To Its Friends of Forty Years

who helped pave the way for another generation of scientific discovery, the Twelfth Edition of

THIS BOOK IS DEDICATED

Preface to Twelfth Edition

This, the Twelfth Edition of "Practical Physiological Chemistry," represents a complete revision of the subject matter of this book. Many of the chapters have been entirely rewritten; all of them have been carefully re-examined to insure their application to present-day knowledge, and the clinical and theoretical phases have been strengthened. Much new material has been added. In addition to many new experiments, tests, methods, and preparations, new sections have been introduced on the polarograph; on isotopes; on the sulfa drugs; on metabolic antagonists and antibiotics; on the Warburg tissue-slice procedure; on the theory and practice of photometric analysis; on the electrophoretic fractionation of the plasma proteins; on the composition of foods; and on the various vitamins whose importance has become recognized since the last edition together with a fuller discussion of the clinical relationships of certain vitamins. Also many new quantitative procedures for blood and urine analysis have been added.

In many respects, this new edition necessarily reflects the fact that the science of biochemistry is passing through a transition period in certain major fields. In colorimetric analysis, for example, where once the visual colorimeter held almost undisputed sway, the use of photoelectric photometers, spectrophotometers, fluorophotometers, etc., is rapidly increasing and bids fair to dominate this field entirely. In the description of quantitative colorimetric methods it has been necessary, therefore, to provide for both visual and photometric methods of measurement. In many instances, analytical procedures developed primarily for visual colorimetry have required slight modifications to permit adaptation to photometric measurement, and unless otherwise stated the authors of this text assume he responsibility for such modifications.

Other fields in which notable changes are occurring include protein chemistry, where the development of electrophoretic and ultracentrifugal methods for protein separation has necessitated a revision and re-evaluation of concepts based upon the use of concentrated salt solutions for this purpose; and intermediary metabolism, where the use of isotopes for "tagging" molecules or portions of molecules as they proceed through the intricate metabolic processes of protoplasm has afforded much new information and frequently impelled a drastic reinterpretation of existing lata. Many other examples could be cited. It is clear that, in presenting his material, it has been necessary for the authors to integrate both the ld and the new phases of a subject to afford a comprehensive factual icture of its present status.

Nomenclature, symbols, etc., are in accordance with modern conventions or follow authoritative recommendations, and have been altered from the style of previous editions whenever such change appeared desirable. For example, the term *milliliter* replaces the less precise term

cubic centimeter as a unit of liquid and gas volume. At the same time, it was not felt desirable to sacrifice simplicity and clarity of presentation by replacing the common symbol H⁺ by other and possibly more correct symbols used to designate the hydrogen ion in aqueous solution. Where an instance such as this occurs in the text, full explanation is given.

Obsolete tests and methods or those of minor importance have been deleted in order to permit the inclusion of new matter and still keep the size of the volume within reasonable bounds. Nothing of fundamental value present in previous editions, however, will be found absent from this edition.

Particular attention has been paid to the illustrations. Some have been redrawn, and many new ones have been added.

It has been a pleasure to welcome my colleague, Dr. Bernard L. Oser, to a major position on the title page. Dr. Oser is eminently deserving of this advancement, not only because of his services in connection with the present edition but also because of the outstanding work he has done on several previous editions. It may not be out of place for the senior author to say that he is very proud of the position that Dr. Oser has come to occupy in the field of biochemical investigation, notwithstanding the fact that almost his entire professional career has been passed in association with the writer.

A new name on the title page is that of Professor William H. Summerson, of Cornell University Medical College. Dr. Summerson is an old friend of this book, having used it as student and teacher for over twenty years. The fact that he has been associated for a considerable period of time with Professor Vincent du Vigneaud and the late Professor Stanley R. Benedict testifies to his thorough groundwork in biochemistry. His contributions, both as a teacher and as an investigator, have earned for him the esteem in which he is held by his contemporaries. Dr. Summerson has assumed a major role in this revision.

The authors are under particular obligation to Professor James B. Sumner, Professor of Biochemistry, Cornell University (Ithaca), and his colleague, Dr. G. Fred Somers, for revising the chapter on "Enzymes and Their Action"; to Professor D. L. Thomson, Professor of Biochemistry. McGill University, and his colleague, Dr. R. D. H. Heard, for contributing the manuscript on "Hormones"; to Professor Armand J. Quick, Professor of Biochemistry, Marquette University, for revising the chapter on "Putrefaction and Detoxication" and for making other suggestions; to Dr. Richard J. Block, of New York Medical College, for revising the copy on Proteins, Amino Acids and Nucleoproteins; to Mr. Melvin Hochberg for assistance in revising the chapter on "Vitamins and Deficiency Diseases"; to Dr. Maxwell Karshan of the College of Physicians and Surgeons (Columbia) for the revision of the section on Teeth; to Dr. Thomas W. Jukes of Lederle Laboratories for the section on Folic Acid; to Miss Mona Oser for revising the section on "Maintenance of Animals"; to Dr. Daniel Melnick for his cooperation in many ways; to Mrs. Gladys Hawk for assistance in indexing; and to Dr. J. A. Behre for contributing material on ketosis and related subjects.

The authors are likewise under obligation to various other teachers and investigators for suggestions as to the betterment of the book.

Thanks of the authors are also due the various companies from whom illustrations were obtained, and to various individuals and journals for permission to reproduce material.

The unfailing courtesy and cooperation of The Blakiston Company have been an inspiring experience and are gratefully acknowledged.

It is also a pleasure to testify to the efficiency of the Maple Press which has been the typographical godfather of this book for over 40 years.

NEW YORK

PHILIP B. HAWK

Preface to First Edition

The plan followed in the presentation of the subject of this volume is rather different, so far as the author is aware, from that set forth in any similar volume. This plan, however, he feels to be a logical one and has followed it with satisfactory results during a period of three years in his own classes at the University of Pennsylvania. The main point in which the plan of the author differs from those previously proposed is in the treatment of the food stuffs and their digestion.

In Chapter IV the "Decomposition Products of Proteids" has been treated although it is impracticable to include the study of this topic in the ordinary course in practical physiological chemistry. For the specimens of the decomposition products, the crystalline forms of which are reproduced by original drawings or by microphotographs, the author is indebted to Dr. Thomas B. Osborne, of New Haven, Conn.

Because of the increasing importance attached to the examination of feces for purposes of diagnosis, the author has devoted a chapter to this subject. He feels that a careful study of this topic deserves to be included in the courses in practical physiological chemistry, of medical schools in particular. The subject of *solid tissues* (Chapters XIII, XIV and XV) has also been somewhat more fully treated than has generally been customary in books of this character.

The author is deeply indebted to Professor Lafayette B. Mendel, of Yale University, for his careful criticism of the manuscript and to Professor John Marshall, of the University of Pennsylvania, for his painstaking revision of the proof. He also wishes to express his gratitude to Dr. David L. Edsall for his criticism of the clinical portion of the volume: to Dr. Otto Folin for suggestions regarding several of his quantitative methods, and to Mr. John T. Thomson for assistance in proof reading.

For the micro-photographs of oxyhemoglobin and hemin reproduced in Chapter XI the author is indebted to Professor E. T. Reichert, of the University of Pennsylvania, who, in collaboration with Professor A. P. Brown, of the University of Pennsylvania, is making a very extended investigation into the crystalline forms of biochemic substances. The micro-photograph of allantoïn was kindly furnished by Professor Mendel. The author is also indebted for suggestions and assistance received from the lectures and published writings of numerous authors and investigators.

The original drawings of the volume were made by Mr. Louis Schmidt whose eminently satisfactory efforts are highly appreciated by the author.

Some Physicochemical Properties of Solutions

Living matter differs from nonliving in its possession of certain characteristic properties such as growth, reproduction, respiration, motion, etc. The science of physiological chemistry deals with the application of chemical and physicochemical principles and methods to the study of these phenomena. In the early days of the science this meant the analysis of foods entering the organism and of excreta leaving it; it involved the study of the composition of the various tissues and organs of the body, the blood, the digestive secretions, etc. In this way a great deal of information has been collected concerning the composition of living matter and the fate of the substances that are necessary for continuance of life and growth. Although far from complete these researches have progressed to the point where we now possess a fairly comprehensive picture of the gross changes that take place in protoplasm.

The experimental methods used, however, for the most part involved the destruction of the living cell. In recent years the emphasis has been placed on the mechanisms concerned in the reactions of the living protoplasm itself. Since protoplasm is largely water, this requires a study of the nature of solutions and the complex behavior of mixtures of electrolytes. Since the physical basis of protoplasm is colloidal in character, a study of the peculiar structure and properties of colloidal solutions is also necessary. Some of the more important physicochemical properties of solutions that are finding wide and fruitful application in the study of life phenomena are discussed briefly in the following page.

THE COLLOIDAL STATE

True and Colloidal Solutions. Thomas Graham, in 1861, classified all substances into two groups, crystalloids and colloids, depending upon their ability to diffuse through membranes such as parchment. According to Graham, crystalloids readily passed through parchment membranes while colloids did not. We now recognize the fact that matter cannot be classified in this manner since many typical colloids, such as certain proteins, are crystallizable while practically all crystalloids may, under proper conditions, be brought into the colloidal state.

According to modern conceptions, colloidal solutions, instead of being solutions of particular types of matter, are solutions with a characteristic kind of structure. Substances such as glucose or sodium chloride, which form true solutions in water, disintegrate, when dissolved, into individual molecules or ions which are less than 1 m μ (1 millionth mm.) in diameter.

The smallest particle that can be seen with a high-power microscope has a diameter of about 200 m μ . When the particles of solute are larger than 200 m μ they are said to be in suspension; on standing such particles will gradually separate out. When, however, the solute is dispersed into particles which are intermediate in size between ordinary molecules, such as exist in true solutions, and the coarse particles found in suspensions, it is said to be in the colloidal state and solutions containing particles of that size are known as colloidal solutions or sols; sols which have become jellylike are called gels.

Colloidal solutions, true solutions, and suspensions thus differ from each other fundamentally only in the size of the particles of solute (the disperse phase) dispersed in the solvent (the dispersion medium). Because of the dimensions of the disperse phase, colloidal solutions exhibit certain characteristic and unique properties (to be discussed in later sections) which confer upon them their great importance in the structure of living protoplasm. This importance resides in the fact that protoplasm is considered to be a complex system containing many different crystalloidal and colloidal components. Although the structure and properties of this system are too complex to permit exact characterization in the present state of our knowledge, we may gain an insight into these questions by a study of similar, though very much simpler, colloidal systems such as are discussed below.

Preparation of Colloidal Solutions. The relationship between colloidal solutions, true solutions, and suspensions indicated above suggests two general methods by which colloidal solutions may be prepared. These methods are classified as (1) condensation or (2) dispersion methods, depending upon whether the colloidal particles are formed by aggregation of individual molecular or by disintegration of coarse particles of matter.

CONDENSATION METHODS. The principles underlying the preparation of colloidal solutions by condensation methods are similar to those involved in ordinary precipitation reactions. In both processes the solution is permitted to become supersaturated with respect to some particular substance. Such supersaturated solutions, in the presence of suitable condensation nucleii, develop molecular aggregates which continue to increase in size as long as any available material remains in solution. In precipitation reactions this process of growth continues until the particles become visible in a microscope, or to the naked eye, when they flocculate from solution. By proper regulation of the experimental conditions, which differ for different substances and procedures, the growth of molecular aggregates may be checked when the particles attain the size characteristic of the colloidal state, thus forming colloidal solutions. Whether a particular reaction will lead to the formation of a colloidal solution or a visible precipitate depends, therefore, entirely upon the conditions under which the experiment is carried out. Von Weimarn, who studied this question very extensively, showed that by merely varying the concentrations of Ba(CNS), and MnSO, from N/20,000 to 7 N, the form of the BaSO₄ precipitated could be made to vary from large crystals to a colloidal gel. The colloidal state, as indicated in the following scheme, is merely an

intermediate stage between coarse precipitates and true solutions which may be approached, under proper conditions, from either direction.

← Dispersion Methods

Most of the inorganic colloids may be formed by condensation methods involving such reactions as reduction, oxidation, hydrolysis, and double decomposition. Thus if a dilute solution of gold chloride is treated with formaldehyde under proper conditions, the gold ions are reduced to atoms of gold which then aggregate into particles of colloidal size. Practically all of the metals yield colloidal solutions under similar conditions. Boiling a very dilute solution of ferric chloride results in hydrolysis of this salt with the formation of a colloidal solution of ferric hydroxide. Similar solutions may be obtained by using salts of Cr, Al, or Sn. A dilute solution of arsenious oxide in water, when treated with hydrogen sulfide, undergoes double decomposition with the formation of colloidal arsenious sulfide. In the preparation of colloidal solutions by these methods it is essential that the reactions used do not lead to the formation of soluble, strong electrolytes. This condition is important because colloidal solutions of the type discussed here are extremely sensitive to small amounts of electrolytes. which cause aggregation of the colloidal particles into larger particles which precipitate out of solution.

DISPERSION METHODS. The dispersion methods for preparing colloidal solutions involve, as indicated above, the subdivision of coarse material into particles of colloidal size under conditions which will prevent coalescence of those particles. Many substances may be recorded to approximately colloidal size by grinding in a colloid mill, which consists essentially of two flat metal plates placed almost in contact and rotated at very high speeds in opposite directions. Colloidal solutions of most of the metals may be prepared by producing an electric arc between electrodes of the metal held under water or some other suitable liquid. It is quite probable that this method involves some condensation of metal vapors as well as disintegration of the metal itself. Solutions prepared by either of these methods will gradually flocculate unless some stabilizing agents are added to prevent coalescence of the particles. For this purpose use is made of certain substances, either electrolytes or other colloids, called peptizing agents. The electrolytes usually act by conferring an electrical charge on the colloidal particle, which is an essential condition for stability of colloidal solutions of this class. Peptizing colloids, also called protective colloids, apparently form a film about the individual particles, which converts them into particles resembling the protective agent in stability and other properties.

General Properties of Colloidal Solutions. It has already been pointed out that the essential difference between colloidal and true

solutions lies in the sizes of the particles of solute dispersed in the solvent. Although the particles in a colloidal solution are too small to be retained by ordinary filter paper, they are too large to pass through such membranes as collodion, parchment, or cellophane, which are permeable to most substances in true solution. This inability of the colloidal particles to diffuse through certain membranes is made use of in the process known as dialysis, by which colloidal solutions may be freed from molecularly or ionically dispersed impurities. The solution is placed in a suitable dialyzing bag and is suspended in a large volume of distilled water which is changed at frequent intervals until the liquid inside the bag no longer gives a test for the particular substance to be removed. This process of dialysis is used extensively in the preparation of salt-free solutions of such biological colloids as the proteins. Last traces of electrolytes may be removed by the process known as electrodialysis, in which an electrical current is passed through the solution in a suitably designed apparatus.

If the colloidal solution is forced through a suitable membrane by pressure, the membrane becomes an ultrafilter and the process is called ultrafiltration. By this means it is possible to separate the crystalloidal and colloidal components of such a fluid as blood plasma, for example. Furthermore it is possible to prepare membranes containing pores of almost any desired size, so that colloidal particles of any particular size may be separated from smaller particles as well as from material in true solution. Another widely used method for separating colloidal particles of different sizes is based upon the use of the high-speed centrifuge or ultracentrifuge, as developed and applied by Syedberg and others. In this apparatus a force or many thousand times gravity can be applied to the particles in collectal suspension. Naturally the heavier particles will settle out of the solution under these conditions faster than the lighter or smaller parvities, and the actual separation and isolation of individual colloidal substances has been achieved in this way. Furthermore by the use of suitable optical devices it is possible to follow the rate of settling of the various types of colloidal particles which may be present, and thus establish not only whether the disperse phase consists of colloidal particles of several different sizes (heterogeneous) or of only one size (homogeneous), but also the average size of the particles themselves. If it can be shown that the colloidal particle is a single molecule of the substance, the particle size then becomes a measure of the molecular weight of the substance. This method of approach has found particular application in the field of protein chemistry.

Since the particles in a colloidal solution consist either of very large molecules or of aggregates of large numbers of individual molecules, it follows that a colloidal solution will contain only a minute fraction of the number of particles present in a true solution of the same concentration. Such physicochemical properties of solutions as vapor pressure and osmotic pressure depend almost entirely upon the number of particles in solution, the chemical nature of these particles being immaterial. Colloidal solutions, with their comparatively small number of particles, therefore exhibit only very small osmotic pressures, while their vapor pressures, as

2. Colorimetric Determination of Hydrogen-ion Concentration Without Use of Buffer Solutions: 10 This procedure is most simply carried out using indicators changing from colorless to a single colored form such as phenolphthalein or the nitrophenols. Within the effective range of the indicator, the depth of color varies with the pH and depends upon the amount of dissociated indicator present. The amount of completely dissociated indicator required to give the same tint as the unknown is a measure of the pH of the latter. The standards are made up by adding measured amounts of indicator solution to portions of solution in which the indicator gives its maximum color (complete dissociation).

To 10 ml. of unknown solution in a test tube add 1 ml. of indicator solution. To another tube (the standard) add 9 ml. of a solution giving the maximum color with the indicator (e.g., 0.02 N NaOH) and then add indicator solution diluted ten times from a microburet or Mohr pipet until a color is obtained which on diluting the standard to the same volume as the unknown (11.0 ml.) matches that of the unknown. If the first standard does not exactly match, make a second one; if more than 2 ml. of diluted indicator are needed, repeat, using undiluted indicator.

Calculation:

$$pH = pK' + \log \frac{C}{1 - C}$$

where pK' is a constant for the indicator (consult table) and C is the volume in ml. of indicator added to the standard, expressed on an undiluted basis. If 1 ml. of diluted indicator were used (0.1 ml. of undiluted) and the indicator is p-nitrophenol (pK' 7.18) we have pH = $7.18 + \log \frac{0.1}{0.9} = 7.18 + (\log 0.1 - \log 0.9) = 7.18 + (-1 - (9.95 - 10)) = 7.18 - 0.95 = 6.23$. A chart giving values of $\log \frac{C}{1-C}$ is convenient in making calculations. ⁿ

Other Colorimetric Methods for Determining Hydrogen-ion Concentration: The method without buffers may also be applied to two-color indicators (Gillespie). In this case each standard consists of two tubes set one behind the other in the Walpole comparator. One tube contains for example a known amount of phenol red in alkaline solution (red) and the other in acid solution (yellow). By varying the proportions any shade of this indicator may be obtained. For further details, see Clark.

²⁰ Michaelis suggests the following indicators:

Name	('omposition	рК′ 18° С.	Range of pH	Stock Solution of Indicator
β-Dinitrophenol. α-Dinitrophenol. γ-Dinitrophenol. p-Nitrophenol m-Nitrophenol Phenolphthalein	1-oxy-2, 6-dinitrobenzol 1-oxy-2, 4-dinitrobenzol 1-oxy-2, 5-dinitrobenzol	3.69 4.06 5.15 7.18 8.33 9.73	2.2-4.0 2.8-4.5 4.0-5.5 5.2-7 0 6.7-8.4 8.5-10.5	0.1 g.: 300 ml. H ₂ O 0.1 g.: 200 ml. H ₂ O 0.1 g.: 200 ml. H ₂ O 0.1 g.: 200 ml. H ₂ O 0.3 g.: 100 ml. H ₂ O 0.04 g.: 30 ml. alcohol + 70 ml. H ₂ O

²¹ For chart, see Michaelis: "Practical Physical and Colloid Chemistry," translated by Parsons, Cambridge, W. Heffer and Sons, 1925, and Clark: "Determination of Hydrogen Ions," 3d ed., Baltimore, Williams and Wilkins Co., 1928,

¹⁹ Michaelis and Gyemant: Biochem. Z., 109, 165 (1920).

Indicator paper ("Hydrion," "Accutint," etc.) may also be used for the determination of pH. Such paper is convenient and sufficiently accurate for many purposes. For the method of preparation and application, see Chapter 15, Gastric Analysis.

3. Comparison of Hydrogen-ion Concentration and Titratable Acidity: (A) Determine colorimetrically the hydrogen-ion concentration of a 0.01 N solution of hydrochloric acid using thymol blue as an indicator and of a 0.01 N acetic acid solution using bromcresol green as an indicator. Note the great difference between the true acidities of the two solutions.

Titrate 10-ml. portions of 0.01 N hydrochloric acid and of 0.01 N acetic acid with 0.01 N NaOH, using phenolphthalein as an indicator. Note that identical results are obtained for the titratable acidities of the two.

(B) Mix equal portions of M/15 potassium dihydrogen phosphate and M/15 disodium phosphate (see chart). Note that the mixture is practically neutral to litmus. Titrate one 10-ml. portion of this mixture with 0.1 N NaOH, using phenolphthalein as an indicator. Titrate another portion with 0.1 N HCl solution, using methyl orange. Explain results.

4. Differential Titration of Strong and Weak Acids: Mix 5.0 ml. of 0.1 N HCl with 5.0 ml. of 0.1 N acetic acid. Add thymol blue, and titrate with 0.1 N NaOH to pH 2.8 to 3.0 (use a pH standard as a control). Read the buret, then continue titrating until the indicator changes to blue (pH 8.5). Again read the buret. Compare the buret readings with those expected if (a) only the strong acid were titrated and (b) both acids were completely titrated. Explain. This principle finds clinical application in the titration of gastric juice.

ELECTROMETRIC DETERMINATION OF HYDROGEN-ION CONCENTRATION

Electrode Potentials. If an excess of solid glucose is placed in water, some of the molecules of the solid, being in a continual state of vibration, escape into the liquid. As the molecules of glucose in solution accumulate, some of them collide with the particles of solid and are retained. An equilibrium is finally established in which there is a balanced exchange of molecules between the solid and the solution. At this stage the solution is saturated with glucose and the solution pressure of the solid is said to be equal to the osmotic pressure of the dissolved substance.

If a strip of metal (electrode) is dipped into water, it also tends to dissolve owing to its solution pressure, P. The metal goes into solution as positive ions leaving its electrons (presumably less firmly bound valence electrons) behind as a negative charge on the electrode. This charge, by attracting the positive ions of metal already in solution, builds up an electrical double layer at the interface between electrode and solution which opposes the entrance of any more positive ions into the solution, and the process of solution ceases therefore when this charge becomes large enough to prevent the further separation of positive ions from the metal. Although equilibrium is established before a measurable quantity of the metal dissolves, since the charge on each ion is comparatively large, a measurable potential difference is developed between the electrode and the solution.

When a metal is dipped into a solution of one of its salts the conditions are somewhat altered because the positive ions of the metal already in solution oppose the separation of more ions from the metal. The point of

equilibrium therefore will depend upon the relative values of the two opposing forces: the solution pressure (P) of the metal and the osmotic pressure (p) of its ions in solution. We may therefore distinguish between three possibilities (see Fig. 7):

- 1. P > p. In this case the metal continues to send positive ions into the solution until the accumulated charges oppose further action. The metal thus acquires a negative charge relative to the solution.
- 2. P < p. In this case the positive ions in solution deposit on the metal, yielding to it their positive charges, until the accumulated charges oppose further deposition. The metal thus acquires a positive charge relative to the solution.

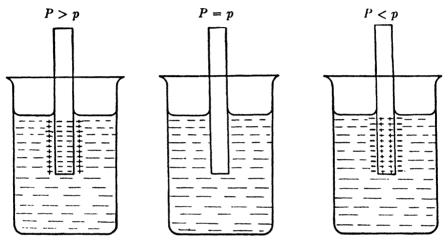

Fig. 7. Diagram showing relations existing at surface of a metal dipping into solutions containing its ions in different concentrations. (P =solution pressure of the metal; p =osmotic pressure of metallic ions.)

3. P = p. In this case there is neither solution nor deposition and no potential difference develops between the metal and the solution.

Nernst has shown by thermodynamic reasoning that the potential difference between a metal and a solution of one of its salts is given by

$$E = \frac{RT}{nF} \ln \frac{P}{p}$$

where E = electrode potential, R = "gas constant" = 8.316 joules per degree, T = absolute temperature, n = valency of metal ion, F = faraday = 96,500 coulombs, P = solution pressure and p = osmotic pressure of metal ions in solution. ("ln" is the symbol for the natural logarithm.)

From this equation it becomes evident that, since RT/F is a constant for any given temperature, the magnitude and sign of the electrode potential, E, is determined by n and P, which depend solely upon the nature of the metal used, and p, which is a function of the concentration of metal ions in solution. If therefore we have two electrodes of the same metal dipping into solutions of different concentrations, the two electrode poten-

tials will be different. And if we make suitable connections²² between the two electrodes and the two solutions an electrical current will pass from one electrode to the other, the electromotive force of which will be equal to the difference between the two electrode potentials—i.e.

$$E = E_1 - E_2$$

$$= \frac{RT}{nF} \ln \frac{P_1}{p_1} - \frac{RT}{nF} \ln \frac{P_2}{p_2}$$

$$= \frac{RT}{nF} (\ln P_1 - \ln p_1 - \ln P_2 + \ln p_2)$$

$$= \frac{RT}{nF} \ln \frac{p_2}{p_1} (\text{since } P_1 = P_2 \text{ for the same metal})$$

If osmotic pressure is regarded as proportional to concentration, we may replace p_1 and p_2 by c_1 and c_2 , and get

$$E = \frac{RT}{nF} \ln \frac{c_2}{c_1}$$

An arrangement such as here described is known as a concentration cell, and the above equation permits us to calculate the concentration of metal ions in an unknown solution from the electromotive force developed when that solution is combined in a cell with a similar solution of known ionic concentration. It should be noted that the concentration calculated by the use of the above equation will be that of electromotively active ions, which is not necessarily the same as that obtained by ion conductivity or other means. For a further discussion of this point, the reader is referred to Clark.

The Hydrogen Electrode. A strip of platinum, coated with platinum

black and saturated with hydrogen gas, acts exactly as the metal electrodes described above when dipped into a solution containing hydrogen ions. We can therefore construct a concentration cell by dipping two such electrodes into two solutions of different hydrogen-ion concentrations, and, if the concentration of hydrogen ions in one solution is kept at a known constant value, we can use the electromotive force developed by such a cell to calculate the hydrogen-ion concentration in the second unknown solution. If the concentration of hydrogen ions in the known solution is normal, the equation for the electromotive force becomes $E = \frac{RT}{nF} \ln \frac{1}{[H^+]}$. By substituting the values for R, T, n, and F at 25° C. and multiplying by 2.303 to change from the natural to the common system of logarithms, we get $E = 0.059 \log \frac{1}{[H^+]}$ or E = 0.059 (– log [H⁺]). Hydrogen-ion concentrations, following the convention introduced

²² The two solutions are usually connected by a salt bridge consisting of an inverted U-tube filled with saturated KCl solution. This tends to eliminate any differences of potential which may be built up at the junction of the two solutions by the unequal diffusion of the ions. The electrodes are connected by wire in the ordinary manner.

by Sørensen, are usually expressed in terms of pH where, by definition,

pH =
$$-\log [H^+]$$
. Therefore, E = 0.059 pH or pH = $\frac{E}{0.059}$.

In practice it is convenient to use, instead of a hydrogen electrode in a normal solution of hydrogen ions, a calomel electrode which has been standardized against such a solution. A calomel electrode is made up of mercury in contact with calomel in a solution of potassium chloride, the latter being either normal, tenth-normal, or, more often, saturated. The normal hydrogen electrode is approximately 0.25 volt more positive than the saturated calomel electrode²³ so that the difference of potential between the calomel electrode and the unknown will be 0.25 volt greater than that between the latter and the normal hydrogen electrode. Therefore, using the saturated calomel electrode at a temperature of 25° C.,

pH = $\frac{E - 0.246}{0.059}$. We may read E directly in volts on a voltmeter, or by

means of a potentiometer, so that the calculation becomes very simple. Variations of pH with E may be plotted in the form of a curve. In some instruments the voltmeter is graduated to read pH directly.

Regardless of the types of electrodes used in the chain, the measurement of E must be conducted by means which do not entail an appreciable flow of current from the system, because this introduces polarization effects at the electrodes. The potentiometric method is ideally adapted for this purpose. The principles involved in this method are described in detail in Clark's book, and also in the descriptive literature which accompanies the special apparatus required.²⁴

Hildebrand's method, described below, requires only such electric apparatus as is usually found in any laboratory, and serves to illustrate the principles of the electrometric method. The use of a potentiometer, instead of the voltmeter indicated, increases the accuracy of the determination and is to be preferred.

Determination of Hydrogen-ion Concentration by Hildebrand's Method;²⁵
Set up the apparatus as indicated in Fig. 8. The battery may be an ordinary dry cell. The voltmeter V should have a range of 1.2 volts and scale divisions to 0.01 volt. The portable galvanometer G should have a sensitivity of at least one megohm. A capillary electrometer may be used in place of the galvanometer. The rheostat R may be a tubular wire rheostat having at least 150 turns of wire. K is a contact key for opening and closing the circuit. C is the calomel electrode.²⁶ H is a hydrogen electrode of the Hilde-

²³ This figure varies with the temperature and with the concentration of KCl solution in the calomel electrode (see values for E₀ in the table on p. 37).

¹⁴ Assemblies suitable for various purposes may be obtained from manufacturers and dealers. The equipment manufactured by the Leeds and Northrup Co., Philadelphia, has been widely used.

¹⁵ Hildebrand: J. Am. Chem. Soc., 35, 847 (1913).

²⁶ Calomel Electrode: Place about 3 ml. of carefully purified mercury in the bottom of the electrode vessel. Rub together mercury and mercurous chloride (calomel) with a little saturated KCl solution to form a paste. Place a layer of this paste about a half inch thick over the mercury and fill the vessel to the end of the side tube with saturated KCl solution. If it is desired to make a normal or tenth normal calomel electrode corresponding solutions of KCl should be used instead of the saturated solution. It is convenient to make a permanent connection between the upper side arm and a reservoir bottle containing KCl solution. By running a little of the solution through the calomel cell before each series of determinations

brand type especially suitable for solutions not containing protein. The Clark electrode is a type frequently employed in biochemical work and may be used with a shaking device to assist in obtaining equilibrium rapidly.

The essential part of the hydrogen electrode is the piece of platinum foil which is to dip into the unknown solution. This must be given a spongy coat of platinum black so that it will retain as much hydrogen as possible and must be saturated with hydrogen just before use.²⁷

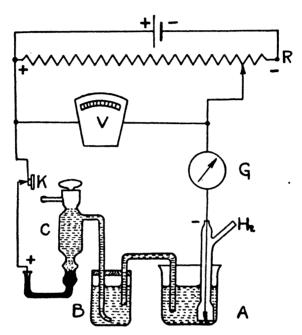

Fig. 8. Showing arrangement of apparatus for electrometric determination of hydrogen-ion concentration. (Method of Hildebrand.) H is the hydrogen electrode, C the calomel electrode, V a voltmeter, G a galvanometer, R a rheostat, A the beaker containing the unknown solution, and B a connecting vessel.

The unknown solution is placed in beaker A. The calomel electrode is clamped in place, as also is the prepared hydrogen electrode. A stream of

the side arm may be washed free from materials that may have diffused up into it. The stop-cock of this electrode should be tight but should not be greased. A typical calomel electrode is shown in C, Fig. 8.

The platinum electrode thoroughly with chromic acid. Connect with the negative pole of a dry cell and connect another strip of platinum with the positive pole. Dip both in a dilute (2 per cent) solution of platinic chloride. Electrolyze for 10 to 15 minutes, frequently reversing the current. Dip into 10 per cent sulfuric acid, with the electrode as the cathode, and let the current run for a few minutes. The platinum is saturated with hydrogen. Wash with distilled water. Keep under distilled water when not in use. The platinum coat should last for several weeks but must be saturated with hydrogen just before use. Instead of a strip of platinum a wire about 1 mm. in diameter slightly flattened at the end may be used. Equilibrium with such an electrode may be brought about more rapidly. Shorter periods of electrodeposition produce electrodes which some to equilibrium more rapidly but which are not so permanent.

hydrogen¹⁸ is passed through the side arm of the hydrogen electrode so that it bubbles up through the solution at the rate of about two bubbles per second. Beaker B contains saturated KCl solution. The connecting tube contains saturated KCl made up in warm 3 per cent agar and allowed to solidify in the tube. This prevents syphoning between B and A.

Stir the solution well—an automatic stirring device is best for this purpose. Move the sliding contact on the rheostat until the voltage drawn from the dry cell is equal to that produced in unknown solution. This is indicated by the fact that no current passes through the galvanometer when the contact key K is pressed down, and there is therefore no deflection of the needle. Until a balance is reached the spring contact key should be closed only momentarily by a slight tap. At the balance point read the voltmeter.

Calculation of pH. See the discussion preceding Determination. At 25° using saturated calomel electrode pH = (E - 0.246)/0.059. If for example the voltmeter reads 0.652 then pH = (0.652 - 0.246)/0.059 = 7.0 and the solution possesses a neutral reaction. Corrections for different electrodes and temperatures are given in the following table. This apparatus should have an accuracy of about 0.1 pH. Test the apparatus first using buffer solutions of known pH.²⁹

30	0.3372	0.2836	0.2437	0.0601
40	0.3360			

The hydrogen electrode under carefully defined conditions is the ultimate standard of reference for the determination of hydrogen-ion concentration in aqueous solution. The technical difficulties associated with its routine use, as well as its limitations under certain conditions, have led to a search for other electrodes suitable for the electrometric determination of pH. Among those which have found use may be mentioned the antimony electrode, ³⁰ the quinhydrone electrode, ³¹ and the glass electrode, of which the glass electrode has superseded all others for most purposes.

24 See Eleventh Edition of this book.

^{**} Hydrogen may be purchased in cylinders, or may be prepared by electrolysis of an NaOH solution or from pure zinc. To purify pass through a wash bottle containing alkaline pyrogallol solution and two bottles containing water. Connect one of these bottles with a third tube dipping below the surface of mercury in another vessel. This acts as a safety. With gas tanks a gas regulator for adjusting flow is desirable.

²⁹ A suitable solution tenth normal with respect to both acetic acid and sodium acetate may be used. At 25° with the saturated calomel electrode this gives 0.519 volt and with the 0.1 N electrode 0.6108 volt. Mix 50 ml. N NaOH and 100 ml. N acetic acid with water to make 500 ml.

^{*} For review, see Perley: Ind. Eng. Chem., Anal. Ed., 11, 316 (1939).

The Glass Electrode. One type of glass electrode in common use consists of a bulb of special glass which is filled with some standard electrolyte, such as 0.1 N HCl, in contact with a suitable metallic electrode. When this bulb is immersed in an unknown solution a potential difference develops between the two solutions, the magnitude of which depends upon the hydrogen-ion concentration of the solution. This potential difference is measured as with the hydrogen electrode by combining the glass electrode with some standard half cell, such as the saturated calomel electrode, and measuring the voltage of the system. Because of the high resistance of the glass, however, the usual methods of determining the voltage, such as those used with the hydrogen electrode, cannot be used. Instead, a vacuum tube amplifier is inserted in the potentiometer circuit. Various types of apparatus ("pH meters") using this type of amplification and calibrated to read directly in pH units are available. Since they make use of various types of electrodes, amplification circuits, etc., the literature supplied with each instrument should be consulted for further details concerning the construction and operation of that instrument.

In general the determination of pH with a pH meter is quite simple. The solution is placed in a small container and the glass electrode and calomel electrode immersed in the solution. The potentiometer circuit is closed and adjusted until the null point is reached. The pH may then be read directly. Two general precautions are ordinarily necessary. The pH meter must be calibrated frequently by checking against a standard buffer of known pH, readjusting the scale setting if necessary. Failure to do this is the most frequent cause of error with a pH meter, since the calibration may change significantly from time to time, particularly if the glass electrode is new or has been allowed to become dry. It is best to keep both glass and calomel electrodes immersed in water when not in use. The temperature of the solution will also influence the determination of pH. In the Beckman pH meter illustrated (Fig. 9), for example, the temperature control must be set at the temperature of the unknown solution before making the reading.

The glass electrode is used for determinations of pH in all types of biological systems. Since no gas is bubbled through the solution, as is the case with the hydrogen electrode, it may be used on systems like blood which contain dissolved CO₂. The sample is not contaminated, so that the method is especially applicable where the amount of material is limited. Electrodes are available which require only a few tenths, or even hundredths, of a milliliter of solution for each determination. Determinations with the glass electrode are rapid, and with most instruments the accuracy is within 0.05 pH. It may be used on unbuffered, colored, or turbid solutions and solutions containing sediments. With the ordinary glass electrode determinations are accurate up to a pH of 10, or even higher, provided the solutions do not contain appreciable quantities of sodium, lithium, or potassium ions. Sodium ions, especially, exert a considerable effect on determinations in solutions with a pH of 9 or above, when they are present in a concentration of normal or greater. Corrections may be applied in such cases (Dole). Special electrodes have been developed for use in strongly alkaline solutions, for solids such as cheese, and for many other purposes.

Electrometric Titration of Acids and Bases. In many cases the use of indicators in titration is unsatisfactory because of color or turbidity of solutions to be examined or the presence of buffer substances which make the end point uncertain. The hydrogen or glass electrodes may be used in such cases in titrating solutions to a definite acidity or alkalinity. This method also makes it possible to follow the changes in acidity during

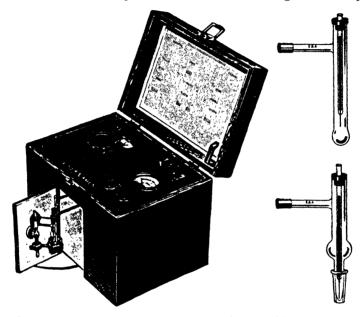

Fig. 9. Glass electrode apparatus (Beckman). Glass electrode shown at right (above) and calomel electrode (below).

the course of a titration and gives information as to the character of the acids or bases in solution. Some applications of this method are illustrated in Fig. 10.

Procedure: The apparatus already described and illustrated in Fig. 8 may be used. The unknown solution is placed in beaker A, into which are introduced both the hydrogen and calomel electrodes. Beaker B and the connecting tube are omitted. Hydrogen is bubbled through the solution and acid or alkali added from a buret with stirring. At intervals read the voltmeter. Plot a curve of voltage or pH against milliliters of acid or alkali added. Neutralization is indicated by a rapid change of voltage or pH. Dior tribasic acids or bases may show two or more such changes. See the curve for titration of phosphoric acid (Fig. 10).

The glass electrode pH meter is particularly suitable for this purpose. Special electrodes with long leads are available, for direct titration in an ordinary beaker.

As will be seen from Fig. 10, in the titration of a strong acid such as hydrochloric acid with a strong base such as sodium hydroxide, the change in $[H^+]$ at the end point is very sharp because, as long as even 0.1 ml. of

the acid remains unneutralized, the pH is still quite low and 0.1 ml. of 0.1 N NaOH in excess gives a very large increase of pH. Evidently either methyl orange, litmus, or phenolphthalein may be used in the titration. With acetic acid however the beginning [H+] is lower because this acid is weakly dissociated. The change in pH is at first fairly rapid because the sodium acetate formed yields acetate ions which repress the ionization of the acid. As the titration is continued the ionization of the acid is almost completely repressed by the larger amounts of acetate formed. When an equivalent amount of alkali has been added the reaction is alkaline due to slight hydrolysis of the sodium acetate to form acetic acid, nearly all undissociated, and highly dissociated NaOH. The actual end point of the

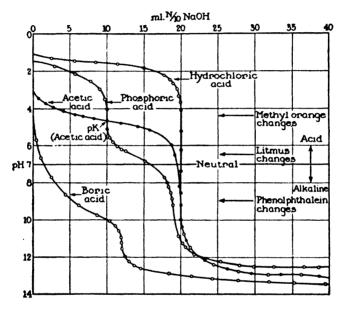

Fig. 10. Titration curves of various acids, obtained by electrometric measurement. 20 ml. of 0.1 N hydrochloric and acetic acids used. Phosphoric acid about 34 molar. Boric acid, saturated solution.

titration is therefore on the alkaline side and phenolphthalein is the proper indicator.

Fig. 10 shows also how it is possible to titrate the first hydrogen of phosphoric acid using methyl orange as an indicator and the second using phenolphthalein, while the third cannot be titrated because the change is too gradual. Neither can boric acid be titrated with phenolphthalein as an indicator.

Electrometric Oxidation and Reduction Titrations. When an ion is oxidized it loses electrons or negative charges; when it is reduced it gains electrons. Thus when Fe⁺⁺ is oxidized to Fe⁺⁺⁺ there is a loss of one electron. The process is therefore similar to that resulting in the loss of an electron when hydrogen passes into solution as H⁺. If a platinum wire is placed in a solution containing ferrous and ferric ions, the ferrous ions tend to give

up electrons to the platinum and the ferric ions tend to take them away. A difference of potential will arise depending upon the concentrations of the two ions. If an oxidizing agent is now added there will be a change of potential, slow at first and then very rapid, as the concentration of ferrous ions becomes very small compared to that of the ferric ions. This rapid change of potential marks the end point of the titration.

Procedure: The apparatus used is the same as for the electrometric titration of acids and bases. The platinum electrode should however be small and should not be platinized but be bright, and kept in 1:1 HCl when not in use. The calomel electrode should be connected to the negative side of the main circuit instead of the positive. Instead of a beaker a flask may be used and a current of CO₂ passed over the surface of the solution (not through it) to prevent oxidation by the air. ³² Run in an oxidizing or reducing agent from a buret. Readings of the voltmeter are taken at intervals and at the end point a drop or two of solution produces a marked change of potential.

An electronic pH meter with the glass electrode replaced by a platinum electrode may also be used. See the manufacturer's directions for the proper connection and use.

The Polarograph. Instead of adding a reactant to the solution and using the change in potential at an electrode for quantitative purposes as described above, it is possible to apply an external voltage across the electrodes and electrolyze the ions by forcing them to react at the electrodes. At the cathode for example the univalent metallic ion M^+ will accept an electron ϵ and be reduced to the metallic state:

$$M^+ + \epsilon = M$$

Under the proper conditions the voltage required to bring about such a reaction is characteristic of the chemical nature of the ion, and the current resulting from electron transfer may be used as a measure of the concentration of the ion. This principle has been utilized by Heyrovsky and his associates, in conjunction with the dropping mercury electrode, for the development of the instrument commonly known as the polarograph.

The construction of the polarograph and the principles upon which it operates may be illustrated by reference to Fig. 11, which presents schematically the components of a simplified and inexpensive form of this apparatus (Müller). The dropping mercury electrode C consists of a reservoir of mercury connected to the electrical circuit as cathode and to the solution being analyzed (in the right-hand vessel, directly under C) by a length of rubber tubing which is attached to a fine glass capillary dipping into the solution. In operation the mercury is allowed to flow from the capillary in a continuous succession of small drops. The solution is connected by salt bridges J_1 and J_2 through a protecting vessel to the anode A which is usually a saturated calomel electrode. With switch T_1 in position a, a known potential may be applied across the electrodes by means of a potentiometer arrangement (battery B and slide wire R_1). The applied potential is read directly from the potentiometer scale, whose cali-

²⁵ If desired the voltmeter may be eliminated. In this case adjust the rheostat so that there is no galvanometer deflection at the beginning of the titration. The end point is indicated by the galvanometer needle being thrown off the scale.

bration is maintained by the suitable use of resistance R_2 and voltmeter V. As the mercury drops fall through the solution, the applied potential is increased in successive small steps; for each step the current flowing through the system is measured on a galvanometer (G), whose sensitivity may be varied by the use of a shunt switch (S).

The value of the current obtained at each applied voltage is plotted on the y axis against the various values of applied voltage; the resulting curve is called a polarogram. As described here the polarogram is obtained manually; most commercial polarographs 33 provide for the continuous and automatic recording of the polarogram, usually by photographic means. Such a recorded polarogram is shown in Fig. 12 which shows also some of the characteristics of a simple polarogram. As the applied voltage is increased the initial portion of the curve shows a slight rise due to the "residual current" which is usually characteristic for a particular set of

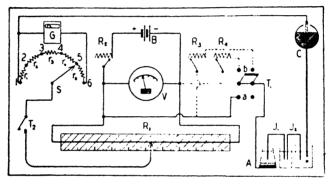

Fig. 11. Diagrammatic representation of components of simple polarograph: for explanation, see text. (From Müller: J. Chem. Education, 18, 112 (1941).)

experimental conditions. A voltage is soon reached however at which one ion species present begins to be electrolyzed (reduced) at the surface of the mercury drops.

This produces an increase in current and initiates a concentration gradient of ions between the surface of the mercury and the body of the solution. As the applied voltage is increased electrolysis is accelerated, the concentration gradient increases, and the current rises markedly. When the applied voltage is sufficiently high the concentration gradient reaches a maximum value and the current becomes constant. No further change in current will occur until the applied voltage is sufficient to bring about reduction of some other type of ion which may be present, when a second wave will be obtained, and so on.

The current-voltage curve for a particular ion is approximately symmetrical around the half-wave potential, which is determined by the kind of ion undergoing reduction. Under the proper conditions the wave height becomes a measure of the concentration of the ion.

²² Manufacturers of polarographs include the E. H. Sargent Co. of Chicago, Leeda and Northrup of Philadelphia, the Fisher Scientific Co. of Pittsburgh, the American Instrument Co. of Silver Springs, Md., and others.

Few polarograms are as simple as that illustrated; some are so complex as to require careful study before their significance is clear, but the fundamental principles outlined are generally applicable. The concentration of material required for polarographic analysis is quite low, ranging from 10^{-3} M to 10^{-5} M under ordinary circumstances in a volume of 1 ml. or more. It is worthy of note that solutions may be regarded as essentially unchanged in composition after polarography, since the actual amount of electrolysis which occurs is ordinarily almost undetectable in terms of concentration.

In addition to its obvious application to the field of inorganic analysis, the polarograph is finding increasing application in organic and physiological chemistry. It has been applied for example to the determination of

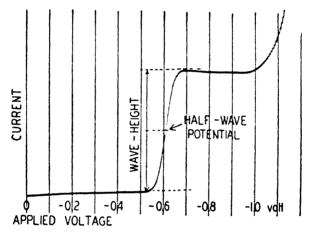

Fig. 12. Typical polarogram. Air-free solution of 0.001 M CdSO₄ in 0.1 M CoCl₂ buffered at pH 5. (From Müller: J. Chem. Education, 18, 71 (1941).)

certain hormones and vitamins, to a differentiation between normal and pathological blood serum, and to the measurement of oxygen consumption by plant and animal cells.

Electrical Conductance of Solutions. The power of a solution to conduct an electrical current depends on the number of ions in the solution and the mobility of those ions. Strong acids and bases, or the salts of strong acids and bases, are completely dissociated in solution. Weak acids and bases and their salts are but slightly dissociated, and neutral organic substances other than salts do not ionize.

It follows that the conductance of most biological fluids is dependent upon their content of salts of strong acids and bases, especially sodium and potassium chlorides. This is particularly true because of the relative abundance of chlorides of sodium and potassium in body fluids. Thus the blood and bile of most mammals are higher in chlorides and possess considerably higher conductances than milk and saliva, which are lower in chlorides.

When we study the gastric juice we at once note that while the ash of this fluid is very low as compared with blood, bile, pancreatic juice, etc., its conductance is much higher than that of these fluids. Thus the specific conductance of bile at 18° is 130×10^{-4} reciprocal ohms, that of blood serum about 110×10^{-4} , and that of saliva about 50×10^{-4} , whereas the

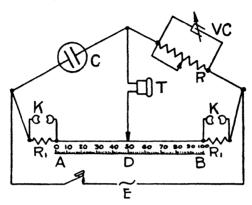

Fig. 13. Diagram of apparatus for determination of electrical conductivity. C is the conductivity cell, R the resistance box, AB the slide wire resistance, T a telephone, and E a source of alternating current.

conductance of pure gastric juice is over 400×10^{-4} reciprocal ohms. The total chlorine of gastric juice is not notably higher than in blood, bile, or pancreatic juice, but it conducts a current much more readily because of the great mobility of the hydrogen ion. The ionic speed (at 18° and a po-

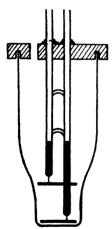

Fig. 14. Conductivity cell.

tential of one volt per cm.) of the sodium ion is 43.5×10^{-6} cm. per second, of the potassium ion 64.6×10^{-5} , of the chlorine ion 65.5×10^{-5} , whereas that of the hydrogen ion is 318×10^{-5} cm. per second. A tenth normal solution of hydrochloric acid at 18° has a specific conductance of 351×10^{-4} as compared with 92.5×10^{-4} for sodium chloride and 111.9×10^{-4} for potassium chloride.

It is easy to understand therefore why the conductivity of gastric contents generally runs parallel with the free hydrochloric acid, although in low acidities, especially following regurgitation of pancreatic juice and bile, the alkali chlorides become an important factor. Conductivity determinations are also used for the measurement of the volume of red cells in blood (the plasma conducts, but the red cells do not) and for other studies on blood and urine. Studies on suspensions of other types of cells also throw light on

the conductivity of protoplasm and the permeability of the cells for ions.

Procedure: Set up apparatus as indicated in Fig. 13. The conductivity cell C contains the unknown solution between two platinum electrodes. A cell suitable for biochemical work and requiring but small amounts of material

is illustrated in Fig. 14. R is a resistance box, AB is a resistance wire mounted on a meter stick or similar scale. D is a sliding contact, T is a telephone headset, and E is a source of alternating current.²⁴

Introduce the solution to be tested into the conductivity cell so that it covers both electrodes. Allow to come to a constant temperature. Put on the headset and press down the sliding contact. A hum is noted showing that a current is passing through the telephone. Introduce resistances at R by removing plugs or turning dials until on moving sliding contact along the wire a point of silence or minimum sound is obtained. Adjust resistances further until the point of minimum sound is somewhere near the center of the slide wire.

The current entering the circuit at the junction of C and R divides, part

going through C and AD, and the other part through R and DB. At the point of silence the two ends of the slide wire have the same potential and C/AD = R/BD or C/R = AD/BD. Add up the resistances introduced at R and take the reading of the slide. Then X (resistance of cell): R:: AD: BD or $X = R \frac{AD}{BD}$. With a scale of 100 divisions this becomes $X = R \frac{a}{100 - a}$ or if extension coils are used $X = R \frac{450 + A}{550 - A}$. Thus if the resistance box reads 100 ohms and the slide wire 40, the resistance of the cell $X = 100 \frac{40}{40} = 66.7$ ohms. Conduct-

- 14 A suitable assembly may consist of:
- 1. A cell of the type illustrated. For solutions of high resistance the electrodes should be large and close together and for solutions of low resistance they may be small and placed farther apart. The electrodes should be platinized by electrolyzing a dilute solution of platinic chloride (reversing the current so as to platinize both electrodes), then one of dilute sulfuric acid, and washing thoroughly with water. When not in use the cell should be kept filled with distilled water. During the determination the cell should be kept in a constant-temperature bath as conductance increases about 2 per cent with each degree rise in temperature. Connections to the cell are best made through mercury.
 - 2. A Resistance Box. The dial type is most convenient.
- 3. A Telephone Receiver (double with headband). An ordinary 2000-ohm headset may be used but for more accurate work a special receiver of lower residence should be used. Instead of a telephone receiver a galvanometer suitable for use with 110-volt 60-cycle alternating current may be used for most biological work.
- 4. A Slide Wire Resistance. An ordinary half-meter slide wire resistance may be used. More compact and accurate are the Kohlrausch circular slide wires. Resistance coils at each end of the slide wire are generally desirable. Each should have a resistance four and one-half times that of the slide wire.
- 5. A Source of Alternating Current. Alternating current must be used to provent polarization of the cell. Ordinary 110-volt 60-cycle current may be used with a suitable galvanometer. For the telephone higher frequencies are required. For high accuracy the Vreeland oscillator with 110-volt direct current may be used. A microphone hummer with four dry cells in series may be used. The simplest arrangement consists of one or more dry cells in series with an ordinary telephone buzzer. The buzzer should be placed in a soundproof box some distance from the rest of the apparatus.
- 6. A variable air condenser, VC compensates for the capacity of the cell C and results in sharper readings.
- 7. A single contact key or pushbutton. All connections should be made with low-resistance wire. The resistance of the wires from the electrode to the bridge should be the same as that of the wires connecting the resistance box with the bridge. If necessary the lead resistance may be corrected for by measuring the resistance with the cell filled with mercury, this resistance then being subtracted from measured resistances.
- 8. Determination of Cell Constant. Measure the resistance of the cell when filled with 0.1 N potassium chloride. The specific conductance of this solution at 18° is 0.01119. The cell constant is equal to the measured resistance multiplied by the specific conductance. R_1 and R_1 are cell resistances each four and one-half times that of the slide wire. Putting them into the circuit (by removing plugs K and K) multiplies the resistance of the slide wire by ten and makes possible more accurate readings.

ance being the reciprocal of resistance $\left(C = \frac{1}{R}\right)$, the conductance of the cell is 1/66.7 = 0.015 reciprocal ohm or mho, the mho being the unit of conductance. As cells vary, this value must be corrected to obtain the specific conductance of the solution, By specific conductance we mean the conductance of a regular cube of the conductor having sides 1 cm. long, such as would exist between two platinum electrodes each 1 cm. square placed 1 cm. apart. To correct for the cell constant K we then have k (specific conductance) = K × C (measured conductance). Or to combine the calcula-

tions $k = \frac{K}{R} \cdot \frac{a}{100 - a}$ where a is the slide-wire reading. With any given cell

a curve may be plotted for K $\frac{a}{100-a}$ and the calculation thus simplified.

Carbohydrates

Definition. The name carbohydrates is given to a class of substances which are especially prominent constituents of plants and which are found also in the animal body either free or as components of certain proteins, lipids, and other compounds. They are called carbohydrates because they contain the elements C, H, and O, the H and O being present in the proportion to form water. The term is not strictly appropriate inasmuch as there are compounds (such as acetic acid, lactic acid, and inositol) which have H and O present in the proportion to form water, but which are not carbohydrates, and there are also true carbohydrates which do not have H and O present in this proportion—e.g., rhamnose, C₆H₁₂O₅. Chemically considered the carbohydrates are aldehyde or ketone derivatives of polyhydric alcohols, or condensation products of such substances. The aldehyde derivatives are spoken of as aldoses, and the ketone derivatives are spoken of as ketoses. It is worthy of note that the pure organic compound prepared in the largest quantity in the United States is sucrose, a carbohydrate.

Classification. The carbohydrates are usually classified according to the number of simple carbohydrate groups which they contain as mono-, di-, tri-, and polysaccharides. The monosaccharides, which contain only a single such group and cannot therefore be hydrolyzed into simpler substances, are further characterized according to the length of the carbon chain as trioses $(C_3H_6O_3)$, tetroses $(C_4H_8O_4)$, pentoses $(C_5H_{10}O_5)$, hexoses $(C_6H_{12}O_6)$, etc. The disaccharides give two molecules of simple sugars on hydrolysis and the more common ones have the general formula $C_{12}H_{22}O_{11}$. The polysaccharides give many molecules of simple sugars on hydrolysis and the formula for the more important members of this group is $(C_6H_{10}O_5)_x$ where x represents the number of simple sugar groups present. In a general way the solubility of the carbohydrates varies with the complexity, the more complex being the least soluble. This means simply that, as a class, the monosaccharides (hexoses) are the most soluble and the polysaccharides (starches and cellulose) are the least soluble.

The more common carbohydrates may be classified as follows:

- I. Monosaccharides.
 - 1. Hexoses (C₆H₁₂O₆). Glucose, fructose, galactose, mannose.
 - 2. Pentoses (C₅H₁₀O₅). Arabinose, xylose, ribose, rhamnose (methyl-pentose) C₅H₁₂O₅, desoxyribose (C₅H₁₀O₄).
- II. Disaccharides (C₁₂II₂₂O₁₁).

Maltose, lactose, sucrose, gentiobiose, isomaltose, cellobiose.

III. Trisaccharides (C₁₈H₃₂O₁₆). Raffinose.

- IV. Polysaccharides (C₆H₁₀O₅)_x.
 - 1. Starch Group. Starch, inulin, glycogen, dextrin.
 - 2. Cellulose Group.
 - (a) Cellulose.
 - (b) Hemicelluloses.
 - (1) Pentosans, Gum arabic.
 - (2) Hexosans. Galactans; agar-agar.
 - (3) Hexo-pentosans. Pectin.

Photosynthesis. It is interesting to note that the bulk of these highly complex carbohydrates found in nature, whose structures in many instances are as yet unknown, are synthesized by plants from such simple precursors as water and carbon dioxide. Although the mechanism of such synthesis is still obscure, it has long been recognized that the synthetic process is related to the presence of sunlight and chlorophyll or other such coloring matter in the plant.

The simplest possible formulation of the over-all reaction for the production of a carbohydrate such as glucose, C₆H₁₂O₆, from carbon dioxide and water by photosynthesis is the following:

$$CO_2 + H_2O \rightarrow [CH_2O] + O_2$$

$$6 [CH_2O] \rightarrow C_6H_{12}O_6$$

The postulated intermediate compound [CH₂O] has the elementary composition of formaldehyde, and in fact it was suggested many years ago by Baeyer that formaldehyde was indeed the intermediate in the photosynthesis of carbohydrate. Although the Baeyer formulation does serve to explain the observed 1:1 ratio between carbon dioxide utilization and oxygen evolution during photosynthesis, there is little positive evidence that formaldehyde or its equivalent is concerned in the processes of photosynthesis, despite the large amount of work which has been done in this connection.

It is generally agreed that photosynthesis occurs in two distinct phases, one involving reactions which proceed in the absence of light ("dark reaction" or "Blackman reaction"), and the other involving the presence of light and a photosensitive catalyst such as chlorophyll or other pigment. Opinions vary as to the relative contributions of these two phases to the total process; earlier views postulated that while carbon dioxide utilization took place in the dark, oxygen evolution was associated with the presence of light and chlorophyll. More recent views incline to the belief that both carbon dioxide assimilation and oxygen production are dark reactions in the sense that they do not fundamentally require light, the function of the light being to initiate and maintain the sequence of dark reactions by the photochemical decomposition of a suitable substance, possibly water itself, in the presence of the photocatalyst chlorophyll or similar pigment. According to this latter viewpoint, the photochemical process may be visualized as follows (Van Niel):

Some support for this view is found in the evidence obtained by the use of the oxygen isotope O¹⁸ ("heavy" oxygen; see Chapter 34) as a "tracer," that the oxygen evolved during photosynthesis is derived from the water entering the reaction and not from the carbon dioxide utilized. There is furthermore abundant evidence for the existence within protoplasm of catalysts which promote the reduction of a wide variety of substrates by the transfer of hydrogen derived either directly or indirectly from water or similar sources, and it does not appear unreasonable to postulate that this same general mechanism may hold for photosynthetic reactions.

That the reduction reaction probably does not involve carbon dioxide directly is indicated by studies based upon the use of carbon dioxide containing radioactive carbon as a marker. The results of these studies have been interpreted as demonstrating that carbon dioxide is assimilated by the formation of a carboxyl group, as follows:

$$R \cdot H + CO_2 \rightarrow R \cdot COOH$$

The carboxyl group is then assumed to undergo reduction by reaction with water:

$$R \cdot COOH + H_2O \rightarrow R \cdot CH_2OH + O_2$$

If the assimilation of carbon dioxide is then repeated and the newly formed carboxyl group again reduced, a chain containing carbohydrate groups may be built up:

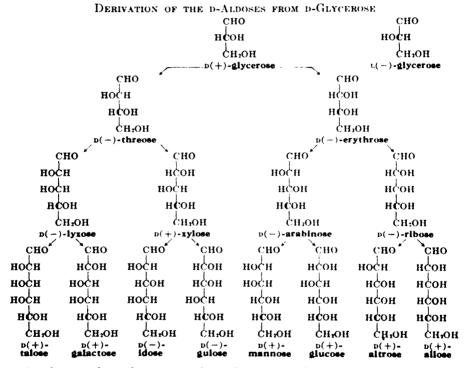

$$R \cdot CH_2OH + CO_2 \rightarrow R \cdot CHOH \cdot COOH$$

 $R \cdot CHOH \cdot COOH + H_2O \rightarrow R \cdot CHOH \cdot CH_2OH + O_2$ etc.

This hypothesis is attractive and is not incompatible with the concept expressed above that the purpose of the light energy is to activate the water so as to permit it to enter into the reaction. It is of interest to note that the formation of a carboxyl group by the uptake of carbon dioxide as described above is known to occur in both plant and animal tissues, independent of photosynthesis, and has even been directly related to the synthesis of carbohydrate within the animal body. It is nevertheless clear that much is yet to be learned concerning the mechanisms of photosynthesis, and that our present knowledge is extremely limited.

It should not be inferred that photosynthesis is of importance solely in connection with carbohydrates. Plants also produce nitrogenous and non-nitrogenous substances such as amino acids, proteins, and fats, which are of fundamental significance to animal nutrition, and there is no reason to believe that the energy of photosynthesis is not used directly or indirectly for the formation of these compounds also.

Spatial Configuration of the Sugars. The triose glycerose has one asymmetric carbon atom and therefore exists in two optically active forms, one dextrorotatory and the other levorotatory. The spatial arrangement of the groups around the asymmetric carbon atom of the dextrorotatory form of glycerose is arbitrarily called the D configuration, while that for the levorotatory form is called the L configuration. The connotation of D and L refers to spatial configuration only and is not an indication of the direction of rotation of polarized light by the compound. If it is desired to indicate the direction of rotation for the compound, the symbols (+) meaning dextrorotatory and (-) meaning levorotatory, may be used. Thus a dextrorotatory compound with the D configuration may be indicated as D(+), while a levorotatory compound with the same configuration has the symbol D(-).

As the number of asymmetric carbon atoms in the sugar molecule increases on going from the trioses to the higher monosaccharides, the number of stereoisomers increases in accordance with the van't Hoff formula 2^a, where n represents the number of asymmetric carbon atoms. All of these stereoisomers which have a configuration identical with that of p-glycerose around a suitably selected reference asymmetric carbon atom are called p sugars, regardless of their direction of rotation. The reference carbon atom is, for sugars containing more than one asymmetric carbon, the asymmetric carbon atom farthest removed from the active (i.e., alde-

¹The carbohydrate nomenclature used in this chapter follows the recommendations of the Committee on Carbohydrate Nomenclature of the American Chemical Society.

hyde or ketone) end of the molecule. These relationships for the D aldoses are illustrated by the preceding chart, in which the reference asymmetric carbon atom is indicated by heavy black type. In this connection note that if the structure is written with the active group at the top it is conventional to write the OH group on the right-hand side of the reference asymmetric carbon atom for the D configuration and on the left-hand side for the L configuration. Naturally occurring sugars are mainly of the D configuration; L sugars have, however, been isolated from certain plant and animal sources.

MONOSACCHARIDES

HEXOSES, $C_6H_{12}O_6$

The hexoses are monosaccharides containing a chain of six carbon atoms in the molecule. They may be either aldoses or ketoses. They are among the most important of the simple sugars and occur widely distributed in nature, either in the free state or in combination with other molecules. from which they may usually be separated by hydrolysis. The most important hexoses biologically are glucose, fructose, galactose, and mannose. Of these, fructose is a ketohexose; the others are aldohexoses. The various aldohexoses differ structurally from one another solely in the spatial arrangement of the H and OH groups around certain of the carbon atoms in the molecule (see p. 50). This difference may result in markedly different physiological properties. As a class the hexoses are extremely soluble, are optically active, and possess certain characteristic general and specific chemical properties which are used in their identification and determination.

Glucose, also called dextrose or grape sugar, is found widely distributed in nature either in the free state or combined with other compounds. Together with fructose, it occurs in the juice of many fruits, and is obtained commercially by the hydrolysis of starch. It is the sugar found in the blood, where its concentration normally is about 0.1 per cent. Ordinarily it is not present in the urine except possibly in traces, but appreciable amounts are found under certain conditions, such as in diabetes mellitus.

It is dextrorotatory in stable solutions, having a specific rotation of +52.5°. As an aldohexose it may be oxidized to the corresponding sugar acids or reduced to an alcohol.

$$\begin{array}{c|cccc} CH_2OH & CHO & COOH & COOH \\ | & (red.) & | & (ox.) & | & (ox.) & | \\ (CHOH)_4 \leftarrow & & (CHOH)_4 & \longrightarrow & (CHOH)_4 & \longrightarrow & (CHOH)_4 \\ | & & | & | & | & | \\ CH_2OH & CH_2OH & CH_2OH & COOH \\ \textbf{Sorbitol} & \textbf{Glucose} & \textbf{Gluconic} & \textbf{Saccharic} \\ \textbf{acid} & \textbf{acid} & \textbf{acid} \end{array}$$

Another oxidation product, glucuronic acid, CHO·(CHOH)₄·COOH is of considerable physiological importance, being found in the urine in combination with certain excretory products (see Chapters 20 and 29).

The behavior of glucose solutions indicates that only a small fraction of the substance is present in the free aldehyde form, the remainder existing chiefly in a less active modification in which the carbon atom of the

aldehyde group is linked to the fifth carbon atom by means of an atom of oxygen. (See formulas.) This type of linkage is known as the amylene oxide ring and since, in its formation, the first carbon atom has become asymmetric, we find that two modifications of this form exist: the first, known as α -D-glucose, has a specific rotation of +113.4° and the second, known as β -D-glucose, has a specific rotation of +19°. In solution these forms are in equilibrium with each other and probably also with a small amount of the more active form having the free aldehyde group, the specific rotation of the equilibrium mixture, which is the rotation ordinarily measured, being +52.5°.

In freshly prepared solutions of glucose the α form exists alone, the solution having a specific rotation of $+113.4^{\circ}$. On standing, however, some of the molecules are slowly transformed into the β form and an equilibrium is finally established between the two forms. A trace of alkali hastens the formation of this equilibrium. The specific rotation of the solution falls as the amount of the β form increases until equilibrium, with its characteristic specific rotation of $+52.5^{\circ}$, is reached. This phenomenon is known as mutarotation. Mutarotation is observed not only with glucose but with all sugars which have a free or potentially free aldehyde or ketone group in the molecule.

In addition to the amylene oxide configurations glucose may exist in forms where the terminal carbon atom is linked through an oxygen atom to other carbon atoms than the fifth, thus forming ethylene, propylene, and butylene oxide rings each of which may exist in the α and β forms. Of these various forms the butylene oxide form predominates, but there is evidence that all of the forms mentioned may exist in glucose solutions. These modifications are more reactive than the ordinary amylene oxide

form and are presumably responsible for the concept of an "active" form of the glucose molecule, the so-called γ -glucose.

 α and β forms, respectively, of butylene oxide structure of ν -glucose

Haworth has pointed out that the amylene oxide and butylene oxide rings are structurally related to pyran and furan, respectively. Normal

glucose, using the nomenclature proposed by Haworth and now widely used, thus becomes glucopyranose while the butylene oxide form is called glucofuranose.

X-ray examinations indicate that the five carbon atoms of the pyranose ring lie in the same plane while the oxygen atom lies in a different plane. The H and OH groups are placed above and below this plane of carbon atoms in accordance with the chemical evidence concerning the positions of these groups in the sugar molecule.

In common with other reducing sugars glucose is quite labile to the action of alkali. A trace of alkali accelerates the attainment of equilibrium between the α and β forms. Further contact with alkali results in

the appearance of fructose and mannose in the solution in equilibrium with glucose, probably through the intermediate formation of a common enol tautomer involving the first two carbon atoms. Strong alkali (with heating) decomposes the molecule completely, producing a number of smaller fragments and condensation products which usually give a brown color to the solution (Moore's test, now obsolete).

Glucose is one of the sweetest of the common sugars, being excelled only by fructose and sucrose. The following table gives the relative sweetness of some of the sugars considering sucrose as 100:

Sugar	Relative Sweetness (Sucrose = 100)		
T 4	. 10.0		
Lactose	16.0		
Raffinose	22.6		
Galactose	32.1		
Rhamnose	32.5		
Maltose	32 5		
Xvlose	40.0		
Glucose	74 3		
Sucrose	100.0		
Invert sugar	130.0		
Fructose.	173.3		

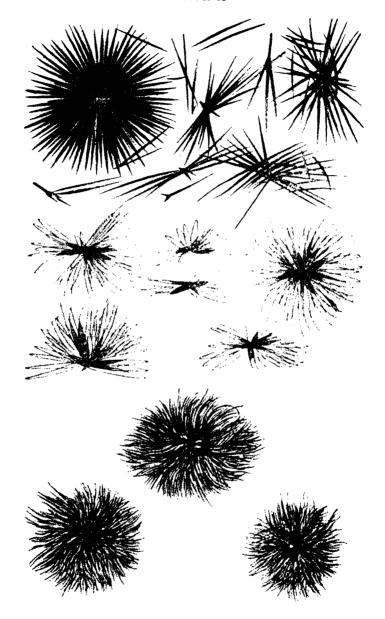

Experiments on Glucose

The following tests are made on glucose (1 per cent solution) as a typical carbohydrate, and are not specific for this sugar. A specific test for glucose is the formation of glucosazone by the Phenylhydrazine Reaction (3) without the preliminary formation of an insoluble hydrazone (mannose) and in the absence of a positive Resorcinol-Hydrochloric Acid Reaction (fructose).

- Solubility: Test the solubility of glucose in water and in alcohol. If in doubt
 about the solubility of a compound, filter from excess solid and test the filtrate for the substance in question; or if the solvent is nonaqueous, allow
 it to evaporate and examine it for a residue.
- 2. α-Naphthol Reaction (Molisch): To 5 ml. of sugar solution in a test tube, add 2 drops of Molisch's reagent (a 5 per cent solution of α-naphthol in alcohol). Mix thoroughly. Incline the tube and allow about 3 ml. of concentrated sulfuric acid to flow down the side of the tube, thus forming a layer of acid beneath the sugar. A reddish-violet zone appears at the junction between the two liquids. Repeat the test, using 5 ml. of 0.1 per cent furfural solution instead of the sugar. Instead of α-naphthol, 3 to 4 drops of a 5 per cent alcoholic solution of thymol may be used.

The reaction is due to the formation of furfural and furfural derivatives, such as hydroxymethylfurfural, by the acid acting on the sugar.

Thymol has the advantage that its solutions do not deteriorate. Like the α -naphthol test it is also given by aldehydes and by acids such as formic, lactic, oxalic, citric, etc., and by acetone. The tests are very delicate, being given by solutions of 0.001 per cent glucose and 0.0001 per cent sucrose.

OSAZONES.

 $\label{thm:local_potential} \begin{subarray}{ll} $Upper\ form,\ dextrosazone\ (glucosazone)\ ;\ central\ form,\ maltosazone\ ;\ lower\ form,\ lactosazone. \end{subarray}$

The test is thus given by furfural and all furfural-yielding substances and is not a specific test for carbohydrates. Concentrated solutions of organic compounds may give a red instead of a violet color due to the charring action of the sulfuric acid. In case of doubt the reaction should be repeated on a more dilute solution of the material to be tested.

3. Phenylhydrazine Reaction: To a small amount of phenylhydrazine mixture (about ½ inch in a small test tube), 2 add 5 ml. of the sugar solution, shake well, and heat on a boiling water bath for one-half to three-quarters of an hour. Allow the tube to cool slowly (not under the tap) and examine the crystals microscopically (see Plate II). Better crystals may be obtained if the tubes are allowed to cool in the water bath.

If the solution has become too concentrated in the boiling process it will be light red in color and no crystals will separate until it is diluted with water.

Yellow crystalline bodies called osazones are formed from certain sugars under these conditions, each individual sugar in general giving rise to an osazone of a definite crystalline form which is typical for that sugar. It is important to remember in this connection that, of the simple sugars of interest in physiological chemistry, glucose, fructose, and mannose yield the same osazone because of similarities in their molecular structures. Of the various osazones, it is generally possible to recognize glucosazone by its crystalline form. Maltosazone may also be recognized if it happens to crystallize in its most characteristic form. Otherwise it may not be possible to distinguish it from lactosazone. The melting points of the recrystallized osazones may be used as a further means of identification but since they extend over a range of several degrees and are not far apart for the different sugars, the determination of melting points is of doubtful value.3 The reaction with glucose is sufficiently delicate to produce under favorable conditions a visible precipitate with solutions containing as little as 0.01 per cent glucose.

The reaction leading to the formation of glucosazone is indicated by the following equations. The intermediate steps between hydrazone and osazone are not known with certainty.

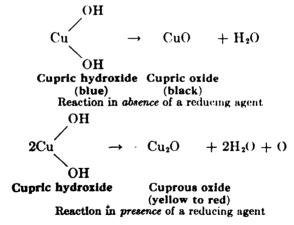

² See Appendix.

⁸ See Moore and Link: J. Biol. Chem., 133, 293 (1940), for a method of obtaining crystalline sugar derivatives claimed to be superior to the osazone reaction.

4. Diffusibility of Glucose: Test the diffusibility of glucose through a membrane, using a dialyzing bag similar to the type described under Experiments on Colloidal Solutions in Chapter 1.

All monosaccharides and disaccharides are diffusible, but many polysaccharides are not.

5. Reduction Tests. To their free or potentially free aldehyde or ketone groups many sugars owe in part the property of readily reducing in alkaline solution the ions of certain metals such as copper, bismuth, mercury, iron, and silver. Upon this property of reduction the most widely used tests for sugars are based. For example, when blue cupric hydroxide in suspension in an alkaline liquid is heated it is converted into insoluble black cupric oxide, but if a reducing agent like certain sugars be present the cupric hydroxide is reduced to insoluble yellow or red cuprous oxide. These changes are indicated as follows:

The use of a suspension of a metallic oxide or hydroxide as a reagent is obviously impractical. Certain organic compounds, particularly those containing one or more alcoholic OH groups in the molecule (e.g., tartaric acid, citric acid, glycerol, even the sugars themselves), react in alkaline solution with metallic hydroxides to form a soluble complex ion which, while relatively little ionized, nevertheless dissociates to yield sufficient ions of the metal so that reduction reactions may occur. The formation of such a complex is the basis for most of the heavy metal reagents for reducing sugars.

The alkali in these reagents brings about considerable decomposition of the sugar molecule into reactive fragments which may also reduce the metal ions. Thus while the total reduction for a given concentration of sugar may be constant under carefully defined conditions and is therefore utilizable for quantitative purposes, it is impossible to write a balanced equation for the reaction in terms of the simple oxidation of the sugar and reduction of the metal ion.

The chemical reactions here discussed are exemplified in the following tests. (For the application of these and other tests to the detection of sugar in urine, see Chapter 29.)

a. Fehling's Test: To about 1 ml. of Fehling's solution in a test tube add about 4 ml. of water, and boil. This is done to determine whether the solution will of itself cause the formation of a precipitate of brownish-red cuprous oxide. If such a precipitate forms, the Fehling's solution must not be used. To the warm Fehling's solution add sugar solution a few drops at a time and heat the mixture after each addition. The production of yellow or brownish-red cuprous oxide indicates that reduction has taken place. The differences in color of the cuprous oxide precipitates under different conditions are apparently due to differences in the size of the particles, the more finely divided precipitates having a yellow color while the coarser ones are red (see Exp. 11, p. 10). In the presence of protective colloidal substances the yellow precipitate is usually formed.

In testing a solution preserved by chloroform a positive reaction may be obtained in the absence of sugar. This is due to the fact that the hot alkali produces reducing substances from the chloroform.

Ammonium salts also interfere with Fehling's test. If present in excess the solution (e.g., urine) should be made alkaline with Na₂CO₃ and boiled in order to decompose the ammonium salts. Prolonged contact with hot strong alkali may lead to destruction of the sugar present.

If the solution under examination by Fehling's test is acid in reaction it must be neutralized or made alkaline before applying the test.

b. Benedict's Test: Benedict modified the Fehling solution to produce an improved reagent which has largely displaced the latter in routine laboratory practice. The following is the procedure for the detection of glucose in solution. To 5 ml. of the reagent in a test tube add exactly 8 drops of the solution under examination. Mix well. Boil the mixture vigorously for two minutes (or place in boiling water for three minutes), and then allow the fluid to cool spontaneously (do not hasten cooling by immersion in cold water). In the presence of dextrose the entire body of the solution will be filled with a precipitate which may be red, yellow, or green in color, depending upon the amount of sugar present. In the presence of over 0.2 to 0.3 per cent of glucose, the precipitate will form quickly. If no glucose is present, the solution will remain perfectly clear.

Even very small quantities of glucose (0.1 per cent) yield precipitates of surprising bulk with this reagent, and the positive reaction for glucose is the filling of the entire body of the solution with a precipitate, so that the solution becomes opaque. Since amount rather than color of the precipitate is made the basis of this test, it may be applied, even for the detection of small quantities of glucose, as readily in artificial light as in daylight.

^{&#}x27;See Appendix.

See Appendix.

Chloroform does not interfere with this test nor do uric acid or creatinine interfere to such an extent as in the case of Fehling's test.

c. Bismuth Reduction Test (Nylander): To 5 ml. of sugar solution in a test tube add one-tenth its volume of Nylander's reagent⁶ and heat for five minutes in a boiling water bath. The solution will darken if reducing sugar is present, and upon standing for a few moments a black color will appear.

This color is due to the precipitation of metallic bismuth. If the test is made on a solution containing albumin this must be removed, by boiling and filtering, before applying the test, since with albumin a similar change of color is produced. Glucose when present to the extent of 0.08 per cent may be easily detected by this reaction. Uric acid and creatinine which interfere with the Fehling's test do not interfere with the Nylander test. It is claimed that the bismuth reduction tests give a negative reaction with solutions containing sugar when mercuric chloride or chloroform is present. The inhibitory action of mercuric chloride is questionable; the inhibitory influence of chloroform may be overcome by raising the temperature of the urine to the boiling point for a period of five minutes previous to making the test.

A positive bismuth reduction test is probably due to the following reactions:

(a)
$$Bi(OH)_2NO_3 + KOH \rightarrow Bi(OH)_3 + KNO_3$$

(b) $2Bi(OH)_3 - 3O \rightarrow 2Bi + 3H_2O$

d. Barfoed's Test: To 5 ml. of Barfoed's solution in a test tube, add 0.5 ml. of glucose solution and heat to boiling. Reduction is indicated by the formation of a red precipitate of cuprous oxide. If the precipitate does not appear after boiling for 30 seconds, allow the tube to stand for about 15 minutes and examine.

To compare reactions of mono- and disaccharides, place 0.5-ml. portions of glucose, fructose, maltose, lactose, and sucrose solutions in each of five test tubes, add 5 ml. of Barfoed's solution to each tube, mix, and place in a boiling water bath. Note the time when signs of reduction first appear in each tube. Continue boiling for 15 minutes, remove the tubes from the bath, and note the amounts of precipitate in the bottom of each tube after standing for 15 minutes. Record your observations.

Barfoed's test is not a specific test for glucose, serving simply to detect monosaccharides. Disaccharides will also respond to the test under proper conditions of acidity. Also if the sugar solution is boiled sufficiently long in contact with the reagent to hydrolyze the disaccharide through the action of the acetic acid present in the Barfoed's solution, a positive test results. Barfoed's is a copper reduction test, but differs from Fehling's and other reduction tests in that the reduction is brought about in an acid solution. It is unsuited for the detection of sugar in urine or in any fluid containing chlorides.

e. Tauber and Kleiner Modification of Barfoed's Test: Introduce into one test tube 1 ml. of an approximately 0.1 per cent solution of the sugar to be

⁴ See Appendix,

tested. Put into another tube 1 ml. of water. Add 1 ml. of copper reagent⁷ to each. Heat in a boiling water bath for 3 minutes, cool for 2 minutes. Add 1 ml. of color reagent⁸ to each. Mix. A blue color will be obtained if monosaccharides are present. With only disaccharides present the color will be the same as in the control. Chlorides interfere but not in amounts as large as 5 mg. per ml. of solution.

f. Picric Acid Test: To 5 ml. of the sugar solution add 2 to 3 ml. of saturated picric acid solution and about 1 ml. of 10 per cent Na₂CO₂: Warm. Note the development of a mahogany-red color in the presence of glucose due to reduction of the picric acid with the formation of picramic acid:

e picric acid with the formation of picramic acid

$$\begin{array}{c} C_6H_2\text{-}OH(NO_2)_3 \longrightarrow C_6H_2\text{-}OH\text{-}NH_2(NO_2)_2 \\ \text{Pieric acid} & \text{Picramic acid} \end{array}$$

6. Alcoholic Fermentation: Prepare 500 ml. of a concentrated (10 per cent) solution of glucose, add a small amount of egg albumin or commercia peptone, and introduce the mixture into a liter flask. Add yeast, and by

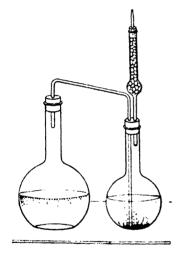

Fig. 15. Fermentation apparatus.

means of a bent tube connect this flask with a second flask containing a solution of barium hydroxide protected from the air by a soda-lime tube in the stopper (Fig. 15). Place the flasks in a warm place and note the passage of gas bubbles into the barium hydroxide solution. As these gas bubbles (CO₂) enter, a white precipi-

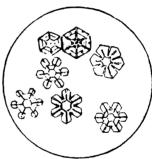

Fig. 16. Iodoform (Autenrieth).

tate of barium carbonate will form. The glucose has been fermented according to the following equation:

$$C_6H_{12}O_6 \rightarrow 2C_2H_bOH + 2CO_2$$

The important intermediate products formed during this reaction are indicated below. (For further details see Chapter 33 on carbohydrate metabolism.)

$$\begin{array}{cccc} \textbf{Hexose} & \rightarrow & \textbf{Hexose} & \rightarrow & \textbf{Phosphoglyceric} & \rightarrow & \textbf{Pyruvic} & \rightarrow & \textbf{Acetaldenyde} & \rightarrow & \textbf{Ethyl} \\ \textbf{di-phosphoric} & & \textbf{acid} & & \textbf{acid} & & \textbf{alcohol} \\ & & & & \textbf{acid} & & & & & & \\ \end{array}$$

When the activity of the yeast has practically ceased, decant the supernatant fluid, return it to the cleaned flask, connect with a condenser, and distil. Catch the first portion of the distillate, which may be redistilled if its alcohol content is low, and test for alcohol by the following reaction:

⁷ See Appendix.

^{*}Benedict's or Folin's phosphomolybdic reagents for sugar in blood may be used. See blood-sugar methods, Chapter 23.

lodoform Test: Render 2 to 3 ml. of the distillate alkaline with sodium hydroxide solution and add a few drops of strong iodine solution—e.g., Lugol's. Warm gently and note the formation of iodoform crystals. Examine these crystals under the microscope and compare them with those in Fig. 16.

7. Fermentation Test:

Fig. 17. Einhorn saccharometer.

"Rub up" in a mortar about 20 ml. of the sugar solution with a small piece of compressed yeast. Transfer the mixture to a saccharometer, and stand it aside in a warm place for about 12 hours. If the sugar is fermentable, alcoholic fermentation will occur and carbon dioxide will collect as a gas in the upper portion of the tube. On the completion of fermentation introduce 2 to 3 ml. of 10 per cent sodium hydroxide solution into the graduated portion by means of a bent pipet, fill the bulb portion with water, place the thumb tightly over the opening in the apparatus, and invert the saccharometer. Remembering that NaOH has the power to absorb CO2, how do you explain the result?10 Filter some of the mixture. To 5 ml. of the filtrate add several drops (enough to give a yellow color to the whole mixture), of a strong solution of iodine in potassium iodide (e.g., Lugol's). Warm gently. Note the iodoform odor and examine under a microscope for crystals of iodoform. What does a positive test here indicate?

8. Demonstration of Optical Activity: A demonstration of the use of the polariscope should be made by the

instructor, each student being required to take readings and apply the polariscope to the determination of either the specific rotation or the concentration of a sugar.

The Polariscope

For a detailed description of the different forms of polariscopes, the method of manipulation, and the principles involved, the student is referred to any standard textbook of physics. A brief description follows.

Waves of ordinary light vibrate in all planes perpendicular to the direction of propagation. By certain means light may be caused to vibrate in but a single plane, and is then said to be plane polarized. Thus if a ray of light is passed through a crystal of calcite (natural crystallized calcium carbonate), it is divided into two rays each polarized and vibrating in planes perpendicular to each other (Fig. 18). As the two rays are unequally bent it is possible to completely separate them and thus obtain light vibrating in but a single plane. For this purpose we may use a Nicol prism consisting of two pieces of calcite cemented together with Canada balsam. The ray of light l on entering the prism is divided into two rays. One, called the ordinary ray o, is reflected from the Canada balsam to

The formation of iodoform may be represented by the following equations:

CH₁·CH₂OH + I₂ + 2NaOH \rightarrow CH₁·CHO + 2NaI + 2H₂O CH₂·CHO + 3I₁ + 3NaOH \rightarrow CI₁·CHO + 2NaI + 3H₂O CI₂·CHO + NaOH \rightarrow CHI₂ + HCOONa

¹⁶ The liberation of carbon dioxide by yeast is not necessarily a criterion of the presence of sugar. The presence of an ensyme, called *carboxylase*, has been demonstrated in yeast which has the power of splitting off CO₂ from the carboxyl group of amino- and other aliphatic acids.

the exterior and absorbed by the black varnish coating the prism. The other, the extraordinary ray e, passes through the balsam and emerges from the prism as polarized light. Many organic substances (sugar, proteins, etc.) have the power of twisting or rotating this plane of polarized light, the extent to which the plane is rotated depending upon the nature of the molecule and upon the number of molecules which the polarized light passes. Substances which possess this power are said to be "optically active." The specific rotation of a substance is the rotation expressed in

Fig. 18. Path of light ray through Nicol prism.

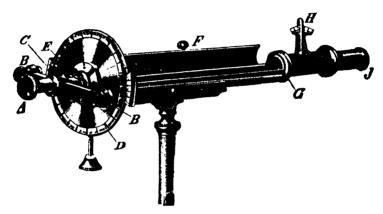

Fig. 19. One form of Laurent polariscope. (B) Microscope for reading the scale; (C) a vernier; (E) position of the analyzing Nicol prism; (H) polarizing Nicol prism in the tube below this point.

degrees which is afforded by 1 g. of substance dissolved in 1 ml. of water in a tube 1 dm. in length. The specific rotation, $(\alpha)_D$, may be calculated by means of the following formula:

$$(\alpha)_{p} = \frac{\alpha}{p \cdot l}$$

in which

p = sodium light,

 α = observed rotation in degrees,

p = g. of substance dissolved in 1 ml. of liquid,

l = length of the tube in decimeters.

If the specific rotation has been determined and it is desired to ascertain the percentage of the substance in solution, this may be obtained by the use of the following formula:

$$p = \frac{\alpha}{(\alpha)_D l}$$

The value of p multiplied by 100 will be the percentage of the substance in solution.

Rhamnose	+ 9.0°	Glycogen	$+197.0^{\circ}$

An instrument by means of which the extent of the rotation may be determined is called a polariscope or polarimeter. Such an instrument designed especially for the examination of sugar solutions is termed a saccharimeter or polarizing saccharimeter. The form of polariscope in Fig. 19 consists essentially of a long barrel provided with a Nicol prism at either end (Fig. 20). The solution under examination is contained in a

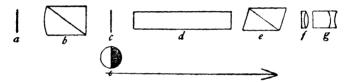

Fig. 20. Diagrammatic representation of course of light through Laurent polariscope. (The direction is reversed from that of Fig. 19.) (a) Bichromate plate to purify light; (b) polarizing Nicol prism; (c) a thin quartz plate covering one-half the field and essential in producing a second polarized plane; (d) tube to contain liquid under examination; (e) analyzing Nicol prism; (f) and (g) ocular lenses.

tube which is placed between these two prisms. At the front end of the instrument is an adjusting eyepiece for focusing and a large recording disk which registers in degrees and fractions of a degree. The light is admitted into the far end of the instrument and is polarized by passing through a Nicol prism. This polarized ray then traverses the column of liquid within the tube mentioned above and if the substance is optically active the plane of the polarized ray is rotated to the right or left. Compounds rotating the ray to the right are called dextrorotatory and those rotating it to the left levorotatory.

Within the apparatus is a disk which is so arranged as to be without lines and uniformly light at zero. Upon placing the optically active substance in position, however, the plane of polarized light is rotated or turned and it is necessary to rotate the disk through a certain number of

¹¹ The specific rotation varies with the temperature and concentration of the solution. The figures here given are for concentrations of about 10 per cent and temperatures of about 20° C. Fresh solutions may give markedly different values due to mutarotation, the figures here given representing the constant values obtained on standing.

degrees in order to secure the normal conditions—i.e., "without lines and uniformly light." The difference between this reading and the zero is α or the observed rotation in degrees.

Sugar solutions (glucose, levulose, lactose, maltose, but not sucrose) when freshly prepared possess a changing rotation—so-called mutarotation. For this reason such solutions before polariscopic examination should be allowed to stand over night, heated to 100° C. and then cooled, or treated with a drop of ammonia followed by a drop of acid. This brings about an equilibrium between the α and β forms possessing different rotations and of which ordinary glucose is a mixture.

Polarizing saccharimeters are also constructed by which the percentage of sugar in solution is determined by making an observation and multiplying the value of each division on a horizontal sliding scale by the value of the division expressed in terms of dextrose. This factor may vary according to the instrument.

Methods embracing the determination of the optical rotation are utilized in many analytical procedures, for identifying liquids, or solutions, as well as for establishing the composition of solutions.

As already stated, fructose, sometimes called levulose or fruit sugar, occurs widely disseminated throughout the plant kingdom in company with glucose. It has been prepared commercially from the inulin of the Jerusalem artichoke. It is not found free in detectable amounts in animal tissues or fluids except under certain exceptional conditions, but in the form of its phosphoric acid esters it is a recognized intermediate in carbohydrate metabolism.

Although fructose is a ketose it nevertheless reduces metallic oxides in alkaline solution due to the presence of the terminal group CO·CH₂OH. For the same reason monohydroxyacetone (CH₃·CO·CH₂OH) also reduces such solutions although acetone (CH₃·CO·CH₃) does not. With phenylhydrazine, fructose forms the same osazone as glucose. With methylphenylhydrazine, it forms an osazone more rapidly than does glucose.

Fructose in solution undergoes mutarotation just as glucose does, and for similar reasons, the rotation of a fresh solution being -133.5° which changes to -92.3° on standing or in the presence of a trace of alkali. The relation between the free ketone form and the α and β forms, and the existence of pyranose and furanose structures, is similar to the situation already described for glucose and is illustrated by the formulas which follow:

Ordinary fructose consists chiefly of the pyranose form; fructose in the combined state, as in sucrose and inulin, appears to be invariably in the more reactive furanose form.

Experiments on Fructose

- 1-6. Repeat Solubility, Benedict's, Phenylhydrazine, Barfoed's, Nylander's, and Fermentation tests as given for Glucose.
- 7. Resorcinol-Hydrochloric Acid Reaction (Selivanoff): To 5 ml. of Selivanoff's reagent¹² in a test tube add 5 drops of a fructose solution and heat the mixture to boiling. A positive reaction is indicated by the production of a red color with or without the separation of a brown-red precipitate. The latter may be dissolved in alcohol, to which it will impart a striking red color.

To compare the reactions of aldose and ketose sugars, place 0.5-ml. portions of glucose, fructose, maltose, lactose, and sucrose solutions into each of five test tubes, add 5 ml. of Selivanoff's reagent to each tube, mix, and place in a boiling water bath. Note the time when color first appears in each tube. Continue boiling for 15 minutes, noting the color developed in each tube at approximately five-minute intervals. Record your observations.

This test is also given by sucrose which is hydrolyzed during the course of the test yielding fructose as one product. If the boiling be prolonged a similar reaction may be obtained with solutions of glucose or maltose. This has been explained in the case of glucose as due to the transformation of the glucose into fructose by the catalytic action of the hydrochloric acid. The precautions necessary for a positive test for levulose are as follows: The concentration of the hydrochloric acid must not be more than 12 per cent. The reaction (red color) and the precipitate must be observed after not more than 20 to 30 seconds' boiling. Glucose must not be present in amounts exceeding 2 per cent. The precipitate must be soluble in alcohol with a bright red color.

8. Formation of Methylphenylfructosazone: To a solution of 1.8 g. of levulose in 10 ml. of water add 4 g. of methylphenylhydrazine and enough alcohol to clarify the solution. Introduce 4 ml. of 50 per cent acetic acid and heat the mixture for 5 to 10 minutes on a boiling water bath. 13 On standing 15 minutes at room temperature, crystallization begins and is complete in two hours. By scratching the sides of the flask or by inoculation, the solution quickly congeals to form a thick paste of reddish-yellow silky needles.

¹² See Appendix.

¹⁸ Longer heating is to be avoided.

These are the crystals of methylphenylfructosazone. They may be recrystallized from hot 95 per cent alcohol (m. p. 153° C.). Glucose may give the same osazone more slowly (after five hours).

GALACTOSE

Galactose occurs with glucose as one of the products of the hydrolysis of lactose. It is also found as a constituent of the galactolipids of nervous tissue. Galactose is a typical aldohexose, is dextrorotatory and exhibits mutarotation in solution, and forms a characteristic osazone with phenylhydrazine. It ferments either very slowly or not at all with ordinary yeast, although some varieties of yeast ferment it readily. Upon oxidation with nitric acid galactose yields mucic acid, thus differentiating this monosaccharide from glucose and fructose. Lactose also yields mucic acid under these conditions. Mucic acid is COOH(CHOH)4COOH, the H and OH groups on carbon atoms 2 to 5 having the same spatial configuration as for galactose itself. Although mucic acid contains four asymmetric carbon atoms, it is optically inactive because one-half of the molecule is the mirror image of the other half (so-called internal compensation).

Experiments on Galactose

- 1. Phloroglucinol-Hydrochloric Acid Reaction (Tollens): To equal volumes of galactose solution and hydrochloric acid (sp. gr. 1.09) add a little phloroglucinol, and heat the mixture on a boiling water bath. Galactose, pentose, and glycuronic acid will be indicated by the appearance of a red color. Galactose may be differentiated from the two latter substances in that its solutions exhibit no absorption bands upon spectroscopic examination.
- 2. Mucic Acid Test:¹⁴ Place about 50 mg. of galactose in a clean, dry test tube, add 1 ml. of distilled water and 1 ml. of concentrated nitric acid. Heat in a boiling water bath for 1½ hour. Let stand over night. A crystalline precipitate of mucic acid, which may be identified by microscopical examination of the crystals, forms under these conditions.
- 3. Phenylhydraxine Reaction: Make the test according to directions given for Glucose.

¹⁴ This modification of the mucic acid test was suggested by Dr. A. G. Cole of the University of Illinois College of Medicine. Smaller quantities of galactose (or lactose) may be used (20 mg.), but in such cases crystallisation may take two or three days.

Mannose is an aldohexose, differing structurally from glucose solely in the spatial arrangement of H and OH groups around carbon atom number 2 (see structure, p. 51). It is found in nature chiefly in the form of polysaccharides called mannans or mannosans which occur in plants, particu-

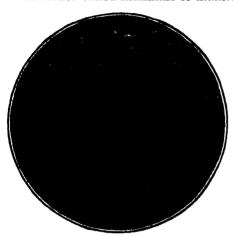

Fig. 21. Mucic acid crystals. (From a photomicrograph furnished by Prof. William H. Welker.)

larly in certain seeds ("vegetable ivory"), and from which mannose may be obtained by hydrolysis. Interest in mannose has been heightened by the discovery that it is present in small amount in certain animal proteins. Mannose is a reducing sugar and is fermentable by yeast. It is readily distinguished from glucose by the formation of a sparingly soluble, colorless, crystalline phenylhydrazone when treated with phenylhydrazine at room temperature.

Experiments on Mannose

1-4. Repeat Benedict's, Barfoed's, Selivanoff's, and Fermentation tests as given for Glucose and Fructose.

5. Reaction with Phenylhydrazine: Place a small amount of solid phenylhydrazine reagent in a test tube and add 5 ml. of mannose solution. Shake well and allow to stand at room temperature for 10 or 15 minutes. Observe the development of a colorless crystalline precipitate of mannose phenylhydrazone (examine a drop under the microscope). When the hydrazone has been obtained, place the tube in boiling water for one-half to three-quarters of an hour, remove, and allow to cool slowly. What change has occurred? Examine a drop of the suspension at this point under the microscope. Explain. As a control, a glucose solution may be carried through the same experimental procedure.

PENTOSES, C₆H₁₀O₆

Pentoses are usually defined as sugars containing five carbon atoms in the molecule, although rhamnose, $C_6H_{12}O_5$, a methylpentose, is an exception to this statement. The pentoses are widely distributed in plant and animal tissues, usually as components of some larger molecule. In plants, and more particularly in certain gums, pentoses occur as complex polysaccharides called pentosans, from which the free pentose (e.g., arabinose, xylose) may be obtained on acid hydrolysis. In both plant and animal

¹⁵ Rimington: Biochem. J., 23, 430 (1929); Sørensen and Hangard; Compt. rend. trav. lab. Carleberg, 19, No. 12 (1933).

tissues certain pentoses (ribose, desoxyribose) are universally found as constituents of the nucleoproteins of the cell, being present in the nucleic acid portion of the molecule. Ribose is likewise an essential component of certain mono- and dinucleotides found in cells, such as adenylic acid, coenzymes I and II, and riboflavin (vitamin B₂).

As a class the pentoses may be either aldoses or ketoses, are non-fermentable by yeast, have strong reducing power, and form osazones with phenylhydrazine. The stereochemistry of the pentoses is similar to that already described for the hexoses. The pyranose ring appears to be the most common. For structures of the various aldopentoses, see p. 50. On distillation with strong hydrochloric acid pentoses and pentosans yield furfural, a reaction which is used not only for the quantitative determination of pentoses but also in the commercial production of furfural from plant by-products such as oat hulls.

Pentoses are an important constituent of the diet of herbivorous animals. Their nutritional role in the human is not well established. In the rare and apparently harmless condition known as pentosuria (Chapter 29) significant amounts of the pentose xyloketose are found in the urine and may lead to a false diagnosis of diabetes mellitus. Pentosuria is also said to occur in normal individuals after the ingestion of large amounts of certain fruits.

The following experiments on pentoses may be carried out on L(+)-arabinose as a typical aldopentose. L-arabinose may be obtained from gum arabic or from plum or cherry gum by boiling for 10 minutes with concentrated hydrochloric acid.

Experiments on Pentoses

Benzidine Reaction (Tauber):¹⁶ To 0.5 ml, of a 4 per cent solution of benzidine in glacial acetic acid in a test tube add 1 drop of pentose solution. Heat to boiling momentarily and then cool immediately in cold water. In the presence of as little as 0.05 mg, of pentose a stable cherry-red color results.

In the authors' experience, this is much the best test for pentoses (for other tests and the application to urine, see Chapter 29) The benzidine reagent is stable for about four days. The common hexoses do not interfere. Substances containing pentose in the molecule, such as the various nucleotides, will give a positive test, but pentosans do not because they are not hydrolyzed under the conditions of the test.

Phenylhydrazine Reaction: Make this test on the pentose solution as described for glucose. For illustration of pentosazone crystals, see Chapter 29.

GLYCOSIDES

Practically all of the carbohydrates or carbohydrate-containing compounds found in nature which are more complex than the simple sugars just described may be considered to be derivatives of these sugars of the type known generally as glycosides. If the sugar is glucose, the compound is known specifically as a glucoside; if galactose, a galactoside, and so on. The di-, tri-, and polysaccharides are glycosides, as well as a wide variety of naturally occurring substances such as phlorisin, salicin, amygdalin,

¹⁶ Tauber: Proc. Soc. Exptl. Biol. Med., 37, 600 (1937).

digitalin, etc., which contain in addition to a sugar residue a specific non-

sugar portion which is known as the aglycone.

Glycoside formation may be illustrated by the reaction between glucose and methyl alcohol, in which under the proper conditions a molecule of water is split off between an OH group in the glucose molecule and the OH of the methyl alcohol, to give a methyl glucoside:

Since the reaction involves the OH group on carbon number 1 of the glucose molecule, two methyl glucosides are possible as shown, corresponding to the α and β forms of the glucose molecule, and in general both α and β glycosides are found in nature. They may be readily distinguished by the use of enzymes which catalyze the hydrolytic splitting of either the α or β glycoside linkage specifically. For example, in the presence of the enzyme maltase only α glycosides are hydrolyzed, whereas the enzyme emulsin behaves similarly with respect to β glycosides. In the presence of acids both types of glycosides are readily hydrolyzed to yield their component molecules.

DISACCHARIDES

The disaccharides may be regarded as glycosides in which both components of the molecule are sugars. The common disaccharides have the general formula C₁₂H₂₂O₁₁, and yield hexoses on hydrolysis, a molecule of water being taken up in the reaction:

$$C_{12}H_{22}O_{11} + H_2O = 2C_6H_{12}O_6$$

The products of hydrolysis of the more common disaccharides are as follows:

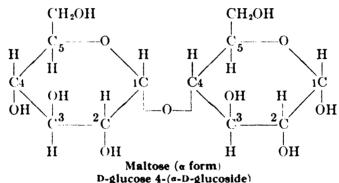

Maltose = glucose + glucose Lactose = glucose + galactose Sucrose = glucose + fructose

In the formation of a glycoside linkage between two hexoses, the reducing property of one hexose is ordinarily lost. If the reducing property of the second hexose is not involved the resulting disaccharide is a reducing sugar and exhibits the general properties of such a substance (e.g., osazone formation, mutarotation, etc.). Maltose and lactose are examples of reducing disaccharides. In sucrose, however, the glycoside linkage involves the potential reducing group of both the glucose and fructose components.

Sucrose therefore is not a reducing sugar, does not form osazones, and does not show mutarotation in solution.

MALTOSE, C12H22O11

Maltose or malt sugar is fermed in the hydrolysis of starch through the action of an enzyme, vegetable amylase (diastase), contained in sprouting barley or malt. Certain enzymes in the saliva and in the pancreatic juice cause a similar hydrolysis. Maltose is also an intermediate product of the action of dilute mineral acids upon starch. It is strongly dextrorotatory, shows mutarotation, reduces metallic ions in alkaline solution, and is fermentable by yeast after being converted to glucose by the enzyme maltase of the yeast. In common with the other disaccharides maltose may be hydrolyzed by dilute acid with the formation of two molecules of monosaccharide. In this instance the products are two molecules of glucose. With phenylhydrazine maltose forms an osazone, maltosazone. The following formula represents the probable structure of maltose.

As its chemical name indicates, maltose is a glucose α -glucoside with a 1,4 linkage. Other disaccharides yielding only glucose on hydrolysis are known, differing from maltose in the type and position of the glucoside bond. Thus cellobiose, a glucose β -glucoside with a 1,4 linkage, is formed during the partial hydrolysis of cellulose. Gentiobiose, a rare disaccharide obtained from the roots of *Gentiana lutea*, is a glucose β -glucoside with a 1,6 linkage. Trehalose, obtained from yeast, is a nonreducing glucose α -glucoside with a 1,1 linkage. Isomaltose, found as a minor end product of the action of amylases upon starch, is a glucose α -glucoside with a 1,6 linkage.

Experiments on Maltose

1-6. Repeat Solubility, Benedict's, Nylander's, Phenylhydrazine, Barfoed's, and Fermentation tests as given for Glucose.

LACTOSE, C12H22O11

Lactose or milk sugar occurs ordinarily only in milk, but it has often been found in the urine of women during the period of lactation. It may also occur in the urine of normal persons after the ingestion of unusually large amounts of lactose in the food. Lactose is a reducing disaccharide, is dextrorotatory, exhibits mutarotation in solution, and forms an osazone with phenylhydrazine. On hydrolysis it yields glucose and galactose. Chemical evidence indicates that the glycoside linkage involves carbon number 1 of the galactose molecule; lactose is therefore a galactoside. Enzymatic studies indicate that the galactoside linkage has the β configuration. The structure of lactose is probably as follows:

Lactose (α form)
D-glucose 4-(β-D-galactoside)

Since lactose exhibits mutarotation, it exists in α and β forms. The α form is the commonly obtained variety. Recently the β form has become commercially available. It is more soluble than the α form and has been recommended for infant feeding.

Lactose is not fermentable by ordinary bakers' yeast. Thus when glucose and lactose are present together in solution they may be differentiated in terms of the reducing power of the solution before and after fermentation. On oxidation with nitric acid lactose yields the sparingly soluble mucic acid because of the presence of galactose in the molecule. This reaction may be used to identify lactose under the proper conditions.

In the souring of milk the Lactobacillus acidophilus or Streptococcus lacticus and certain other microörganisms bring about lactic acid fermentation by transforming the lactose of the milk into lactic acid CH₃CHOH·COOH, and alcohol. This same reaction may occur in the alimentary canal as the result of the action of L. acidophilus and certain other organisms. In the preparation of kefir and koumiss the lactose of the milk undergoes alcoholic fermentation, through the action of ferments other than yeast, and at the same time lactic acid is produced.

Experiments on Lactose

1-6. Repeat Solubility, Benedict's, Phenylhydrazine, Barfoed's, Nylander's, and Fermentation tests as given for Glucose.

7. Mucic Acid Test: Repeat test as given for Galactose.

SUCROSE, C12H22O11

Sucrose, also called saccharose or cane sugar, is one of the most important of the sugars and occurs very extensively distributed in plants, partic-

ularly in the sugar cane, sugar beet, sugar millet, and in certain palms and maples.

Sucrose is dextrorotatory, and, as before mentioned, upon hydrolysis the molecule of sucrose takes on a molecule of water and breaks down into two molecules of monosaccharide. The monosaccharides formed in this instance are glucose and fructose. This is the reaction:

$$C_{12}H_{22}O_{11} + H_2O \rightarrow C_6H_{12}O_6 + C_6H_{12}O_6$$
Sucrose

Glucose Fructose

This hydrolysis may be produced by bacteria, enzymes, and certain weak acids. After hydrolysis the previously strongly dextrorotatory solution becomes levorotatory. This is due to the fact that the fructose molecule is more strongly levorotatory than the glucose molecule is dextrorotatory. The reaction is therefore frequently called inversion, and the mixture of glucose and fructose obtained is called invert sugar.

Sucrose does not reduce metallic ions in alkaline solution and forms no osazone with phenylhydrazine. Prolonged boiling in the presence of an acid phenylhydrazine solution will, however, hydrolyze the sucrose and cause the formation of glucosazone. It is not fermentable directly by yeast, but must first be inverted by the enzyme sucrase (invertase or invertin) contained in the yeast. The probable structure of sucrose may be represented by the following formula. Note the absence of any potential ketone or aldehyde group. Upon inversion the active form of fructose indicated in the formula is rapidly transformed to the more stable modification.

Sucrose a-D-glucopyranosyl &-D-fructofuranoside

Experiments on Sucrose

- 1-7. Repeat Solubility, Benedict's, Nylander's, Barfoed's, Phenylhydrazine, Selivanoff's, and Fermentation tests according to the directions given for Glucose.
- 8. Inversion of Sucrose: To 25 ml. of sucrose solution in a beaker add 5 drops of concentrated H₂SO₄ and boil one minute. Cool the solution and render neutral with saturated barium hydroxide. Filter off the precipitate of barium sulfate and upon the resulting fluid repeat the Phenylhydrazine, Benedict, Nylander's, and Barfoed's reactions as given for Glucose.

TRISACCHARIDES, C18H32O16

RAFFINOSE

This trisaccharide, also called melitose or melitriose, occurs in cotton seed, Australian manna, and in the molasses from the preparation of beet sugar. It is dextrorotatory, does not reduce Benedict's solution, and is only partly fermentable by yeast.

Raffinose may be hydrolyzed by weak acids just as the polysaccharides are hydrolyzed, the products being fructose and melibiose. Further hydrolysis of the melibiose yields glucose and galactose. Raffinose may also be hydrolyzed by the enzyme raffinase, occurring in certain bacteria and yeasts.

POLYSACCHARIDES

The polysaccharides are complex carbohydrates of high molecular weight, either quite insoluble in water or, when soluble, forming colloidal solutions. Polysaccharides in the solid state do not ordinarily appear to be crystalline, but a few crystalline polysaccharides have been isolated and x-ray analysis indicates that certain polysaccharides (e.g., cellulose) possess a definite crystalline structure. Through the action of certain enzymes or of acids the polysaccharides may be hydrolyzed with the formation of simpler compounds which are regarded as constituent units of the polysaccharide. Some polysaccharides yield only simple sugars on hydrolysis; others yield not only sugars but various sugar derivatives such as glucuronic or galacturonic acid (known generally as the *uronic* acids), hexosamines, and even nonsugar compounds such as ethyl alcohol, sulfuric acid, etc.

The constituent units of the polysaccharide molecule appear to be arranged in the form of a long chain, either unbranched (cellulose, amylose) or branched (glycogen, amylopectin). The linkage between units is generally the 1,4 glycoside bond already described, with either the α or β configuration as the case may be. Other types of linkage are known, however. As a class the polysaccharides are nonfermentable and are nonreducing except for a trace of reducing power due presumably to the free reducing group at the end of a chain. They are optically active but do not exhibit mutarotation, and are relatively stable to alkali. This latter fact is utilized for example in the separation of glycogen from tissues prior to analytical determination.

Starch, $(C_6H_{10}O_5)_x$

Occurrence and Composition. Starch is widely distributed throughout the vegetable kingdom, occurring in grains, fruits, and tubers. It is found in cells in the form of granules, the microscopical appearance being typical for each individual starch (see p. 75). The granules differ in size according to the source and they also differ somewhat in composition. The chief constituents are known as amylose and amylopectin, which usually exist in a proportion of about 1:3 in the granule, although some variation in this ratio may be found. Amylopectin appears to contain a small amount of phosphoric acid as a part of the molecule. An amylo-

hemicellulose containing silica has also been reported as present in cereal starches.

When boiled with water, starches form pastes. The starch granules may merely swell without disintegration and thus give a high viscosity to the solutions. Potato-starch granules disintegrate more easily and form less viscous solutions. If starch is ground in a ball mill, much of it disperses readily in water like soluble starch. Soluble starch is formed by the action of dilute hydrochloric acid upon starch. It is so called because it readily forms a limpid, clear solution with hot water. The acid apparently modi-

fies the amylopectin of the granules so that it disintegrates more completely on heating with water.

Structure. On hydrolysis with acids, starch yields glucose. The two major constituents of the starch granule, amylose and amylopectin, must differ largely, therefore, in their molecular structure. The amylose molecule appears to consist of about 300 glucose units in an unbranched chain, with a molecular weight of about 50,000. When pure, amylose is sparingly soluble in water to form a clear solution, gives a deep blue color with iodine, and is

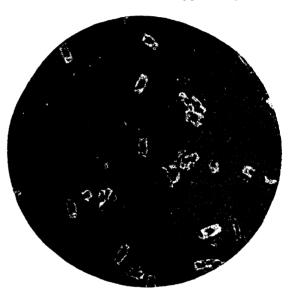

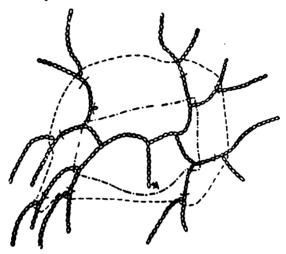

Fig. 22. Crystalline corn amylose (Kerr).

completely hydrolyzed to maltose by the enzyme β -amylase. Amylose has been obtained in the crystalline form by Kerr (Fig. 22). Amylopectin on the other hand forms opalescent solutions, gives a purple to violet color with iodine which is much less intense than the amylose reaction, and is only partly hydrolyzed to maltose by β -amylase. Amylopectin appears to contain many branched glucose chains in the molecule, each chain having about 25 glucose units, and the entire molecule having a molecular weight up to 20 times that of amylose (Fig. 23).

The linkage between glucose units is the 1,4 glycoside bond described previously. The structure of a portion of the starch chain is probably that indicated in the formula:

In the course of digestion of starch by salivary or pancreatic amylase there is first formed soluble starch (a clear solution giving a blue color with iodine), then dextrins giving blue or red colors with iodine, next achroodextrins giving no color with iodine, and finally maltose. Some maltose is, however, formed almost from the beginning of the digestion. The amylase apparently catalyzes the hydrolytic splitting of every other glycoside bond, thus producing maltose units. In the case of acid hydrolysis the same intermediate products are formed but glucose is the end product.

coccocco Glucose units.

- A Aldehydic end-group.
- (Limit of degradation produced by α-glucosidase, giving dextrin II, hydrolyzable by β-amylase.
- ----- End of further attack by β-amylase, yielding residual dextrin III.

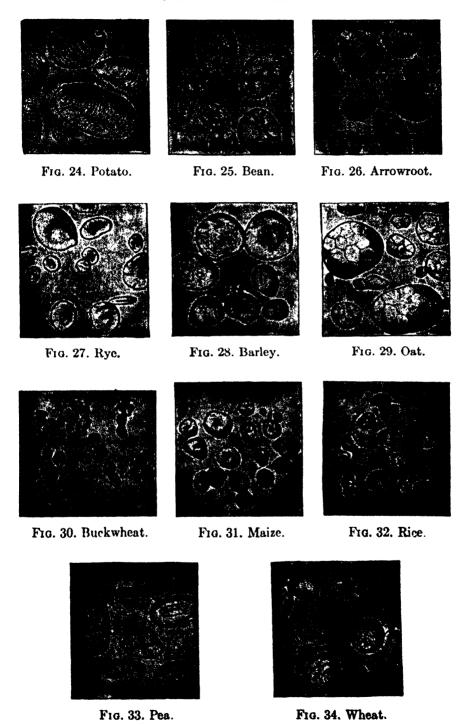

Fig. 23. Meyer's schematic representation of the branched amylopectin molecule (Hassid). (Courtesy, Wallerstein Laboratories, Inc.)

The hydrolysis of starch by acid is an example of the catalytic action of the hydrogen ion.

Synthetic starches have been prepared by the action of certain muscle and potato enzymes on glucose-1-phosphate, the Cori ester (see Chapter 12 for experiment demonstrating such a synthesis). These synthetic starches resemble amylose in their general properties.

Experiments on Starch

1. Preparation of Potato Starch: Pare a raw potato, comminute it upon a fine grater, mix with water, and "whip up" the pulped material vigorously before straining it through cheesecloth or gauze to remove the coarse particles. The starch rapidly settles to the bottom and can be washed by repeated decantation. Allow the compact mass of starch to drain thoroughly

Figs. 24-34. Starch granules from various sources (Leffmann and Beam).

and spread it out on a watch glass to dry in the air. If so desired this preparation may be used in the experiments which follow.

- 2. Microscopical Examination: Examine microscopically the granules of the various starches submitted and compare them with those shown in Figs. 24 to 34. The suspension of the granules in a drop of water will facilitate the microscopical examination.
- 3. Solubility: Try the solubility of one form of starch in cold water, then in hot water. If uncertain regarding the solubility, filter and test the filtrate with todine solution as given under 5 below. The production of a blue color would indicate that the starch had been dissolved.
- 4. Iodine Test: Place a few granules of starch in one of the depressions of a porcelain test tablet and treat with a drop of a dilute solution of iodine in potassium iodide. The granules are colored blue due to the formation of a starch-iodine complex.
- 5. Iodine Test on Starch Solution: Place 2 to 3 ml. of dilute starch solution¹⁷ in a test tube, add a drop of the dilute iodine solution, and observe the production of a blue color. Heat the tube and note the disappearance of the color. It reappears on cooling.

In similar tests note the influence of alcohol and of alkali upon the reaction between starch and jodine.

The composition of the blue-colored substance is not well defined. It appears to be an adsorption complex of starch and iodine rather than a definite compound. In performing this test the solution must always be neutral or acid in reaction.

- 6. Benedict's Test: On starch solution¹⁷ (see p. 57). Does starch have any detectable reducing ability?
- 7. Hydrolysis of Starch: Place about 25 ml. of 1 per cent starch solution 17 in a small beaker, add 10 drops of concentrated HCl, and boil gently. By means of a small pipet, at the end of each minute remove a drop of the solution to the test tablet and make the regular iodine test. At the end of the same one-minute intervals add exactly 3 drops of the mixture to 5-ml. portions of Benedict's solution in a series of test tubes. As the testing proceeds the reaction with iodine should become weaker and finally be negative. At this point place all the tubes containing Benedict's solution in a boiling water bath for 3 minutes, then remove and allow to cool. Note the degree of reduction in each case and compare with the rate of disappearance of the iodine reaction. Make the phenylhydrazine test upon some of the hydrolyzed starch. What sugar has been formed?
- 8. Diffusibility of Starch Paste: Test the diffusibility of starch through a suitable dialyzing membrane. Compare with glucose in this respect.

INULIN, (C₆H₁₀O₅),

Inulin is a polysaccharide which may be obtained as a white, odorless, tasteless powder from the tubers of the artichoke, elecampane, or dahlia. It has also been prepared from the roots of chicory, dandelion, and burdock. The rubber-producing plant guayule also contains inulin. It is very slightly soluble in cold water and quite easily soluble in hot water. In cold alcohol of 60 per cent or over it is practically insoluble. Inulin gives a negative reaction with iodine solution. It is very difficult to prepare inulin which does not reduce Benedict's solution slightly. This reducing power may be due to an impurity. Practically all commercial preparations of inulin possess considerable reducing power. Inulin is a polymerized form of fructofuranose, containing about 30 fructofuranose units in the molecule, united by 1,2 linkages.

Inulin is levorotatory and upon hydrolysis by acids or by the enzyme inulase it yields the monosaccharide fructose which readily reduces Benedict's solution. The preparation of fructose by hydrolysis of the inulin of the Jerusalem artichoke has become of commercial importance. The ordinary amylolytic enzymes occurring in the animal body do not digest inulin. A small part of the ingested inulin may be hydrolyzed by the acid gastric juice, but the value of inulin as a significant source of energy in human dietaries must be questioned. Rats may form some glycogen from inulin. Inulin administered intravenously is readily excreted by the kidneys, apparently because the inulin molecule, while colloidal, is sufficiently small to pass through the renal glomerular membrane. Use is made clinically of this property in the "inulin clearance" test of kidney function and in other studies of renal physiology.

Experiments on Inulin

- 1. Solubility: Try the solubility of inulin powder in hot and cold water and alcohol. If uncertain regarding the solubility, filter and test the filtrate with the Resorcinol-Hydrochloric acid (Selivanoff) test (see below).
- 2. Iodine Test: (a) Place 2 to 3 ml. of the inulin solution in a test tube and add a drop of dilute iodine solution. Compare with a control containing water instead of inulin solution. What do you observe?
 - (b) Place a small amount of inulin powder in one of the depressions of a test tablet and add a drop of dilute lodine solution. Is the effect any different from that observed above?
- 3. Resorcinol-Hydrochloric Acid Test: Test a portion of inulin solution by this test, following the directions given on p. 64. Explain the results.
- 4. Benedict's Test: Make this test on the inulin solution according to the instructions given for Glucose. Is there any reduction? Explain.
- 5. Hydrolysis of Inulin: Place 5 ml. of inulin solution in a test tube, add a drop of concentrated hydrochloric acid, and boil for one minute. Now cool the solution, neutralize it with concentrated sodium carbonate solution, and test the reducing action of 1 ml. of the solution upon 1 ml. of Benedict's solution. Compare with a control using 1 ml. of unhydrolyzed inulin solution. Also try the Resorcinol-Hydrochloric Acid reaction as given on p. 64, likewise comparing with a control of untreated inulin solution. Explain the results.

GLYCOGEN, $(C_6H_{10}O_5)_x$

Glycogen is the form in which carbohydrate is stored in the animal organism. It is found in the liver, muscles, kidneys, and other tissues, but is notably absent from brain. On hydrolysis with amylase it yields maltose, and with acid it yields glucose. It thus resembles starch and the dextrins in these respects but differs significantly from these compounds in molecular architecture. In the glycogen molecule the component glucose residues are linked in chains by a 1,4 α -glycoside bond as with the starches, but the glycogen chains are apparently arranged in a highly branched structure as contrasted to the unbranched amylose or slightly branched amylopectin chains of starch (see Fig. 35). Glycogen is soluble in cold water to form an opalescent solution and ordinarily gives a red color with iodine, although some forms of glycogen which give blue or purple colors with iodine are known. These color differences are apparently related to

the extent of chain branching, the blue color representing relatively unbranched chains and the red color with iodine corresponding to highly branched chains.

For a further discussion of glycogen, and experiments, see Chapter 10, Muscular Tissue.

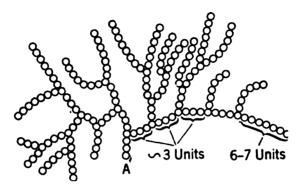

Fig. 35. Structure of glycogen (Meyer: Advances in Enzymology, 3, 109 (1943).) The circles represent glucose units; (A) the aldehydic end of a chain.

DEXTRIN, (C₆H₁₀O₅)_x

The dextrins are found as intermediate products in the course of hydrolysis of starch to glucose or maltose by acids or enzymes. They are colloidal in nature but of a lower degree of molecular complexity than starch. As would be expected, a variety of dextrins are known, most of which are relatively ill-defined, the higher dextrins resembling starch in certain respects while the lower dextrins more nearly resemble the sugars. As a class the dextrins are readily soluble in water, insoluble in alcohol, and do not diffuse through cellulose membranes of ordinary porosity.

The dextrins may be hydrolyzed by dilute acids to form glucose and by amylases to form maltose. They are not fermentable by yeast. Various dextrins give different colors with iodine, depending apparently upon their molecular complexity: the higher dextrins give a blue or purple color, intermediate dextrins give a red color, and the lower dextrins may give no color at all. As is the case with most other polysaccharides, the glucose chains in the dextrin molecule have a free reducing group at one end; the ability of dextrins to reduce Benedict's solution therefore depends upon the molecular weight and chain organization, with low molecular weight dextrins showing detectable reducing power. The reducing ability of commercial dextrin preparations is ordinarily due to the presence of free sugar. The formation of various dextrins as intermediate products of the action of amylases upon starch is illustrated schematically in Fig. 23.

Experiments on Dextrin

Solubility: Test the solubility of pulverized dextrin in hot and cold water.
Dextrin forms a clear solution in water, distinguishing it from glycogen which gives an opalescent solution.

2. Iodine Test: Place a drop of dextrin solution in one of the depressions of the test tablet and add a dilute solution of iodine in potassium iodide. A red, blue, or purple color results, depending upon the type of dextrin present. Ordinary dextrin preparations may contain some starch, and in the presence of starch it is necessary to have an excess of iodine present. If the reaction is not sufficiently pronounced, make a stronger solution from pulverized dextrin and repeat the test. The solution should be slightly acid to secure the best results.

Make proper tests to show that the red color is influenced by heat, alkali, and alcohol in a similar manner to the blue color given by starch (see p. 76).

The color in the case of dextrin does not reappear as readily on cooling as in the case of starch.

- 3. To Detect Dextrin in Presence of Starch: Treat 5 ml. of dextrin solution with about 10 drops of 1 per cent starch solution. To the mixture add an equal bulk of saturated ammonium sulfate, shake vigorously, and allow to stand for five minutes. The starch is precipitated. Filter through a dry paper, and to a portion of the filtrate add a drop or two of iodine solution. Compare with an iodine test on the dextrin solution alone which has been treated with ammonium sulfate in like manner.
- 4. Benedict's Test: See if the dextrin solution will reduce Benedict's solution.
- 5. Precipitation by Alcohol: To about 50 ml. of 95 per cent alcohol in a small beaker add about 10 ml. of a concentrated dextrin solution. Dextrin is thrown out of solution as a gummy white precipitate.
- 6. Diffusibility of Dextrin: (See Starch, 8, p. 76.)

Cellulose forms a large portion of the cell walls of plants. Physically, cellulose is distinguished from other carbohydrates largely by its extreme insolubility in most of the ordinary solvents. Chemically, cellullose has been shown to consist of a large number of β -glucose units joined together in a chain by 1,4 glycoside bonds, as indicated in the formula given herewith. Various methods for estimating the number of glucose units in the cellulose

molecule yield results which vary from 200 to 2,000 such units, depending upon the method employed. X-ray studies of cellulose indicate that it is crystalline in structure and consists of bundles of long chains with the chains running parallel to the fiber axis. These chains are unbranched and straight rather than coiled, and there is some evidence for the existence of cross-linkages between adjacent chains; the chemical nature of such cross-linkages is obscure. The close packing of the long straight chains produces a fiber with much mechanical strength, and may also account for the insolubility of cellulose.

Cellulose is not soluble in water or the usual organic solvents nor in dilute acid or alkali. It is soluble however in a variety of special solvents.

such as Schweitzer's reagent (ammoniacal copper hydroxide), zinc chloride-hydrochloric acid solution, and sodium hydroxide and CS₂, which latter are the reagents for making viscose, a form of artificial silk. With 10 per cent sodium hydroxide cellulose is converted into "hydrocellulose" and is said to be mercerized. About 70 per cent sulfuric acid converts it into "vegetable parchment." Such commercial products as rayon, cellophane, sausage casing, etc., are made from cellulose. With strong nitric acid and concentrated sulfuric acid it forms nitrocellulose.

Cellulose is not hydrolyzed by boiling with dilute mineral acids. It may be hydrolyzed, however, by treating with concentrated sulfuric acid, then subsequently diluting the solution with water and boiling. The product of this hydrolysis is glucose. Hydrolysis of cellulose by certain bacteria has been reported to yield the disaccharide cellobiose, analogous to the production of maltose from starch.

There is some difference of opinion as to the exact extent to which cellulose is utilized in the animal organism. It is, no doubt, more efficiently utilized by herbivora than by carnivora or by man. It is claimed that about 25 per cent may be utilized by herbivora and less than 5 per cent by dogs, whereas the quantity utilized by man is too small for it to play a nutritional role in the diet of a normal individual. In neither man nor the lower animals has there been demonstrated any formation of sugar or glycogen from cellulose. It is probable that the cellulose which disappears from the intestine is transformed for the most part into lower fatty acids such as acetic, etc., by the action of intestinal bacteria. A cellulase, digesting sawdust and filter paper, has been found in the digestive diverticula attached to the stomach of the shipworm.

Experiments on Cellulose

For these experiments, a high-grade filter paper, absorbent cotton, or cleansing tissue may be used.

- Solubility: Test the solubility of cellulose in water, dilute and concentrated acid, and alkali.
- Iodine Test: Add a drop of dilute iodine solution to a few shreds of cotton on a test tablet. Cellulose differs from starch and dextrin in giving no color with iodine.
- 3. Formation of Amyloid:¹³ To 6 ml. of distilled water in a test tube, add 10 ml. of concentrated sulfuric acid. The acid should be added to the water in small portions and the mixture stirred with a stirring rod and cooled under the tap, or by immersion in a beaker of cold water, between additions. To the cooled mixture add a two-inch square of cleansing tissue and stir for from 5 to 10 minutes, when most of the tissue is dissolved. Pour about 3 ml. of this solution into about 10 ml. of distilled water, and note the flocculent precipitate of amyloid formed. To another small portion of the solution add iodine and note the blue or black color formed. Pour the remainder of the acid solution of tissue into about 25 ml. of distilled water in a small beaker and boil for 15 to 30 minutes. Now cool, neutralize with solid sodium carbonate, and test with Benedict's solution. Glucose has been formed from the cellulose by the action of the acid.

¹⁸ This substance derives its name from amylum (starch) and is not to be confounded with amyloid, the glycoprotein.

- 4. Ammoniacal Cupric Hydroxide Solubility Test (Schweitzer): Place a two-inch square of cleansing tissue in a test tube, add 5 ml. of Schweitzer's reagent, 19 and stir the cellulose with a glass rod. When completely dissolved (5 to 10 minutes), dilute with an equal volume of distilled water, and acidify the solution with acetic acid. An amorphous precipitate of cellulose is produced.
- 5. Hydrochloric Acid-Zinc Chloride Solubility Test (Cross and Bevan): Place a little absorbent cotton in a test tube, add Cross and Bevan's reagent, 19 and stir the cellulose with a glass rod. When solution is complete, reprecipitate the cellulose with 95 per cent alcohol.
- 6. Iodine-Zinc Chloride Reaction: Place a little absorbent cotton or quantitative filter paper in a test tube and treat it with the iodine-zinc chloride reagent. 19 A blue color forms on standing. Amyloid has been formed from the cellulose through the action of the ZnCl₂ and the iodine solution has stained the amyloid blue.
- 7. Other Cellulose Solvents: It has been demonstrated by Deming that there are many excellent solvents for cellulose (filter paper)—for example, the concentrated aqueous solutions of certain salts such as (1) antimony trichloride, (2) stannous chloride, and (3) zinc bromide. In hydrochloric acid solution the solvent action of the above salts is increased. The following salts are also good solvents in hydrochloric acid solution: mercuric chloride, bismuth chloride, antimony pentachloride, tin tetrachloride, and titanium tetrachloride. In the case of the last-mentioned salt the swollen, transparent character of the cellulose fibers preliminary to solution can be seen very nicely.

Try selected solvents suggested by the instructor.

Hemicelluloses

The hemicelluloses differ from cellulose in that they may be hydrolyzed upon boiling with dilute mineral acids. They differ from other polysaccharides in being not readily digested by amylases. Upon hydrolysis hemicellulose may yield pentoses, or hexoses, or both, together with uronic acids. The vegetable gums and pectins may be included under this head.

Pentosans. Pentosans yield pentoses upon hydrolysis. So far as is known they do not occur in the animal kingdom. They have, however, a very wide distribution in the vegetable kingdom, being present in leaves, roots, seeds, and stems of all forms of plants, many times in intimate association or even chemical combination with galactans and uronic acids. In herbivora, pentosans are 40 to 80 per cent utilized. The few tests on record as to the pentosan utilization by man indicate that 80 to 95 per cent disappears from the intestine. According to Cramer, bacteria are efficient hemicellulose transformers. It has not yet been demonstrated that pentosans form glycogen in man, and for this reason they must be considered as playing an unimportant part in human nutrition. Gum arabic, an important pentosan, may be hydrolyzed by boiling with strong hydrochloric acid for a short time: The pentose arabinose results from such hydrolysis.

Galactans. In common with the pentosans the galactans have a very wide distribution in the vegetable kingdom. One of the most important members of the galactan group is agar-agar, a product prepared from certain types of Asiatic or American seaweed. Chemically, the agar

¹⁹ See Appendix.

molecule appears to consist of a chain of p-galactose units linked by a 1,3 glycoside bond, with a single L-galactose unit in a 1,4 linkage at the reducing end of the chain, this latter unit also being esterified in the 6 position with sulfuric acid. Thus the products of hydrolysis include much D-galactose, some L-galactose, and sulfuric acid. This galactan is about 50 per cent utilizable by herbivora and 8 to 27 per cent utilizable by man. Agar ingestion has been shown to be a very efficient therapeutic aid in cases of chronic constipation. This is particularly true when the constipation is due to the formation of dry, hard, fecal masses (scybala), a type of fecal formation which frequently follows the ingestion of a diet which is very thoroughly digested and absorbed. The agar, because of its relative indigestibility and its property of absorbing water, yields a bulky fecal mass which is sufficiently soft to permit of easy evacuation. Agar has been used with good results in the treatment of constipation in children. Agar is not limited to its use in connection with constipation, but may serve in other capacities as an aid to intestinal therapeutics.

The Pectins. The pectins are colloidal carbohydrates which with the proper concentration of acid and of sugar form gels. To form a gel there must be present from 0.3 to 0.7 per cent pectin, 65 to 70 per cent of sugar (usually sucrose) and a pH of 3.2 to 3.5. Commercial pectin is prepared from apples and lemons. On hydrolysis the pectins yield galacturonic acid, arabinose, galactose, acetic acid, and methyl alcohol. The characteristic properties of pectin appear related to the presence of a long chain of anhydrogalacturonide residues, partly methyl esterified. Non-galacturonide material, galactan and araban, which appear to act chiefly as diluents, may however make up a considerable portion of the weight of the pectin.

Experiments on a Pentosan

- Solubility: Test the solubility of gum arabic in hot and cold water and alcohol.
- 2. Iodine Test: Add a drop of dilute iodine solution to a little gum arabic on a test tablet. It resembles cellulose in giving no color with iodine.
- 3. Hydrolysis of Gum Arabic: Introduce a little gum arabic into a test tube, add 5 to 10 ml. of strong hydrochloric acid (conc. HCl and water 1:1), and heat to boiling for 5 to 10 minutes. Cool, neutralize with sodium hydroxide, and test by the Benedict or some other reduction test. A positive reaction should be obtained, indicating that the gum arabic has been hydrolyzed by the acid with the production of a reducing substance. What is this reducing substance? How would you identify it?

Experiments on a Galactan

- Solubility: Test the solubility of agar-agar in hot and cold water. Observe
 its marked property of imbibing water (see above).
- Iodine Test: Add a drop of dilute iodine solution to a little agar-agar on a test tablet. It resembles cellulose in giving no color with iodine.
- 3. Hydrolysis of Agar-agar: Introduce a few pieces of agar-agar in a test tube, add 5 to 10 ml. of strong hydrochloric acid (conc. HCl and water 1:1) and heat to boiling for 5 to 10 minutes. Cool, neutralize with sodium hydroxide, and test by the Benedict or some other reduction test. A positive reaction should be obtained, indicating that the agar-agar has been hydrolyzed by the acid with the production of a reducing substance. What is this reducing substance? How would you identify it?

Experiments on Pectin

- 1. Preparation of Pectin: Pare off the yellow layer from a grapefruit rind. Run through a meat chopper, cover with water, and let stand over night. Strain on cheesecloth and squeeze out the fluid. Boil the pulp with water for about two hours, bringing finally to a low volume. Pour off the fluid and add alcohol to precipitate the pectin. Filter and dry.
- Formation of a Gel: Into a weighed 400-ml. beaker introduce 70 g. of cane sugar, 1 g. of dry pectin, and 0.5 g. of citric or tartaric acid, and 100 ml. of water. Heat to boiling. Concentrate to a weight of 100 g. Let it stand over night.

REVIEW OF CARBOHYDRATES

In order to facilitate the student's review of the carbohydrates, the preparation of a chart similar to the appended model is recommended. The

Fats

THE LIPIDS

The term lipid is applied to a group of naturally occurring substances characterized by their insolubility in water and their solubility in such "fat solvents" as ether, chloroform, boiling alcohol, and benzene. Individual members of this group show large individual variations in solubility, but as a class the lipids are readily distinguishable from the carbohydrates and the proteins, the other two great groups of naturally occurring compounds. Chemically, the lipids are either esters of fatty acids or substances capable of forming such esters. They are very widespread in nature, being found in all vegetable and animal matter. Some members of this group, such as the phosphatides and sterols, are found in all living cells where, with the proteins and carbohydrates, they form an essential part of the colloidal complex of protoplasm. Complex lipids are also found in large quantities in brain and nervous tissues, thus indicating the important role these substances must play in the living organism. Other lipids, such as the fats and oils, represent the chief form in which excess foodstuffs are stored in the animal body. They arise from ingested lipids and from the metabolism of carbohydrates and proteins, and are stored in fat deposits, such as in the subcutaneous connective tissue, the intermuscular connective tissue, the omentum, etc., where they act as heat insulators and as reserve supplies of energy. The lipids may be classified as follows:

CLASSIFICATION

SIMPLE LIPIDS

The simple lipids are esters of fatty acids with certain alcohols. They are usually further classified according to the nature of the alcohols, as follows:

- 1. Fats and Oils. Esters of fatty acids and glycerol. Oils are fats which are liquid at room temperature.
- 2. Waxes. Esters of fatty acids with long chain aliphatic alcohols and with aromatic alcohols, such as sterols. (Beeswax, spermaceti, cholesterol esters.)

COMPOUND LIPIDS

The compound lipids are esters of fatty acids which, on hydrolysis, yield other substances in addition to fatty acids and an alcohol. Some important members of this group are:

FATS 87

- 1. Phospholipids (Phosphatides). Lipids which, on hydrolysis, yield fatty acids, phosphoric acid, an alcohol (usually but not always glycerol), and a nitrogenous base (such as choline or ethanolamine). (Lecithins, cephalins, and sphingomyelins.)
- 2. Glycolipids (Cerebrosides). Lipids which, on hydrolysis, yield fatty acids, a complex alcohol, and a carbohydrate. They contain nitrogen but no phosphoric acid. (Phrenosin and kerasin.)
- 3. Aminolipids, Sulfolipids, etc. These groups have not been studied sufficiently to permit exact classification. The sulfolipids yield sulfuric acid on hydrolysis.

DERIVED LIPIDS

The derived lipids are substances liberated during hydrolysis of simple and compound lipids.

- 1. Fatty Acids. Fatty acids of various series.
- 2. Aliphatic Alcohols. Long chain aliphatic alcohols. (Cetyl alcohol, C₁₆H₃₃OH; myricyl alcohol, C₃₀H₆₁OH.)
- 3. Sterols. Alcohols containing a reduced phenanthrene nucleus. (Cholesterol, ergosterol.)

THE FATS

The Fatty Acids. The fatty acids found in fats and other lipids are of various types. Some of them, like palmitic acid (C₁₆H₃₂O₂) and stearic acid $(C_{18}H_{36}O_2)$, are straight chain saturated acids belonging to the acetic acid series and have the general formula $C_nH_{2n}O_2$. Others are unsaturated and have from one to four, and even more, double bonds in their molecules. Thus oleic acid (C₁₈H₂₄O₂) has one double bond in its molecule, while linoleic acid (C₁₈H₃₂O₂) has two double bonds and linolenic acid (C₁₈H₃₀O₂) has three. Practically all of the fatty acids found in nature contain an even number of carbon atoms, although porpoise oil has been shown to contain valeric acid (C₅H₁₀O₂). In addition to the above types of acids. some lipids contain hydroxy acids, both saturated and unsaturated, and dicarboxylic acids. Thus castor oil contains an unsaturated hydroxy acid. ricinoleic acid (C18H24O2). Certain cyclic saturated and unsaturated fatty acids are likewise found in nature. Some of the more important chemical and physical properties of saturated and unsaturated fatty acids are discussed below.

SATURATED FATTY ACIDS, C.H. O. OR C.H. COOH

The physical properties of the saturated fatty acids depend upon their molecular weights. Whereas those fatty acids that contain ten or less carbon atoms in their molecules are liquids at room temperature, the remainder are solids whose melting points rise with increasing molecular weight. The liquid acids are also known as volatile fatty acids, since they may be distilled with steam, while the others, the nonvolatile acids, are carried over by steam distillation either in traces or not at all. Fatty acids with four or less carbon atoms are miscible with water in all proportions.

As the length of the carbon chain increases beyond this, however, the solubility rapidly diminishes to zero. The common straight chain saturated fatty acids found in nature as constituents of lipid molecules are listed below.

S.	TURATED	FATTY	ACIDS

Common Name	Chemical Name	Structure	Occurrence
Butyric	Hexanoic Octanoic Decanoic	CH ₃ ·(CH ₂) ₂ ·COOH CH ₃ ·(CH ₂) ₄ ·COOH CH ₂ ·(CH ₂) ₆ ·COOH CH ₂ ·(CH ₂) ₈ ·COOH CH ₂ ·(CH ₂) ₁₀ ·COOH	Butter fat Butter fat, coconut oil Butter fat, coconut oil Butter fat, coconut oil Butter fat, coconut oil,
Myristic Palmitic	Hexadecanoic	CH ₃ ·(CH ₂) ₁₂ ·COOH CH ₃ ·(CH ₂) ₁₄ ·COOH	spermaceti Butter fat, vegetable fats Most vegetable and animal fats
Stearic Arachidic		$CH_{3} \cdot (CH_{2})_{16} \cdot COOH$ $CH_{3} \cdot (CH_{2})_{18} \cdot COOH$	Most vegetable and animal fats Butter fat, lard, peanut
Behenic Lignoceric		CH ₂ ·(CH ₂) ₂₀ ·COOH CH ₂ ·(CH ₂) ₂₂ ·COOH	oil Vegetable oils Cerebrosides, sphingo- myelin

UNSATURATED FATTY ACIDS

The unsaturated fatty acids are characterized by the presence of one or more double bonds in the molecule. They have been classified in accordance with the number of double bonds as monoethenoid, diethenoid, triethenoid, etc., and named by reference to the parent hydrocarbon, the position of the double bond or bonds in the chain being indicated by a number, referring to the carboxyl carbon atom as number one. As with the saturated fatty acids many of the unsaturated fatty acids have common names which may be used as frequently as the chemical name.

Because of the presence of the double bond the unsaturated fatty acids are much more reactive than the saturated acids, the reactivity increasing with increase in the number of double bonds. The unsaturated fatty acids are capable of taking up one molecule of water, oxygen, hydrogen, bromine, or iodine at each double bond, and the amount of such substance (e.g., iodine) absorbed by a given weight of acid is used to determine its degree of unsaturation. It is obvious that a variety of isomerism is possible among the unsaturated fatty acids, depending not only on the position of the double bond in the chain but also on cis-trans isomerism across a double bond. Relatively few of the large number of possible isomers of the unsaturated fatty acids are found in nature.

The most common unsaturated fatty acid found in nature is the monoethenoid acid oleic acid (9-octadecanoic acid). This acid is so widely distributed that according to Hilditch no natural fat or phosphatide has as yet been found not to contain oleic acid. Other common unsaturated fatty acids include (1) the diethenoid acid linoleic acid, found in both animal and plant fats; (2) linolenic acid, which is a triethenoid acid found largely in vegetable fats; and (3) arachidonic acid, a tetraethenoid acid which is found in both the fat and phosphatide fractions of many animal tissues, particularly liver. The chemical characteristics of these representative straight chain unsaturated fatty acids follow:

REPRESENTATIVE	IINSATURATED	FATTY	Acina
ILEPREDENIALIVE	UNBALURALED	LVIII	ACIDS

Common Name	Empirical Formula	Number of Double Bonds	Chemical Name
Oleic Acid	C ₁₈ H ₃₂ O ₂ C ₁₈ H ₃₀ O ₂	1 2 3 4	9-Octadecenoic 9,12-Octadecadienoic 9,12,15-Octadecatrienoic 5,8,11,14-Eicosatetraenoic

From the empirical formula it can be seen that oleic, linoleic, and linolenic acids may be considered as derivatives of the saturated C₁₈ acid stearic acid, while arachidonic acid is an unsaturated form of the C₂₀ acid arachidic acid. Similar ethenoid derivatives of many of the other saturated fatty acids found in nature are known.

In addition to the straight chain fatty acids so far described, a number of branched chain and cyclic fatty acids, both saturated and unsaturated, have been isolated from natural sources. Tuberculostearic acid, 10-methylstearic acid, has been obtained from the wax of the tubercle bacillus, as has phthioic acid, a methylated branched chain C₂₆ acid. The latter appears to be associated with some of the clinical manifestations of tuberculosis. It is interesting to note that these and other fatty acids are found in tubercle wax as esters of the disaccharide trehalose (see Chapter 2). In chaulmoogra oil the unsaturated cyclic fatty acids chaulmoogric acid and hydnocarpic acid are found; these acids or their derivatives are used in the treatment of leprosy.

The Fats. The fats are neutral esters of glycerol and fatty acids. An example is tristearin synthesized in living tissues from one molecule of glycerol and three molecules of stearic acid:

CH₂OH HOOCC₁₇H₃₅ CH₂—OOCC₁₇H₃₅
CHOH + HOOCC₁₇H₃₅
$$\rightarrow$$

CH₂OH HOOCC₁₇H₃₅ CH₂—OOCC₁₇H₃₅
Glycerol Stearic acid Tristearin

Of the three molecules of fatty acid entering into the composition of a fat, all three may be the same, as in tristearin, but more commonly two or three different fatty acids are involved. In this case the fat is called a mixed glyceride, the composition being indicated by the name, as oleodipalmitin, stearodiolein, oleopalmitostearin, etc. Mixed glycerides occur much more commonly than pure glycerides such as tristearin, tripalmitin, and triolein. The possibilities of stereoisomerism among the fats are many; they include isomerism due to the same fatty acids being arranged differently in the molecule, as well as optical isomerism when the middle carbon atom of the glycerol portion becomes asymmetric or when an optically active fatty acid is present. Such isomerism appears to be of much less physiological importance in the fats than with carbohydrates and proteins.

Animal Fats. Naturally occurring animal fats consist largely of mixed glycerides of oleic, palmitic, and stearic acid; furthermore they are usually

Fig. 36. Beef fat (Long).

Fig. 37. Mutton fat (Long).

mixtures of individual fats. Fats from various sources differ considerably in their fatty acid composition. Mutton fat contains more stearic acid and less oleic acid than pork fat. Human fats contain a high percentage of oleic acid. Butter fat consists largely of glycerides of palmitic and oleic acids, with small amounts of stearic acid and of the lower fatty acids such as butyric and caproic; significant variation in this connection may be noted from species to species (see Chapter 12).

General Properties of Fats. Pure neutral fats are odorless, tasteless, and generally colorless; the color of natural fats and oils is ordinarily due to pigments mixed with or dissolved in the fat. Fats are insoluble in all aqueous solvents, but are readily soluble in ether, benzene, chloroform, boiling alcohol, and other organic solvents, and this is the common basis for separating fats from other substances. The neutral fats are nonvolatile and may be crystallized, some of them with great facility. The crystalline forms of some of the more common fats are reproduced in Figs. 36, 37, and 38. Each individual fat possesses a specific melting point, which depends upon the nature of the fatty acids in the molecule, and this property of melting at a definite temperature may be used as a means of differentiation if the fat is sufficiently pure. Tristearin for example melts

at 71° C., tripalmitin at 66° C., and triolein at -5° C. With the glycerides containing saturated fatty acids, increase in molecular weight of the component fatty acids results in a higher melting point; the change from a saturated to an unsaturated fatty acid usually lowers the melting point. Both of these statements are illustrated by the data just cited. In the case of natural fats, which are usually mixed glycerides or mixtures of mixed glycerides, the melting point is usually not sharp and is of minor value as an analytical characteristic. When a melted fat is allowed to cool, it will ordinarily solidify at a temperature considerably below its melting point. This discrepancy between melting point and congealing point has never been satisfactorily explained.

Mixed glycerides containing a high proportion of unsaturated fatty acids are usually liquid at room temperature, as indicated above, and

Fig. 38, Pork fat.

are commonly called oils. These oils will take up hydrogen at their doubly bonds, in the presence of catalysts such as finely divided nickel, and may thus be converted into solid fats. This process is called "hardening" or hydrogenation. Many commercial fats are partially hydrogenated vegetable oils. There is no known nutritional objection to the use of properly hydrogenated vegetable oils in place of animal fats. For example, in experiments on man it was shown that hydrogenated vegetable oil was as satisfactorily digested and utilized as was lard, and was less liable to cause gastric or intestinal symptoms of an objective nature. Furthermore, under conditions where oxidation may cause destruction of essential factors in the diet, the use of hydrogenated oil is claimed to be preferable to the use of unhydrogenated vegetable or animal fats.

When a fat is allowed to stand for a sufficient length of time in contact with air and moisture, particularly in the presence of light and heat, cer-

¹ Smith, Miller, and Hawk: J. Biol. Chem., 23, 505 (1915); Smith: Ohio State Med. J., 39, 425 (1943).

¹ Miller: J. Nutrition, 26, 43 (1943).

tain changes occur and it becomes rancid. These changes usually involve the production of free acid, of odoriferous volatile higher aldehydes, and of organic peroxides. The exact chemical nature of the rancid process has not been too well defined; it is known that unsaturated fats, particularly those containing oleic acid, become rancid more rapidly than saturated fats. It would appear that the addition of oxygen at a double bond, in the presence of light and moisture, followed by the production of various split products, is a fundamental basis of rancidity. Rancid fats are unpalatable, appear to be slightly toxic for some individuals, and destructive to other factors in the food, such as carotene and vitamin A,³ and vitamin E.⁴ According to Burr and Barnes, the preservation of a mixed food is frequently a matter largely of the prevention of fat deterioration.

When liquid fats are shaken with water, the fat becomes finely divided and dispersed in the water to form what is known as an emulsion. The emulsion with water is transitory; if substances such as proteins, soaps, bile salts, etc., are present, the emulsion is much more permanent. These substances, which are known as emulsifying agents, act by lowering the surface tension of the aqueous phase and are presumably adsorbed on the surface of the tiny oil globules to form a film which minimizes the tendency of the globules to coalesce. A very fine powder which is wet by oil but not by water will likewise form a film around oil droplets and stabilize the emulsion. The formation of emulsions is of importance in pharmacy, in industrial practice, and in the processes of fat digestion in the intestinal tract.

Hydrolysis of Fats. Fats may be hydrolyzed by various agents with the liberation of fatty acid and glycerol. Such agents are superheated steam, long-continued action of air and light, bacteria and the enzyme lipase. When boiled with alkali the fats give glycerol and the metallic salt of the fatty acid.

$$\begin{array}{ccc} C_3H_5(\mathrm{OOCC}_{15}H_{31})_3 + 3\mathrm{NaOH} \rightarrow \mathrm{C}_3H_5(\mathrm{OH})_3 + 3\mathrm{C}_{15}H_{31}\mathrm{COONa} \\ & \text{Tripalmitin} & \text{Glycerol} & \text{Sodium palmitate} \end{array}$$

This process is known as saponification and the metallic salts of the higher fatty acids are known as soaps. The ordinary hard soaps of commerce are chiefly sodium soaps. Potassium forms soft soaps, of which "green soap" is an example. Calcium and magnesium form insoluble soaps. When ordinary soap is added to hard water a certain amount is used up in the precipitation of calcium and magnesium salts before the soap becomes effective. Lead also forms an insoluble soap.

The detergent (cleansing) action of soaps is due largely to their ability to lower surface tension and thus facilitate emulsification of oily or greasy material which can then be washed away. The commercial production of synthetic detergents has become of importance; these may be exemplified by one type which is a compound of sulfuric acid and cetyl alcohol, C₁₆H₂₂OH, the alcohol analogue of palmitic acid. Synthetic detergents act similarly to soaps by lowering surface tension; they are not inactivated

Lease, Weber, and Steenbock: J. Nutrition, 16, 571 (1938).

⁴ Fitshugh, Nelson, and Calvery: Proc. Soc. Exptl. Biol. Med., 56, 129 (1944).

by calcium and magnesium, however, and are therefore equally effective in hard or soft water, which is not true of the ordinary soaps.

Methods Used in Study of Fats. As the separation and identification of individual fats is a difficult matter the properties commonly studied are of a more general character. The saponification value of a fat is the number of milligrams of KOH required to neutralize the free or combined fatty acid in 1 g. of fat. It is determined by saponification and titration of excess alkali and is a measure of the mean molecular weight of the fatty acids present in the fat. The Reichert-Meissl number of a fat is a measure of the amount of volatile fatty acids and is determined by titration of the steam distillate. The volatile which also include the soluble fatty acids are those containing ten or less carbon atoms. Butter is rich in these while most butter substitutes are not. The determination of these acids is of use in detecting adulteration of butter.

The unsaturated fatty acids, of which oleic acid is an example, differ from the saturated acids in their power to take up iodine at the double bond. $-CH=CH-+I_2 \rightarrow -CHI-CHI-$. The *iodine value* is thus a measure of the amount of unsaturated fatty acid present in a fat.

Waxes. The waxes are esters of fatty acids with monatomic alcohols. Examples are spermaceti containing chiefly the palmitate of cetyl alcohol (C₁₆H₃₃OH), and beeswax consisting mainly of the palmitate of myricyl alcohol (C₃₀H₆₁OH). They are saponified with greater difficulty than fats and are not attacked by lipase.

Compound Lipids and Sterols. See Chapter 11, Nervous Tissue and Chapter 18, Bile.

Biological Importance of Fats. Fats serve as a storage food in plant and animal organisms, and are of great importance for cellular processes, evidently along with other lipids. They are constituents of cell membranes and are thus concerned with the phenomena of cell permeability and cell organization. The highly unsaturated fatty acids, linoleic and linolenic, appear to be necessary in the diet of certain animals to prevent a skin syndrome. (See Chapter 33 for a further discussion of fats and fat metabolism.)

EXPERIMENTS ON FATS

- 1. Fat Solvents: Test the solubility of olive oil in water, dilute acid, and alkali, and in cold alcohol, hot alcohol, benzene, chloroform, ether, and carbon tetrachloride. Which are the best solvents for fats?
- 2. Formation of a Translucent Spot on Paper: Place a drop of olive oil upon a piece of ordinary writing paper. Note the semitransparent appearance of the paper at the point of contact with the fat.
- 3. Reaction: Try the reaction of fresh olive oil to litmus or other suitable indicator paper. (Moisten the paper with distilled water before making the test.) Repeat the test with rancid olive oil. What is the reaction of a fresh fat and how does this reaction change upon allowing the fat to stand for some time?
- 4. Formation of Acrolein from Olive Oil: (a) Place about ½ inch powdered potassium bisulfate (KHSO4) into a clean dry test tube. Drop no more than 3 to 4 drops of olive oil onto the salt and heat, cautiously at first, and then more strongly. Note the irritating odor of acrolein. The glycerol
 - To prepare "rancid" olive oil add 5 drops of oleic acid to 10 ml, of olive oil, Mix well,

of the fat is dehydrated and acrylic aldehyde or acrolein is produced. This is the reaction which takes place:

- (b) Repeat the above test using (1) 3 to 4 drops of oleic acid and (2) a little solid carbohydrate, instead of olive oil. Heat vigorously and note the odor of SO_2 in both tubes. Organic compounds reduce KHSO₄ to SO_2 , which is often mistaken for acrolein. Even fats, if heated too vigorously, yield SO_2 as well as, or after, the acrolein.
- 5. Emulsification: (a) Shake up a drop of neutral olive oil with a little water in a test tube. The fat becomes finely divided, forming an emulsion. This is not a permanent emulsion since the fat separates and rises to the top upon standing.
 - (b) To 5 ml. of water in a test tube add 2 or 3 drops of 0.5 per cent Na₂CO₃. Introduce into this faintly alkaline solution a drop of neutral olive oil and shake. The emulsion, while not permanent, is not so transitory as in the case of water free from sodium carbonate.
 - (c) Repeat (b), using rancid olive oil. What sort of emulsion results? In this case the alkali combines with the free fatty acid to form soap, and this soap, being an emulsifying agent, emulsifies the fat.
 - (d) Shake a drop of neutral olive oil with dilute albumin solution. What is the nature of this emulsion? Examine it under the microscope.
 - (e) Repeat (d), using bile salt solution instead of albumin solution. Compare the stability of the emulsion with that obtained in (a). What is one of the physiological functions of the bile?
- 6. Fat Crystals: Dissolve about 40 drops of melted lard in 10 ml. of ether in a test tube, stopper loosely with some filter paper, and allow the mixture to evaporate spontaneously until crystals begin to separate out. Transfer some of the material to a slide, examine the crystals under the microscope, and compare them with those reproduced in Figs. 36, 37, and 38.
- 7. Saponification of Bayberry Tallow: Place about 10 g. of bayberry tallow in a 600-ml. beaker; add about 150 ml. of distilled water and 50 ml. of 10 per cent potassium hydroxide solution (not sodium hydroxide). Boil the mixture for 10 to 15 minutes, or until saponification is complete (no oily layer remaining on the surface). When saponification is complete, remove 25 ml. of the hot soap solution, dilute it with about 100 ml. of distilled water, and reserve this solution for use in Exp. 8 and 9 below. To the remainder of the hot solution slowly add concentrated hydrochloric acid until the mixture is acid (about 10 ml. are required). The free fatty acid formed will rise to the top as a clear oily layer. Now cool the solution, permitting the fatty acid to solidify and form a cake. In this instance the fatty acid is principally palmitic acid. Remove the cake, break it into small pieces, wash it with water by decantation, and place in a beaker containing about 50 ml. of 95 per cent alcohol. Warm the mixture by placing the beaker in a vessel containing some hot water, until the palmitic

Bayberry tallow is derived from the fatty covering of the berries of the wax myrtle. It is therefore frequently called "myrtle wax" or "bayberry wax."

* Place 1 or 2 drops in a test tube full of hot distilled water. If saponification is complete the soap formed will remain in solution and no oil will separate out.

* Under some conditions a purer product is obtained if the soap solution is cooled before precipitating the fatty soid.

[&]quot;Neutral" olive oil may be prepared by shaking ordinary olive oil with a 10 per cent solution of sodium carbonate. This mixture should then be extracted with ether and the ether removed by evaporation. The residue is neutral olive oil.

acid is dissolved, then filter through a dry filter paper and allow the filtrate to cool slowly in order to obtain satisfactory crystals.

When the palmitic acid has completely crystallized, filter off the alcohol, dry the crystals between filter papers and by exposure to the air, and try the tests given in Exp. 11. Write the reactions which have taken place in this experiment.

- 8. Salting-out of Soap: To 100 ml. of soap solution, prepared as described above, add solid sodium chloride to the point of saturation, with continual stirring. (If the soap has solidified due to cooling, dissolve it by warming before adding the salt.) The soap, which is in colloidal solution, is precipitated when its solution is saturated with sodium chloride. Why?
- Formation of Insoluble Soaps: Introduce 5 ml. of soap solution into each
 of two test tubes. To the contents of one tube add a small amount of a
 solution of calcium chloride and to the contents of the other tube add a

Fig. 39. Palmitic acid.

small amount of a solution of magnesium sulfate. Note the formation of insoluble soaps of calcium and magnesium.

- 10. Surface Tension of Soap Solutions: Determine the "drop number" of the soap solution as compared to pure water, as described on p. 16. What is the approximate surface tension of the soap solution relative to that of water? Is a "drop" of a soap solution equal in volume to a "drop" of an ordinary aqueous solution?
- 11. Palmitic Acid: (a) Examine the crystals under the microscope and compare them with those shown in Fig. 39.
 - (b) Solubility: Try the solubility of palmitic acid in the same solvents as used on fats (see p. 93).
 - (c) Melting Point: Determine the melting point of palmitic acid by the method given on p. %. A value lower than the theoretical will be obtained because of the presence of impurities.
 - (d) Formation of Translucent Spot on Paper: Melt a little of the fatty acid and allow a drop to fall upon a piece of ordinary writing paper. How does this compare with the action of a fat under similar circumstances?
 - (e) Acrolein Test: Apply the test as given under 4, p. 93. Explain the result.
 - (f) Iodine Absorption Test: For directions see Exp. 14.
- 12. Saponification of Lard: To 25 g. of lard in a flask add 75 ml. of alcoholic-potash solution and warm on a water bath until saponification is com-
 - 16 A 20 per cent solution in 40 per cent alcohol may be used.

plete. (This point is indicated by the complete solubility of a drop of the solution when allowed to fall into a little distilled water.) Now transfer the solution from the flask to an evaporating dish containing about 100 ml. of water and heat on a water bath until all the alcohol has been driven off. Acidify the solution with hydrochloric acid and cool. Remove the fatty acid which rises to the surface, "neutralize the solution with sodium carbonate, and evaporate to dryness. Extract the residue with alcohol, remove the alcohol by evaporation on a water bath, and on the residue of glycerol thus obtained make the tests as given below.

13. Glycerol: (a) Taste: What is the taste of glycerol?

(b) Solubility: Try the solubility of glycerol in water, alcohol, and ether.

(c) Acrolein Test: Repeat the test as given under 4, p. 93, using 2 drops of glycerol.

(d) Borax Fusion Test: Fuse a little glycerol on a platinum wire with some powdered borax and note the characteristic green flame. This color is due to the glycerol ester of boric acid.

(e) Benedict's Test: Add a few drops of glycerol to 5 ml. of Benedict's reagent and boil for 2 to 3 minutes. How does the result compare with the results on the sugars?

(f) Solution of Cu(OH)₂: Form a little cupric hydroxide by mixing copper sulfate and sodium hydroxide. Add a little glycerol to this suspended precipitate and note what occurs. Explain.

- 14. Iodine Absorption Test: Dissolve 5 to 10 drops of an unsaturated organic acid, e.g., oleic acid, in about 5 ml. of chloroform. Add some Hübl's iodine solution, 12 a drop or two at a time, and shake between additions. The solution will be decolorized if unsaturated acids are present. This is due to the absorption of the iodine. The test should be controlled by shaking chloroform and iodine solution to which no acid has been added.
- 15. Melting Point of Fat: Into the liquid fat insert one of the melting-point tubes furnished by the instructor and draw up the fat until the bulb of the tube is about one-half full of the material. Then fuse one end of the tube in the flame of a Bunsen burner and fasten the tube to a thermometer by means of a rubber band in such a manner that the bottom of the fat column is on a level with the bulb of the thermometer (see Fig. 40). Fill a beaker of medium size about two-thirds full of water and place it within a second larger beaker which also contains water, the two vessels being separated by pieces of cork. Immerse the bulb of the thermometer and the attached tube in such a way that the bulb is about midway between the upper and the lower surfaces of the water of the inner beaker. The upper end of the tube being open, it must extend above the surface of the surrounding water. Apply gentle heat, stir the water, and note the temperature at which the fat begins to melt. This point is indicated by the initial transparency. For ordinary fats, raise the temperature very cautiously from 30° C. To determine the congealing point remove the flame and note the temperature at which the fat begins to solidify. Record the melting and congealing points of the various fats submitted by the instructor.
- 16. Determination of Saponification Number: Measure 5 ml. of oil into a 250-ml. Erlenmeyer flask with a clean dry pipet. Calculate the weight of the oil from the specific gravity. (The specific gravity of olive oil is 0.916.) (Direct weighing of the oil is more accurate.) Add 50 ml. of alcoholic 0.5 N KOH (made up in 90 per cent alcohol) from a pipet. To another flask not containing oil add a similar 50-ml. portion of the KOH. Fit each flask with a reflux air condenser and boil by immersion in a large beaker of boiling water for half an hour with frequent agitation. Add to each flask 1 ml. of 1 per cent alcoholic solution of phenolphthalein and titrate with

12 See Appendix.

¹¹ After drying the said make an iodine absorption test as described in Exp. 14.

0.5 N HCl. Subtract the titration value of the control from that of unknown. One ml. of the HCl is equivalent to 0.02805 g. of KOH. Calculate the number of mg. of KOH required to saponify 1 g. of the oil.

17. Determination of Iodine Absorption Number: With a clean dry pipet measure 0.3 ml. of oil into a dry 100-ml. Erlenmeyer flask. Calculate the weight of the oil from the specific gravity. (For accurate work the oil must be weighed.) Add 10 ml. of carbon tetrachloride and after solution of the oil add exactly 25 ml. of Wijs' iodine solution. 13 Mix well, stopper, and put

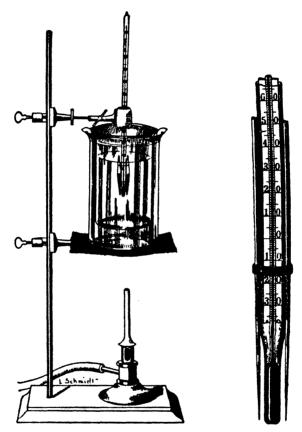

Fig. 40. Melting-point apparatus. (*Lcft*) Complete assembly. (*Right*) Details of attaching melting-point tubes to thermometer.

in a dark place for 1 to 2 hours. Transfer quantitatively to a 500-ml. flask, washing out the small flask with 10 ml. of 10 per cent KI solution and with water to make a volume of about 250 ml. Titrate with thiosulfate to a light brown color, add starch paste and titrate to disappearance of the blue color. After the blue color has disappeared from the aqueous phase, the carbon tetrachloride layer in the bottom of the flask usually contains untitrated iodine as evidenced by a pink or violet color. This iodine may be brought into the aqueous layer by continuous shaking. The end point of the titration is reached when both the aqueous and nonaqueous phases are completely colorless. Calculate the number of centigrams of iodine

absorbed by 1 g. of fat. This is the iodine absorption number, or the iodine value, of the oil.

Proteins: Their Composition and Hydrolysis; Amino Acids

PROTEINS

Definition. Proteins have been defined as extremely complex nitrogencontaining organic compounds which are found in all animal and vegetable cells, where they constitute a major part of the living protoplasm of those cells. The Dutch physiological chemist G. J. Mulder, who derived the word protein from the Greek πρώτος, "first," said in 1840: "In both plants and animals a substance is contained which is produced within the former. and imparted through the food to the latter. It is one of the most complicated substances, is very changeable in composition. . . . It is unquestionably the most important of all known substances in the organic kingdom. Without it no life appears possible on our planet. Through its means the chief phenomena of life are produced." Proteins, carbohydrates. and fats form the three great classes of foodstuffs, but the function of protein in the diet is not primarily to supply energy, as is true of the other two, but to furnish certain essential components of the living tissue of the organism itself. Although plants, including many bacteria, are capable of synthesizing proteins from simple organic and inorganic nitrogenous compounds, this ability has been lost to such an extent by the higher animals that they must depend upon preformed proteins or rather certain of their specific degradation products, the α -amino acids, for the continuance of life.

The capacity of the living organism for storing proteins is limited and relatively small when compared to its capacity for storing carbohydrates and fats. Proteins are, however, stored under special conditions as in eggs and seeds for use by the developing or immature organism until it can obtain food from its environment. Although the carbohydrates and lipids are both essential constituents of the colloidal complex which we call protoplasm, the proteins are of paramount importance not only because of their peculiar chemical and physicochemical properties but also because they appear to confer upon various types of cells their biological specificity. In the main, identical lipids and carbohydrates may be found in cells of both plants and animals of widely different species; the proteins, however, are usually highly characteristic of the species of plant or animal, and, more often than not, of the specific organ in which they are found.

Composition. The proteins differ from carbohydrates and fats not only in their function in the organism, but also in elementary composition. In addition to carbon, hydrogen, and oxygen, the proteins invariably contain nitrogen and generally also sulfur. The percentage composition of the

large number of proteins from different sources which have been studied falls between the following rather narrow limits: C=50 to 55 per cent, H=6.0 to 7.3 per cent, O=19 to 24 per cent, N=15 to 19 per cent, S=0 to 4 per cent. Proteins have also been described which contain phosphorus, iron, copper, iodine, manganese, zinc, and other elements. None of these latter elements, with the exception of iodine, has thus far been found as a constituent of the α -amino acids, the fundamental units from which proteins are built up by the organism, and until we have more exact information concerning the composition and structure of the protein molecule, we may assume that these elements are combined with protein in some unknown way, or, as has been shown in the case of iron, that they are constituents of nonprotein substances which are combined with protein in a way which confers new and characteristic properties upon the complex formed.

General Properties. The almost infinite number of proteins which are present in nature give certain reactions which serve to identify them as a distinct class of biological substances. Almost all soluble proteins form colloidal solutions. This indicates either that the molecules of protein are so large that even when dispersed in molecular solution they have the properties of size and surface which characterize colloidal particles, or else that there is some force connected with protein molecules which predisposes them to form aggregates of colloidal size. There are good reasons for believing that the colloidal properties of protein solutions are due in some cases to the first and in other cases to the second of these possibilities. The colloidal solutions formed by proteins are of the emulsoid type. thus requiring large concentrations of electrolytes for precipitation. The proteins give certain color reactions which, however, are not specific for the protein molecule as such but for various chemical groups which it is thus shown to contain. Although proteins generally precipitate from their solutions in an amorphous condition, many of them have been isolated from both animal and vegetable sources in the form of characteristic crystals. The proteins are precipitated from their solutions by salts of heavy metals, such as silver nitrate, lead acetate, etc.; by acids such as tannic acid, phosphotungstic acid, metaphosphoric acid, etc.; and by many dyes and detergents. These precipitation reactions are probably due, in part at least, to the formation of insoluble compounds of the protein and the precipitating agent and in part to the colloidal character of protein solutions. The proteins exhibit amphoteric properties, combining with both acids and bases to form ionizable salts. Finally, upon complete hydrolysis the proteins yield crystalline substances of definite composition belonging to the class of compounds known as α -amino acids.

Investigation of Protein Composition. The constancy in elementary composition of proteins from widely differing sources and the great individual differences in chemical and physical properties preclude elementary analysis as a method of characterizing individual proteins. There are, however, three main lines of attack used in the investigation of the protein molecule: (1) Complete hydrolysis of the protein into its constituent units, the α -amino acids, (2) partial hydrolysis to yield relatively

small degradation products (di- and tripeptides, etc.) which are capable of separation and complete characterization, and (3) the study of the physicochemical, colloid-chemical, and biological reactions of the completely intact molecule as well as of the slightly changed (denatured) molecule. Until comparatively recently the method of complete hydrolysis was the one most commonly employed. This procedure is of great importance since it yields the individual units from which the protein is formed. However, just as elementary analysis of the less complex organic molecules tells us the percentage composition of the substance under examination without indicating the atomic arrangement within the molecule, so complete hydrolysis of a protein reveals the quantities of the various constituent amino acids without giving much indication as to their special arrangement within the giant molecule. In order to reveal the great individual differences among proteins and to gain an insight into their specific biological functions such as the hormonal action of insulin, the enzymatic effects of pepsin, the role of myosin in muscle contraction, the pathogenicity of tobacco mosaic virus, etc., all three modes of study must be used. The work of the chemist, biologist, physicist, and analyst must be known and appreciated by each member of the team before the problem of the complete structure of even one protein is to be solved.

Hydrolysis. Hydrolysis of proteins may be effected: (1) By boiling with mineral acids or strong alkalies, at atmospheric or increased pressures, (2) by treatment with certain long chain sulfonic acids (cetylsulfonic acid, diphenylbenzenesulfonic acid, etc.), and (3) by digestion with proteolytic enzymes. Commonly, hydrolysis of a protein is carried out by boiling it with five to ten times its weight of 6 N hydrochloric acid or 8 N sulfuric acid for 6 to 24 hours. Under special circumstances other reagents, such as hydriodic acid, oxalic acid, 5 N sodium hydroxide, hot saturated barium hydroxide, or a mixture of formic and hydrochloric acids, can be used. Acid hydrolysis, especially if the protein contains carbohydrate, usually results in the complete destruction of the amino acid tryptophane, and may result in the partial decomposition of certain other amino acids. The prolonged heating necessary to effect complete hydrolysis by strong alkalies does not affect tryptophane, but results in the partial or complete destruction of cysteine, cystine and arginine, and in the racemization and consequent loss of optical activity of all the amino acids. Enzymatic hydrolysis has none of these disadvantages of acid or alkaline hydrolysis but it is very time-consuming and is seldom complete. Hydrolysis of proteins with the above-mentioned sulfonic acids has only recently been introduced and requires further investigation.

Hydrolysis of the protein molecule by any of the above methods leads to the formation of a series of ill-defined fragments of decreasing complexity, known as proteoses, peptones, and polypeptides, the final products being amino acids. Certain amino acids are split off early in the hydrolytic process, this liberation of amino acids continuing until the larger intermediate fragments have all been reduced to these simpler compounds. Physically the hydrolysis of proteins consists in a breaking down of the large, colloidal, nondiffusible complexes into a series of fragments in

which the colloidal character becomes less and less pronounced until, finally, only the simple, crystalloidal, and diffusible amino acids remain. Since the amino acids represent, therefore, the "building stones" of the protein molecule; we may well begin the study of that molecule by a consideration of the structure and reactions of these fundamental units.

AMINO ACIDS

The amino acids thus far isolated from protein hydrolysates are α -amino acids—that is, they have an amino (NH₂) group attached to the same carbon atom that holds the carboxyl (COOH) group. Their general formula¹ is therefore

Individual amino acids differ in the character of the radical R attached to the α carbon atom.

CLASSIFICATION

The amino acids may be conveniently classified according to the number of their amino and carboxyl groups, as follows: (1) Neutral amino acids, containing one amino and one carboxyl group, (2) acidic amino acids, containing an excess of carboxyl groups, and (3) basic amino acids, containing an excess of basic nitrogen. The amino acids in each group may be further subdivided according to whether the radical R in the general formula represents an aliphatic, aromatic, or heterocyclic nucleus.

NEUTRAL AMINO ACIDS

These acids are often referred to as mono-amino-monocarboxylic acids because they contain one amino and one carboxyl group. Solutions of these acids react essentially neutral. These acids form the largest group in the protein molecule and most of them are separated in one fraction from the products of protein hydrolysis. Because of their great chemical and physical similarities, the isolation of the individual acids in this fraction presents great experimental difficulties.

A. Aliphatic Amino Acids

1. Glycine, or glycocoll, C₂H₅O₂N (amino-acetic acid)

¹ The only exceptions to this general formula are found with the two amino acids proline and hydroxyproline (q.v.), in which the α -nitrogen is part of a cyclic structure.

2. Alanine, C₃H₇O₂N (α-amino-propionic acid)

3. Serine, $C_3H_7O_3N$ (β -hydroxy- α -amino-propionic acid or β -hydroxy-alanine)

$$\begin{array}{c} \operatorname{NH_2} \\ | \\ \operatorname{HO--CH_2--C--COOH} \\ | \\ \operatorname{H} \end{array}$$

4. Threonine, C₄H₉O₂N (α-amino-β-hydroxy-n-butyric acid)

$$\begin{array}{c|c} H & NH_2 \\ \hline \\ CH_3-C--C-COOH \\ \hline \\ OH & H \end{array}$$

5. Valine, $C_5H_{11}O_2N$ (α -amino-isovaleric acid or β , β -dimethyl-alanine)

6. Leucine, $C_6H_{13}O_2N$ (α -amino-isocaproic acid or β -isopropylalanine)

7. Isoleucine, $C_6H_{13}O_2N$ (β -methyl- α -amino-valeric acid or β -methyl- β -ethyl-alanine)

8. Norleucine, 10 C₆H₁₃()₂N (α-amino-caproic acid)

In The occurrence of this amino acid in proteins is still questioned by many.

B. Aromatic Amino Acids

9. Phenylalanine, $C_9H_{11}O_2N$ (β -phenyl- α -amino-propionic acid or β -phenyl-alanine)

$$\begin{array}{c} \operatorname{NH_2} \\ \downarrow \\ \operatorname{CH_2-C-COOH} \\ \downarrow \\ \operatorname{H} \end{array}$$

10. Tyrosine, $C_9H_{11}O_3N$ (β -para-hydroxy-phenyl- α -amino-propionic acid or β -para-hydroxy-phenyl-alanine)

C. Sulfur-containing Amino Acids

11. Cysteine, $C_3H_7O_2NS$ (β -thiol- α -amino-propionic acid)

12. Cystine, ² C₆H₁₂O₄N₂S₂ (di-(β-thiol-α-amino-propionic acid))

13. Methionine, C₅H₁₁O₂NS (γ-methylthiol-α-amino-n-butyric acid)

$$\begin{array}{c} \operatorname{NH_2} \\ \operatorname{CH_3--S--CH_2--CH_2--C--COOH} \\ \operatorname{H} \end{array}$$

D. Heterocyclic Amino Acids

14. Tryptophane, C₁₁H₁₂O₂N₂ (β-3-indole-α-amino-propionic acid or β-indole-alanine)

² Cystine is included here among the mono-amino-monocarboxylic acids because its solutions are neutral since it contains two amino and two carboxyl groups.

15. Proline, C₅H₉O₂N (pyrrolidine-2-carboxylic acid)

16. Hydroxyproline, C₅H₉O₃N (oxyproline or 4-hydroxy-pyrrolidine-2-earboxylic acid)

ACIDIC AMINO ACIDS

These acids, often referred to as monoamino-dicarboxylic acids, contain more carboxyl than amino groups and are therefore acid in reaction. They form calcium and barium salts which are insoluble in 80 to 90 per cent ethanol and may thus be removed from the other products of protein hydrolysis.

17. Aspartic acid, C₄H₇O₄N (α-amino-succinic acid)

18. Glutamic acid, C₅H₉O₄N (α-amino-glutaric acid)

BASIC AMINO ACIDS

These acids are predominantly basic in reaction and are precipitated from protein hydrolysates by the addition of phosphotungstic acid.^{2a}

19. Histidine, $C_6H_9O_2N_3$ (β -imidazol- α -amino-propionic acid or β -imidazol-alanine)

20. Arginine, C₆H₁₄O₂N₄ (δ-guanidino-α-amino-valeric acid)

21. Lysine, C₆H₁₄O₂N₂ (α-ε-di-amino-caproic acid)

- 22. Hydroxylysine, C₆H₁₄O₃N₂ (α-ε-diamino-hydroxycaproic acid). The structure is still somewhat in doubt.
 - 23. Citrulline, C₅H₁₃O₃N₃ (δ-carbamino-α-amino-valeric acid)

$$\begin{array}{c} \text{NH}_2\\ \text{NH}_2\text{--}\text{C}\text{--}\text{NH}\text{--}\text{CH}_2\text{---}\text{C'H}_2\text{---}\text{C}\text{--}\text{COOH}\\ \\ \text{O} \\ \end{array}$$

Other Hydrolysis Products of Proteins. Most proteins contain practically all of the amino acids listed above. Occasionally we find that certain amino acids are either entirely absent in a particular protein, or else present in amounts too small to be detected by the available methods of analysis. Thus the protein zein, from maize, contains no lysine or glycine, gelatin yields no tryptophane, and insulin contains no methionine. In other cases we may find that certain specialized proteins contain amino acids not found in any other proteins. The most noteworthy example of this is a globulin obtained from the thyroid gland, thyroglobulin, which

^{*}Proline and cystine are also precipitated to a certain extent by phosphotungstic acid.

normally contains two iodinated tyrosine derivatives, 3, 5-diiodotyrosine or iodogorgoic acid and β -4'-hydroxy-phenyl-3',5',3,5-tetraiodotyrosine or thyroxin. Interestingly enough the bromine analogue of diiodotyrosine—

namely, dibromotyrosine—has been found in a number of Mediterranean corals and gorgonia.

Occasionally substances known as diketopiperazines, which are anhydrides formed by the condensation of two molecules of amino acid, have been found in protein hydrolysates. It is the present opinion that these are formed during the treatment of the hydrolysate.

In addition to the above-mentioned amino acids the probability exists that other less well-recognized amino acids are present in many protein molecules.

Acid hydrolysis of proteins also liberates variable quantities of ammonia which come primarily from the hydrolysis of the acid amide groups of asparagine and glutamine, for it is now known that a portion of these dicarboxylic amino acids exists in the peptide chain with the "omega" carboxyl group aminated. A smaller portion of the ammonia presumably comes from the hydrolytic decomposition of certain amino acids such as cysteine, serine, threonine, etc. If alkaline hydrolysis is employed ammonia is formed from glutamine, asparagine, cystine, cysteine, serine, threonine, and arginine. The last-named substance breaks down to yield ornithine and two molecules of ammonia.

Hydrolysis of proteins also yields small quantities of carbon dioxide, hydrogen sulfide, and free sulfur. These products arise from the destructive decomposition of the more labile amino acids, especially cysteine. Certain proteins (serum albumin, egg albumin, thrombin) yield varying amounts of carbohydrate. These carbohydrates appear to be polysaccharides composed of one molecule of glucosamine and two molecules of hexose (mannose, galactose). It is not known whether the carbohydrates are an integral part of the protein molecule or whether the protein is composed of a carbohydrate-free portion admixed with a small quantity of a carbohydrate-rich protein (glycoprotein) such as seromucoid, seroglycoid, ovomucoid, etc.

Determination of Amino Acids. The quantitative determination of each of the component amino acids produced during hydrolysis of a pro-

tein is a problem of greatest importance since any theory of protein structure must rest ultimately on an exact knowledge of all the units contained in the molecule. This problem is still far from solved since it presents many serious difficulties, not the least of which is the preliminary hydrolysis of the protein molecule into its component amino acids without causing decomposition during the hydrolysis.

METHODS. A. Fractional Distillation of Ethyl Esters. Fischer in 1901 showed that most neutral amino acids formed esters when their solutions in absolute ethyl alcohol were treated with dry hydrogen chloride. The ester hydrochlorides could then be dissolved in dry ether, the molecule of HCl removed with alkali, and the amino acid esters separated by fractional distillation in vacuo. Using this method, Fischer was able to isolate many of the amino acids in pure crystalline form. The method, however, is very tedious, requires large quantities of protein, and does not yield quantitative results.

 c The figures given in this table are somewhat high, since no allowances have been made for the water taken up by the amino acids during hydrolysis.

B. Van Slyke's Nitrogen Distribution Method. When an aliphatic primary amine is treated with nitrous acid, its amino nitrogen is quantitatively converted into free nitrogen.

$$R \cdot NH_2 + HONO \rightarrow R \cdot OH + H_2O + N_2 \uparrow$$

By the use of this reaction, supplemented by other procedures, as indicated in the accompanying diagram, Van Slyke developed a method for the determination of the distribution of amino and nonamino nitrogen in the protein together with fairly accurate determinations of cystine, arginine, lysine, and histidine. The Van Slyke method is comparatively simple and requires only small amounts (3 or 6 g.) of protein. Although it does not differentiate between the neutral and acid amino acids, the information it yields is sufficient for many purposes and it is often used in cases where a more elaborate knowledge of protein composition is unnecessary. It may also be supplemented by methods for determining individual amino acids, thus giving a fair estimation of the amino acid content of proteins.

DISTRIBUTION OF PROTEIN NITROGEN BY VAN SLYKE METHOD

I. Amide Nitrogen. (Distilled off as ammonia, after neutralization of hydrolysis mixture with magnesium oxide.)

/a. Cystine. (Contains only amino N. Estimated from sulfur determinations)

II. Basic Nitrogen. b. Lysine. (Contains only amino N.)
(Precipitated c. Arginine. (Three-quarters of nitrogen is by phospho-

nonamino N. Half of nitrogen liberated as ammonia by boiling with strong NaOH.)

d. Histidine. (Two-thirds of nitrogen is non-

amino N.)

Total Nitrogen (Kieldahl determination on portion of hvdrolvsis mixture)

III. Monoamino Nitrogen + Nonamino Nitrogen. (Kjeldahl determination on filtrate from method.)
precipitated phosphotungb. Nonamino N. (Proline,

tungstic acid.)

- a. Monoamino N. (Neutral and acid amino acid N. One-half of tryptophane N. Determined by Van Slyke method.)
 - hydroxy-proline, and onehalf tryptophane N. Difference between III and IIIa.)
- C. Determination of Individual Amino Acids. Differences in the chemical nature of the various amino acids have been utilized to permit the estimation by chemical means of the quantities of individual amino acids present in a protein hydrolysate. The principal methods in use at the present time are outlined below:
- 1. Glycine gives a green color when condensed with o-phthaldialdehyde, and an insoluble precipitate with potassium trioxalatochromiate.
- 2. Alanine is deaminated to form lactic acid which is then determined by oxidizing to acetaldehyde. α - β -dihydroxybutyric acid, which is formed by the deamination of threonine, likewise yields acetaldehyde on mild oxidation.

- 3. Serine is oxidized with periodic acid to yield formaldehyde which is readily determined.
 - 4. Threonine is oxidized with periodic acid to yield acetaldehyde.
- 5. Phenylalanine is first nitrated to yield 3,4-dinitrophenylalanine; this is reduced to the nitroso compound which has a purple color in alkaline solution.
- 6. Tyrosine, like other 3,5 unsubstituted phenols, gives an intense red color when treated with mercury salts and nitrous acid (Millon-Nasse reaction).
- 7. Tryptophane gives various red and purple compounds when condensed with aromatic or aliphatic aldehydes in the presence of concentrated hydrochloric or sulfuric acid (Hopkins-Cole, Voisenet-Rhode reactions).
- 8. Cystine is reduced to cysteine. The latter is capable of reducing phospho-18-tungstic acid to yield the deep blue lower oxides of tungsten.
- 9. Methionine is demethylated by boiling with concentrated hydriodic acid. The resulting methyl iodide and homocysteine are then determined separately, or treated with sodium nitroprusside to give a colored complex.
- 10. Aspartic acid is first precipitated as the calcium salt and then is isolated as copper aspartate.
- 11. Glutamic acid is oxidized with chloramine-T to β -cyanopropionic acid. The latter is hydrolyzed to succinic acid which is then determined.
- 12. Histidine is precipitated as the silver salt at pH 7.4 and then isolated as histidine nitranilate. Nitranilic acid is 2,5-dihydroxy-3,6-dinitro-p-benzoquinone.
- 13. Arginine is first precipitated by silver nitrate and baryta at strongly alkaline reaction and then isolated as pure arginine 2,4-dinitro-1-naphthol-7-sulfonate (arginine monoflavianate).
- 14. Lysine can be determined in the intact protein by virtue of the fact that almost all of the free amino groups in a protein are the ϵ -amino groups of lysine. Lysine is isolated from a protein hydrolysate previously freed of histidine and arginine, by precipitation with phospho-24-tungstic acid and subsequent isolation as lysine picrate.
- 15. Hydroxylysine is precipitated with phosphotungstic acid. On treatment with periodic acid in alkaline solution, one molecule of hydroxylysine yields one molecule of formaldehyde and one of ammonia.
- D. Bergmann's Solubility Product Method. The solubility product of a sparingly soluble amino acid salt is constant and measurable. It is thus possible to determine the quantity of an amino acid in a mixture if known amounts of the precipitating reagent and of the amino acid are added to aliquots of the unknown solution.
- E. The Isotope Dilution Method of Ussing and of Schoenheimer and l'ittenberg. A compound which has an abnormal isotope content is inseparable from its normal analogue by the usual laboratory procedures. Thus if an amino acid containing a known excess of an isotope is added to a protein hydrolysate, the quantity of the amino acid present in the hydrolysate can be easily calculated by a determination of the isotope

content of the isolated amino acid. The yield of amino acid actually isolated is of no importance in this method.

F. Microbiological Procedures. Various microörganisms such as Lactobacillus arabinosus, etc., require certain amino acids for normal growth (Lyman, et al., Shankman). Preparation of synthetic media lacking in only one of these amino acids permits the determination of the specific amino acid in the unknown solution. Growth of the microörganism on the synthetic medium supplemented by the solution undergoing analysis is compared with that obtained in the presence of known amounts of added amino acid. In other cases, mutants of the mold, Neurospora crassa, have been developed which require only one amino acid for growth (Beadle and Tatum). These microbiological methods may greatly facilitate accurate protein analysis especially for those amino acids for which there are no adequate chemical methods.

General Properties of Amino Acids. The amino acids derived from proteins are all α -amino acids. The α carbon atom in all the acids, with the exception of glycine, is asymmetric, so that these acids are all optically active. They are white crystalline substances, the crystal form being characteristic for each acid. They are all soluble in water, except cystine and tyrosine, the latter being more soluble in hot than in cold water. With the exception of proline, they are all insoluble in alcohol, and all are insoluble in ether. They are, as a rule, all soluble in solutions of strong acids and bases. They are not precipitated by ammonium sulfate or sodium chloride, but with the exception of proline are precipitated by alcohol. They form crystalline salts with metallic bases and with mineral acids. Many of the amino acids (such as glycine, alanine, serine, and proline) have a sweet taste; some, like tryptophane and leucine, are tasteless; others, like arginine, are bitter. The amino acids are all amphoteric, ionizing both as acids and as bases, by virtue of their carboxyl and amino groups, thus forming salts with alkalies and with acids.

Spatial Configuration and Optical Activity of Amino Acids. The amino acids have the following general structure:

In this structure the α carbon atom is asymmetric—i.e., there are four different substituent groups. Thus all the amino acids except glycine (where R=H) are optically active, and are capable of existing in two different spatial forms, which are "mirror images" of one another, with equal and opposite optical rotatory power, and which differ solely in the arrangement of the substituent groups in space around the α carbon atom. These two different spatial arrangements are known respectively as the d and l configurations.

The configuration of a particular amino acid is based in its spatial relationship to an arbitrary reference compound, just as the configuration

of p-glucose is based on that of dextrorotatory p-glyceraldehyde (see Chapter 2). This relationship, for the amino acids, is illustrated as follows:

Thus the naturally occurring amino acid alanine, which is dextrorotatory, may by suitable means be related structurally to either dextrorotatory lactic acid or levorotatory glyceraldehyde, both of which have the same configuration, which in this case is known as the l configuration when referring to amino acids. As with the sugars there is no necessary agreement between configuration and the direction of optical rotation; to indicate the latter the signs (+) for dextrorotatory and (-) for levorotatory are used. Naturally occurring alanine is therefore l (+)-alanine; its "mirror image" is d(-)-alanine.

The spatial configuration of an amino acid appears to have important physiological significance. For instance certain (but not all) of the amino acids cannot be utilized by the animal body if the configuration is opposite to that found naturally. It is an interesting fact that the bulk of the amino acids found in nature, either free or as part of proteins, have the l configuration. Certain d amino acids have however been isolated from natural sources; thus d glutamic acid is a major constituent of the capsule of Bacillus anthracis and related microorganisms, the naturally occurring antibiotic polypeptide, gramicidin, contains a high proportion of d amino acids, and d valine is a decomposition product of the penicillins. The significance of these stereochemical findings remains to be elucidated.

Chemical Reactions of Amino Acids. The amino acids give three general types of chemical reactions: (1) Reactions due to the presence in the molecule of the carboxyl (COOH) group, (2) reactions due to the amino (NH₂) group, and (3) reactions due to the radical R. Of these three types of reactions, those due to the carboxyl and amino groups are perfectly general reactions and are given by all of the amino acids.

The reactions given by the radical R are usually specific reactions, given only by those acids which contain certain particular groups. Thus cystine gives a reaction for sulfur, tryptophane gives certain color reactions because its molecule contains the indole group, tyrosine gives other color reactions because of its phenolic group, etc. Some of these color reactions that are specific for individual amino acids are used as general color reac-

tions for proteins since most proteins contain one or more of these acids in their molecules. The most important of these reactions are therefore described in the next chapter, under the general reactions of proteins.

The reactions given by all amino acids by virtue of their carboxyl and amino groups are of great importance. Some of these reactions, such as the formation of a great variety of crystalline derivatives with organic and inorganic compounds, are useful in the isolation, purification, and quantitative determination of individual amino acids. Among such derivatives we may mention the ethyl esters, picrates, flavianates, picrolonates, copper, barium, cadmium, calcium, nickel, and zinc salts, and double salts with compounds such as phosphotungstic acid, chloroplatinic acid, gold chloride, silver nitrate, mercuric acetate, and mercuric chloride. Many of these reactions are given by the intact protein, since the latter always contains a certain number of free amino and carboxyl groups. The more important of these reactions of amino acids which give us an insight into the complex chemical and physicochemical behavior of the protein molecule are discussed below.

REACTIONS OF AMINO ACIDS WITH ACIDS AND BASES. Since the amino acids contain both carboxyl and amino groups, they behave like typical amphoteric compounds, ionizing both as acids and as bases:

The addition of acid favors the ionization to the left and leads to the formation of salts of the amino acid similar to those formed by ammonia and other substituted ammonia derivatives. With hydrochloric acid, for example, a hydrochloride is formed which ionizes into a positive amino acid ion and a negative chlorine ion:

With alkalies, such as sodium hydroxide, the ionization proceeds to the right leading to the formation of a sodium salt of the amino acid which is ionized, giving a positive sodium ion and a negative amino acid ion:

$$H$$
 R
 C
 $COO^- + H^+ + NaOH $\rightarrow H_2O + R$
 C
 $COONa \rightleftharpoons R$
 C
 $COO^- + Na^+$
 NH_2
 $NH_2$$

In acid solutions, therefore, the amino acid carries a positive charge and in an electrical field migrates to the cathode, while in alkaline solutions it carries a negative charge and migrates to the anode. For every amino acid there is a definite hydrogen-ion concentration, specific for that acid, at which the degrees of acid and basic ionization are equal. At this particular pH, known as the isoelectric point, the amino acid is electrically neutral and will not migrate in an electrical field.

In past years there has been a great accumulation of experimental evidence indicating that this electrically neutral form of the amino acid consists of a mixture of undissociated molecules and a tautomeric form, known as a zwitter-ion, in which both the amino and carboxyl groups

are ionized to the same extent. In solutions of aliphatic amino acids, more than 99 per cent of the molecules are present in the form of zwitter-ions, while in the aromatic acids the two forms are present in approximately equal amounts. The addition of acid to the zwitter-ion suppresses the

ionization of the carboxyl group, thus leaving a positively charged ion which is free to form salts with the acid. Similarly, alkali suppresses the ionization of the amino group, thus leaving a negatively charged ion which can form salts with the base. Thus the effects of adding acid or

alkali to the amino acid are the same regardless of whether the neutral amino acid is considered to be an undissociated molecule or a zwitter-ion.

These reactions of amino acids with acids and with bases are of great importance in protein chemistry since, as we shall see in Chapter 5, a great many of the physicochemical reactions of proteins are explainable on the basis that the protein molecule contains a definite number of free amino and free carboxyl groups, the exact number of each being characteristic of each particular protein. Depending upon the pH of the solution, therefore, proteins combine with acids and bases, and carry a preponderance of either positive or negative charges, or behave as though they were electrically neutral.

REACTIONS OF AMINO ACIDS WITH NITROUS ACID. The amino acids, as their general formula indicates, are primary amines, and like all such amines yield nitrogen when treated with nitrous acid. This reaction

$$\begin{array}{c} H \\ \downarrow \\ R-C-COOH + HNO_2 \rightarrow R-C-COOH + N_2 + H_2O \\ \downarrow \\ NH_2 \end{array}$$

forms the basis for Van Slyke's method for the determination of free amino groups, as has already been indicated. For this purpose use is made of a specially devised apparatus in which the nitrogen gas evolved during the reaction is collected and its volume measured. This reaction is important for the determination of free amino groups in amino acids, or mixtures of amino acids, and is also used in estimating the amounts of amino acids in biological fluids, such as blood. It is also used to determine the percentage of the total nitrogen of the protein that is present in the form of free amino nitrogen. Since the latter increases during acid or enzymatic hydrolysis, the method is also of great value in determining the rate and extent of protein degradation by any of the hydrolytic agents.

REACTIONS OF AMINO ACIDS WITH NINHYDRIN. The amino acids in general react with the compound ninhydrin (C₆H₄·(CO)₃·H₂O, triketohydrindene hydrate) to yield carbon dioxide, ammonia, and usually (but not always) an aldehyde containing one less carbon atom than the original amino acid.

$$\begin{array}{c} \operatorname{NH_2} \\ \operatorname{R-C-COOH} \to \operatorname{R-C=O} + \operatorname{NH_3} + \operatorname{CO_2} \\ \downarrow \\ \operatorname{H} \end{array}$$

This reaction has been made the basis for several different types of quantitative methods for the determination of amino acids. These are based upon (1) the color change which results from the reaction (see p. 157), (2) determination of the ammonia produced, and (3) measurement by gasometric means of the carbon dioxide evolved. This latter procedure has been accurately established by Van Slyke and associates as possibly the most satisfactory method available for the determination of α -amino nitrogen (in terms of CO_2), exceeding the nitrous acid method in specificity for this purpose. For a description of this method as applied to the determination of amino acid nitrogen in urine, see Chapter 32.

REACTIONS OF AMINO ACIDS WITH FORMALDEHYDE. The carboxyl group of the simple amino acids is not readily titratable with alkali under ordinary conditions, presumably because of the influence of the neighboring amino group. In 1899 Schiff observed that in the presence of formaldehyde the amino acids became as readily titratable as any simple organic acid. Sørensen formulated the reaction between amino acids and formal-dehyde as follows:

There is considerable evidence against this view, however, and Harris believes that only an amino acid-formaldehyde complex is formed:

The presence of formaldehyde decreases the basicity of the amino group. permitting the carboxyl group to exert its maximum acidity. This acidity may then be titrated with standard sodium hydroxide, using phenolphthalein as indicator. This reaction forms the basis for Sørensen's "formol titration" method for the estimation of free carboxyl groups in amino acids and mixtures of amino acids. It is also widely used for determining the increase in carboxyl groups which accompanies the enzymatic hydrolysis of proteins.

REACTIONS OF AMINO ACIDS WITH AMINO ACIDS. Many of the amino acids readily form anhydrides when their solutions are evaporated. This reaction involves a condensation between the amino group of each molecule with the carboxyl group of the other, the resulting compounds being known as diketopiperazines. In 1901 Fischer and Fourneau subjected

glycine anhydride to weak hydrolysis with acids and obtained a compound, glycyl-glycine, in which the amino group of one acid was combined with the carboxyl group of the other. This was the starting point of a great

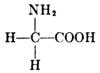

many researches whereby Fischer and his co-workers, using various derivatives of amino acids, prepared a large number of similar compounds between amino acids, called dipeptides. Although the details of these methods would be out of place in a book of this character the reactions involved were chosen so that the amino group of one acid always combined with the carboxyl group of the other, resulting in the so-called peptide linkage. Since these dipeptides still contained a free amino and a

carboxyl group, by the use of various ingenious methods Fischer was able to lengthen these chains of amino acids, forming polypeptides containing as many as 18 acids. According to the modern conceptions of protein structure the protein molecule consists in large part, at least, of amino acids linked together through their amino and carboxyl groups. The evidence for this point of view will be discussed more fully in the section on the structure of the protein molecule in Chapter 5.

DISCUSSION OF THE INDIVIDUAL AMINO ACIDS Glycine, C₂H₆O₂N (amino-acetic acid, glycocoll).

Glycine was discovered by Braconnot, in 1820, by boiling meat or gelatin with dilute sulfuric acid. It was the first amino acid to be isolated as a primary decomposition product of the proteins. Glycine is prepared

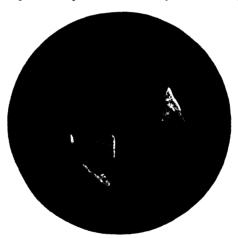

Fig. 41. Glycine (synthetic). (From Keenan: J. Biol. Chem., 62, 163 (1924).) See also Fig. 114.

synthetically by the action of ammonia on monochloroacetic acid. It crystallizes in rather large colorless monoclinic crystals usually in four-sided prisms. It is soluble in water and saturated ammonium sulfate solution but insoluble in alcohol and ether. Its water solution possesses a sweet taste. It melts with decomposition at 232° to 236°. Glycine possesses no asymmetric carbon atom and is therefore not optically active.

In addition to being present in many animal proteins, glycine is found in the body as a constituent of various nonprotein nitrogenous compounds. It is a component of (1) glutathione, a tripeptide of glutamic acid, cysteine, and glycine (see p. 134); (2) glycocholic acid, a compound

of glycine and cholic acid, found in the bile (Chapter 18); and (3) hippuric acid, or benzoyl-glycine, which is found in the urine after the ingestion of benzoic acid or compounds which give rise to benzoic acid in metabolism. The reaction leading to the formation of hippuric acid from benzoic acid and glycine is as follows:

$$C_6H_5COOH + H_2N-CH_2COOH \rightarrow C_6H_5CO-NH-CH_2COOH + H_2O$$

Benzoic acid Glycine Hippuric acid

EXPERIMENTS ON GLYCINE

- 1. Preparation of Glycine from Hippuric Acid: Put 5 g. of hippuric acid in a 100-ml. round-bottom flask. Attach the flask to a reflux condenser after adding 20 to 25 ml. of 30 per cent sulfuric acid. Boil the contents of the flask on a wire gauze for one hour, cool under the tap, and fliter. The boiling acid splits the hippuric acid into benzoic acid and glycocoll. The benzoic acid, being quite insoluble in cold acid, begins to crystallize out and is retained on the paper. In order to remove the remainder of the benzoic acid from the filtrate, shake the filtrate with twice its volume of ether in a separatory funnel. The filtrate is next diluted with three volumes of water and heated with sufficient barium carbonate, in the presence of caprylic alcohol to minimize foaming, until the sulfuric acid has been precipitated out as barium sulfate. Filter off the barium sulfate and evaporate the filtrate on a water bath until the glycine begins to crystallize out.
- 2. Preparation of Glycine from Gelatin (Fischer Ester Method): Place 300 ml. of concentrated HCl and 100 g. of ordinary gelatin in a 600-ml, roundbottom flask. Heat on a water bath with frequent shaking until the gelatin has gone into solution. Connect the flask with a reflux condenser, place on a wire gauze, and heat to boiling for 3 to 4 hours. Transfer the contents of the flask to a liter distilling flask and distil in vacuo, until the contents of the flask become thick and viscous. Attach the flask again to the reflux condenser, pour 500 ml. of absolute alcohol into the flask, and heat until the solution in the alcohol is complete. To the alcoholic solution add 5 g. of animal charcoal and boil for 1 to 2 minutes. Filter hot, cool the filtrate under the water tap, and saturate with dry HCl gas. Boil under the reflux condenser on a water bath for one hour, cool, and allow the flask to stand over night in the icebox. Seed. The glycine ethyl ester hydrochloride should crystallize out as a mass of colorless needles. In case this does not occur it may be necessary to concentrate in vacuo, seed again and scratch to induce crystallization. The glycine ethyl ester hydrochloride has the following structure:

3. Preparation of Free Glycine: Weigh the glycine ethyl ester hydrochloride, place in a 250-ml. round-bottom flask and add 2 ml. of water for each gram of the substance. Next add about 100 ml. of ether, cool in a freezing mixture, and introduce 30 per cent NaOH until the aqueous layer is neutral to litmus. (0.8 to 1.0 g. is required for every gram of the hydrochloride.) Next add potassium carbonate (powdered) with vigorous shaking, until the aqueous layer becomes pasty. The alkali splits off the hydrochloric acid, leaving the glycine ethyl ester which is soluble in ether. Pour off the ether. To the ethereal solution in a round-bottom flask add 1 volume of water. Boil until no longer alkaline. Evaporate in a porcelain dish on the water bath. Glycine should crystallize out. For the crystalline form see Fig. 41.

l(+)-Alanine, $C_3H_7O_2N$ (α -amino-propionic acid).

Alanine was discovered in 1850 by Strecker, who treated aldehyde ammonia with HCN and hydrolyzed the resulting aminocyanohydrin. It was isolated by Schützenberger and Bourgeois, in 1875, from the decomposition products of silk. It is best prepared from silk, in which it occurs to the extent of 26.4 per cent. Alanine is easily soluble in water and

Fig. 42. Alanine. (From Keenan: J. Biol. Chem., 62, 163 (1924).)

quite insoluble in alcohol and acetone. It has a sweetish taste, is dextrorotatory, and melts with decomposition between 293° to 297°. l(-)-Serine, $C_3H_7O_3N$ (β -hydroxy- α -amino-propionic acid).

This acid was first obtained by Cramer in 1865, in fairly large quantities from sericine, a protein of silk. It was prepared synthetically from glycol aldehyde, hydrocyanic acid, and ammonia by Fischer and Leuchs. Serine crystallizes from water solution as thin irregular plates and has a sweet taste. It melts at about 245° and is soluble in 23 times its weight of water at room temperature.

l(-)-Threonine, $C_4H_9O_3N$ (α -amino- β -hydroxy-n-butyric acid).

Although this amino acid was isolated from proteins by Gortner and Hoffman (1925), Schryver and Buston (1925–1926), and Rimington (1927), it was first isolated in pure crystalline form and its structure determined by McCoy, Meyer, and Rose in 1935. The α carbon atom of naturally

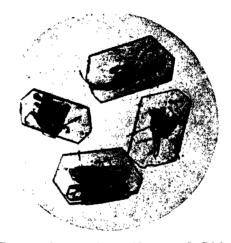

Fig. 43. Serine. (From Keenan: J. Biol. Chem., 62, 163 (1924).)

occurring threonine has the l configuration, as shown. When, however, the configuration of the molecule as a whole is considered, it is seen to resemble that of the sugar p-threose (whence the name) so that this amino acid is sometimes referred to as d(-)-threonine.

l(+)-Valine, $C_5H_{11}O_2N$ (α -amino-isovaleric acid).

Valine was discovered by Von Gorup-Besanez in 1856. It occurs in casein and in egg albumin to the extent of 6 to 7 per cent. It is made synthetically by the interaction of ammonia and α -brom-isovaleric acid under pressure in which process the bromine is split off as HBr and the amino group takes the α -position originally occupied by the bromine.

l(-)-Leucine, C₆H₁₃O₂N (α-amino-isocaproic acid).

Leucine was identified as a product of the hydrolysis of proteins and named by Braconnot in 1820. It was probably discovered in crystalline form in the holes of cheese by Proust, in 1818, who failed however to recognize it as a decomposition product of proteins. Leucine is found in almost all proteins. Free leucine has been found pathologically in urine

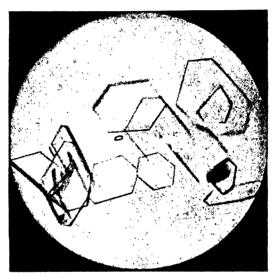

Fig. 44. Threonine. (From McCoy, Meyer, and Rose: J. Biol. Chem., 112, 288 (1935).)

(in acute yellow atrophy of the liver, phosphorus poisoning, and acute febrile conditions).

The pure compound is only slightly soluble in cold water or absolute alcohol but is quite soluble in hot dilute alcohol. It melts at 295° to 297° C. with decomposition. Pure leucine crystallizes in shiny, white, extremely thin plates. Inactive leucine tastes slightly sweet, while d(+)-leucine tastes quite sweet and l(-)-leucine slightly bitter.

EXPERIMENTS ON LEUCINE

Preparation of Leucine: In a 2-liter flask, place 1 liter of defibrinated blood and gradually add 150 ml. of concentrated sulfuric acid, shaking well during the additions. Boil on a sand bath for 12 to 14 hours, being careful to shake continually until it boils evenly. To the hot liquid add a solution of barium hydroxide until the mixture is alkaline to litmus. Filter on a Buchner funnel. Make the filtrate acid to litmus with dilute H,SO4, decolorize with 20 g. of activated charcoal, filter, and concentrate in a porcelain dish

over an open flame to 500 ml. and filter again. Make the filtrate faintly alkaline to litmus through the addition of ammonia and concentrate on a boiling water bath until a crystalline mass forms on top of the liquid. Cool for 24 hours in the icebox. Filter on a Buchner funnel and press the water out of the crystals. Recrystallize from 70 per cent alcohol.

Make the following tests upon the leucine crystals already prepared or upon some pure leucine furnished by the instructor.

1, 2 and 3. Do these experiments according to the directions given for Tyrosine (p. 126).

l(+)-Isoleucine, $C_6H_{13}O_2N$ (β -methyl- α -amino-valeric acid).

This acid was first prepared by Ehrlich, in 1903, from the refuse material in the sugar industry, and later he prepared it synthetically by the action of ammonia on the bromine derivative of the compound ob-

Fig. 45. Leucine. For the material from which the above crystals were prepared, as well as those reproduced in Figs. 46 to 48 and 50 to 51, the authors are indebted to the late Dr. Thomas B. Osborne.

tained from malonic acid ester and secondary butyl iodide. Isoleucine has a bitter taste. It crystallizes in plates like leucine. These melt at 280° and are soluble in 26 parts of water, very soluble in hot glacial acetic acid and hot methyl alcohol.

l(-)-Phenylalanine, $C_9H_{11}O_2N$ (β -phenyl- α -amino-propionic acid).

Phenylalanine was discovered by Schulze and Barbieri in 1881. It is fairly insoluble in water, crystallizing from warm concentrated solutions in small shiny leaves, but from dilute solutions in fine needles. It melts with decomposition between 275° to 280°. This acid is easily soluble in hot water, quite insoluble in cold water, and but little soluble in ethyl and methyl alcohols. It has a slightly bitter taste.

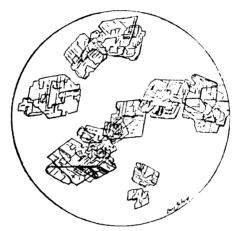

Fig. 46. Phenylalanine.

l(-)-Tyrosine, $C_9H_{11}O_3N$ (β -para-hydroxy-phenyl- α -amino-propionic acid).

$$\begin{array}{c} \operatorname{NH}_2 \\ \downarrow \\ \operatorname{CH}_2 - \operatorname{C-COOH} \\ \downarrow \\ \operatorname{H} \end{array}$$

Tyrosine was discovered by Liebig in 1846. Of all the amino acids it is the least soluble in water (1 part in 2500 of water at room temperature). It is insoluble in ether, alcohol, acetone, and glacial acetic acid, but readily soluble in dilute alkalis and acids. It crystallizes from water in sheathlike groups of fine white needles. Its melting point is indefinite but is usually given as between 315° to 320°. Tyrosine is found in most proteins but is virtually absent in gelatin (0.3 per cent). It may be detected in the faintest traces by means of Millon's reaction. (See p. 154.)

EXPERIMENTS ON TYROSINE

Preparation of Tyrosine: Introduce 200 g. of commercial casein into a 3-liter pyrex flask, add a liter of cold water, and shake well. With con-

tinuous shaking, slowly add a liter of boiling water to this mixture. Now add 40 ml. of 20 per cent sodium hydroxide to dissolve the casein and adjust the reaction of the casein solution to pH 8 by the addition of normal sodium hydroxide.³

Preserve the casein solution and diminish oxidase action by adding 15 ml. of toluol and 2 g. of sodium fluoride dissolved in about 10 ml. of hot water. Shake well, add trypsin in the form of some commercial preparation, and, after mixing the contents of the flask thoroughly, stopper the flask and place it in an incubator at 38° to 40°. Shake the flask thoroughly every day, without removing the stopper, and at the end of the fourth day add an additional quantity of trypsin in one of the forms mentioned. After permitting the digestion to continue for a second period of four days, remove the flask from the incubator, allow it to stand at room temperature for at least 24 hours, then filter off the precipitate of tyrosine, undigested casein, etc. Treat the residue with dilute sulfuric acid (5 ml. of concentrated sulfuric acid in 250 ml. of water) to dissolve the tyrosine, filter through

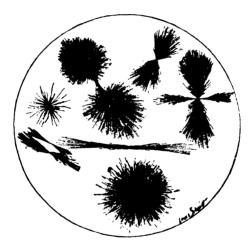

Fig. 47. Tyrosine.

a pleated paper, add 10 ml. of concentrated ammonium hydroxide to the filtrate, and heat on a boiling water bath. The solution, which should now be acid to litmus, is carefully neutralized by the addition of ammonium hydroxide and allowed to cool. Tyrosine, contaminated with more or less calcium phosphate, should crystallize out. Filter off the tyrosine by suction, suspend it in 300 ml. of water in a flask, heat to boiling, add 5 ml. of concentrated ammonium hydroxide, and boil for 15 minutes. Filter off the insoluble calcium phosphate, neutralize the tyrosine filtrate with 5 per cent H₂SO₄, and allow it to stand. Filter off the tyrosine crystals by suction, wash well with cold water and alcohol in turn, and dry in an oven or incubator. If the tyrosine crystals are not well formed (see Fig. 47) they may be recrystallized from hot water (solubility 1:154.)

³ To do this take 10 ml. of the casein mixture, add 10 drops of cresol red and titrate with 0.2 N NaOH (using a microburet or a 1-ml. pipet graduated in 0.01 ml.) until a reddishpurple color is obtained. Multiply this titration volume by 40 and add this quantity of normal sodium hydroxide to the casein solution in the pyrex flask. Shake the mixture at frequent intervals after the hydroxide is added. The reaction should now be acid to phenolphthalein and alkaline to cresol red.

^{&#}x27;If pure trypsin is not available the ensyme may be added in the form of "pancreatin." "liquor pancreaticus," or the finely divided pancreas of a pig or sheep.

This filtration can be speeded up by the use of a distomaceous earth filter aid

Make the following tests with the tyrosine crystals prepared in the above experiment, or upon some pure tyrosine furnished by the instructor.

- 1. Microscopic Examination: Place a minute crystal of tyrosine on a slide, add a drop of water, cover with a cover glass, and examine microscopically. Now run more water under the cover glass and warm in a Bunsen flame until the tyrosine has dissolved. Allow the solution to cool slowly, then examine again microscopically, and compare the crystals with those shown in Fig. 47.
- 2. Solubility: Try the solubility of very small amounts of tyrosine in cold and hot water, cold and hot 95 per cent alcohol, dilute NH,OH, dilute KOH, and dilute HCl.
- 3. Sublimation: Place a little tyrosine in a dry test tube, heat gently, and notice that the material does not sublime. How does this compare with leucine?
- 4. Hofmann's Reaction: This is the name given to Millon's reaction when employed to detect tyrosine. Add about 3 ml. of water and a few drops (avoid an excess) of Millon's reagent to a little tyrosine in a test tube. Upon dissolving the tyrosine by heat the solution gradually darkens and may assume a dark red color. What group does this test show to be present in tyrosine?
- 5. Sulfuric Acid Test (Piria): Warm a little tyrosine on a watch glass on a boiling water bath for 20 minutes with 3 to 5 drops of concentrated H₂SO₄. Tyrosine-sulfuric acid is formed in the process. Gool the solution and wash it into a small beaker with water. Now slowly add CaCO₃ in substance with stirring, until the reaction of the solution is no longer acid. Filter, concentrate the filtrate, and add it to a few drops (avoid an excess) of very dilute neutral ferric chloride. A purple or violet color, due to the formation of the ferric salt of tyrosine-sulfuric acid, is produced. This is one of the most satisfactory tests for the identification of tyrosine.
- 6. Formaldehyde-Sulfuric Acid Test (Mörner): Add about 3 ml. of Mörner's reagent⁶ to a little tyrosine in a test tube, and gently raise the temperature to the boiling point. A green color results.
- 7. Folin's Test: To 1 to 2 ml. of the solution to be tested add an equal volume of "phenol reagent" (the Folin-Ciocalteu modification is satisfactory) and 3 to 10 ml. of a saturated solution of sodium carbonate. A blue color is given by tyrosine. The reaction has a sensitivity of one part in one million. Tryptophane also gives this reaction.
- 1-Diiodotyrosine and 1-Thyroxin. When tyrosine or a protein containing tyrosine is incubated at 37° with sodium bicarbonate and iodine, both diiodotyrosine and thyroxin are formed.

⁷ See Appendix.

l(-)-Cysteine, C₃H₇O₂NS (β-thiol-α-amino-propionic acid).

$$^{
m NH_2}_{
m C}$$
 $^{
m CC-COOH}_{
m II}$

This amino acid is recognized as being present as such in the intact protein molecule but it is not ordinarily obtained as one of the products of protein hydrolysis unless precautions are taken against oxidation, since

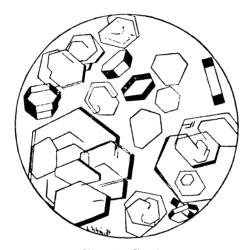

Fig. 48. Cystine.

it is readily converted by oxidation of the —SH group into various sulfinic and sulfonic acids and into cystine. The relation between cysteine and cystine may be illustrated as follows:

$$\begin{array}{ccc}
R-SH & R-S \\
R-SH & R-S \\
2 & Cysteine & Cystine
\end{array}$$

This reversible oxidation-reduction reaction involving the sulfhydryl group (—SH) appears to have considerable physiological significance. Thus it accounts for the oxidation and reduction reactions of glutathione, which contains cysteine (Chapter 12), and it has been suggested that adjacent polypeptide chains in the protein molecule may be linked together through oxidation of cysteine sulfhydryl groups.

Cysteine is usually obtained in the form of its hydrochloride, since the free amino acid, either in the dry state or in neutral or alkaline solution, is readily oxidized. Experiments on cysteine have been grouped with those on cystine.

l(-)-Cystine, $C_6H_{12}O_4N_2S_2$ (di (β -thiol- α -amino-propionic acid)).

Cystine was isolated from a bladder stone by Wollaston in 1810. It is obtained in greatest amount as a product of the hydrolysis of keratin-containing tissue such as horn, hoof, feather, and hair. Cystine crystallizes in characteristic hexagonal plates which are only very slightly soluble in cold water and in alcohol. It dissolves readily in mineral acids or in alkalis but it is insoluble in acetic acid.

EXPERIMENTS ON CYSTINE AND CYSTEINE

Preparation of Cysteine by the Cuprous Oxide Method (after Lucas and Beveridge): Place 300 g. of human hair (barbershop sweepings) in a 2.5-liter flask, and pour in 500 ml. of ether. Boil under a reflux condenser on a water bath for a few minutes to dissolve the oil and fat on the hair. Pour off the ether, and to the hair add 1600 ml. of 9 N HCl. Boil the solution under reflux for 11 hours. Concentrate the solution in vacuo to remove excess HCl, then dissolve the residue in hot water and filter off the humin. Wash the precipitate with dilute HCl. Concentrate the filtrate and washings to a thick syrup. Take up the residue in hot water and again concentrate, this time to dryness. Repeat this process twice more. Dissolve the final residue in 1200 ml. of water.

Grind the amino acid solution with 300 g. of red cuprous oxide in a mortar for 30 minutes. Then slowly add the suspension with stirring to 12 liters of ice water. Cool at 4° C. for 2 hours. Filter the grayish-white cysteine copper mercaptide and wash the precipitate with ice water.

Suspend the mercaptide in water and remove the copper by passing in a stream of H₂S. Filter off the copper sulfide, washing the residue with dilute HCl. Concentrate the filtrate and washings to 500 ml., then decolorize by boiling with 3 g. of charcoal and filtering. Concentrate the filtrate in vacuo under a stream of nitrogen to incipient crystallization. Cool in the refrigerator. An almost solid mass of cysteine hydrochloride should form. Filter off the crystals and wash with cold concentrated HCl.

Preparation of Cystine by Schmidt's Method: Human hair or wool which has been freed from oil by extraction with gasoline is hydrolyzed by heating at 100° C. with twice its weight of concentrated HCl. It requires about 12 hours to effect complete hydrolysis. The mixture must not be heated for any length of time beyond the point at which the bluret test is either negative or feebly positive since cystine is destroyed during the process of hydrolyzing the protein. The greater part of the hydrochloric acid is removed by distilling in vacuo at a temperature between 60° to 70° C. and the original volume of the solution is restored by the addition of water. A thick aqueous suspension of commercial finishing lime is now slowly added, care being taken to avoid any considerable rise in temperature, until the mixture has acquired a chocolate color. It is then filtered by suction through a Buchner funnel and the residue washed a number of times with distilled water. The

filtrate should be clear and possess a light brown color. Hydrochloric acid is now added to partially neutralize the alkaline solution and it is finally acidified by addition of acetic acid. On standing over night in the icebox, sedimentation of the crude cystine takes place. This is filtered off and is dissolved in a minimum quantity of 5 per cent HCI. The solution is decolorized by boiling for several minutes with a small quantity of charcoal which has been previously boiled with HCl to remove the calcium phosphate, and the cystine is precipitated by the addition of sodium acetate to the hot solution until a drop of the solution ceases to turn Congo red paper blue. The mixture is filtered at once and the cystine is washed a number of times with hot water to completely remove the last traces of tyrosine. Typical hexagonal plates of cystine are obtained. (See Fig. 48.)

Tests for Cystine and Cysteine: (a) Sullivan's Tests: Cystine: To 5 ml. of the solution under test (containing not more than 0.04 per cent of cystine in approximately 0.1 N hydrochloric acid, at a temperature of about 25° C.) add 1 or 2 ml. of freshly made 5 per cent aqueous solution of sodium cyanide. Mix and let stand 10 minutes. Then add 1 ml. of a freshly prepared 0.5 per cent solution of 1,2-naphthoquinone-4-sodium sulfonate, sodium sulfite, etc., as given below for cysteine.

Cysteine: To 5 ml. of solution containing not more than 0.04 per cent of cysteine in 0.1 N hydrochloric acid, add 1 ml. of 1 per cent sodium cyanide in 0.8 N sodium hydroxide. Mix and add 1 ml. of a freshly prepared 0.5 per cent aqueous solution of 1,2-naphthoquinone-4-sodium sulfonate. Mix and add 5 ml. of 10 to 20 per cent solution of anhydrous sodium sulfite in 0.5 N sodium hydroxide. Mix and let stand 30 minutes. A reddish-brown color appears. Then add 1 ml. of a 2 per cent solution of sodium hyposulfite (Na₂S₂O₄) in 0.5 N sodium hydroxide. The brown-red color in the presence of cysteine (or cystine treated with sodium cyanide) is converted to a purer red.⁵

(b) Tests for Sulfhydryl (SH) Group: On the addition of a dilute solution of FeCl₁, an indigo-blue color appears and disappears almost immediately. Add a dilute solution of CuSO₄, whereupon a transitory violet color appears. Test 1 or 2 ml. of cysteine solution with a dilute solution of sodium nitroprusside and a drop of NaOII. A deep purple-violet color appears but

gradually fades after a few minutes.

Add a few drops of a 10 per cent aqueous solution of lead acetate to the cystine (or cysteine) solution, then render the solution strongly alkaline with 40 per cent NaOH or KOH. Boil for a few minutes. If cystine or cysteine are present, the solution becomes brown and a black precipitate of PbS appears (lead blackening test).

l(-)-Methionine, $C_bH_{11}O_2NS$ (γ -methylthiot- α -amino-n-butyric acid).

Methionine was first isolated from casein by Mueller, in 1922, and its empirical formula determined in 1923. The structure of methionine was determined by Barger and Coyne in 1928. Methionine is soluble in cold water and alcohol, insoluble in ether. It crystallizes in white hexagonal plates.

The reaction requires a high final pH. In case of hydrolysates of foodstuffs it is necessary to add 1 or 2 ml. of 5 N sodium hydroxide just before adding the final reducing agent, sodium hyposulfite (Na₂S₂O₄). As a rule it is cystine that is found in hydrolysates.

When methionine is treated with concentrated sulfuric acid, the methyl group is split off and the amino acid homocysteine is obtained (Du

Vigneaud). Homocysteine is similar to cysteine in many ways, and its formation and quantitative determination are used for the quantitative determination of methionine. While homocysteine has not as yet been isolated from natural sources, there is good evidence that it is an intermediate in the biological transformation of methionine into cystine (see Chapter 33).

Experiments on Methionine

Methionine can be detected in a mixture of amino acids by the following method (McCarthy and Sullivan): To 5 ml. of unknown, add the following reagents in order and with mixing after each addition: 1 ml. of 5 N NaOH, 1 ml. of 1 per cent glycine, and 0.3 ml. of 10 per cent sodium nitroprusside (freshly prepared). Place the tube in a water bath at 35° to 40° for 5 to 10 minutes, cool in ice water for 2 minutes, and add 2 ml. of 20 per cent HCl. Shake and cool. A reddish-purple color indicates methionine. Tryptophane must be absent.

l(-)-Tryptophane, $C_{11}H_{12}O_2N_2$ (β -3-indole- α -amino-propionic acid).

Tryptophane was discovered by Hopkins and Cole in 1901. Its structure was determined by Ellinger and the inactive compound was synthesized by Ellinger and Flamand from indole aldehyde. The natural levorotatory compound is best prepared by the prolonged action of trypsin on casein (Chapter 16). Tryptophane crystallizes in thin shining rhombic and six-sided plates (Fig. 49). It is almost tasteless. It is quite insoluble in cold water, in cold and hot absolute alcohol, and in cold pyridine, but is quite soluble in hot water and in hot pyridine. The melting point depends to a considerable degree upon the rapidity of heating. By slowly heating it is said to change color slightly at 220°, to turn brown at 240°, and to melt completely at 252°. Tryptophane is yielded by nearly all proteins, but is present in very small amounts in zein of maize, absent from gelatin, and present in maximum amount in blood fibrin.

EXPERIMENTS ON TRYPTOPHANE

Color Reactions for Tryptophane: (a) Hopkins-Cole Test: If a substance containing this amino acid is placed in a test tube, a solution containing a small amount of glyoxylic acid added, and sulfuric acid then stratified on the bottom of the tube, a reddish-violet ring will appear at the juncture of the two liquids. This is also known as the glyoxylic acid test (see p. 155). Pure tryptophane will not give this test except in the presence of a trace of ferric or cupric ions.

(b) Aldehyde Reaction (Voisenet-Rhode): Tryptophane will also give color reactions in the presence of aromatic aldehydes. With p-dimethylamino-benzaldehyde in sulfuric acid it gives a red-violet color. These color reactions are apparently due to the presence of the indole ring in tryptophane.

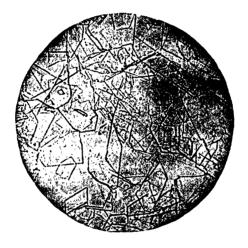

Fig. 49. Tryptophane. (From Keenan: J. Biol. Chem., 62, 163 (1924).)

The indole ring, being a combination of the benzene and pyrrole rings, probably owes its chromogenic properties to the latter ring. For other tryptophane reactions see Chapter 15.

l(-)-Proline, C₅H₉O₂N (pyrrolidine-2-carboxylic acid).

Proline was discovered by Fischer in 1901. It was first obtained from casein but has since been found in most proteins. Sørensen synthesized the compound from α -amino- δ -oxyvaleric acid. Proline is easily soluble in alcohol and in cold water. It has a sweet taste and melts at 153° to 154°.

l(-)-Hydroxyproline, C₅H₉O₃N (4-hydroxy-pyrrolidine-2-carboxylic acid).

Hydroxyproline was discovered by Fischer, in 1902, in the hydrolysate of gelatin. It is very difficult to separate from the other amino acids. It is easily soluble in water and difficultly soluble in absolute alcohol.

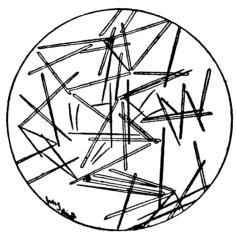

Fig. 50. Proline.

1(-)-Aspartic Acid, C₄H₇O₄N (α-amino-succinic acid).

Aspartic acid was discovered by Plisson in 1827. This amino acid, unlike the others thus far considered, is strongly acidic on account of the predominance of the carboxyl group. The chief source of this acid is the monoamide, asparagine, which is very widely distributed in the vegetable world, being particularly abundant in the asparagus plant and in lentil

sprouts. Aspartic acid crystallizes in rhombic prisms, has a strong acid taste, but is rather insoluble in water (1 part in 256 parts water at 10° and in 18 parts of water at 100°). It is more than likely that the amide (asparagine) rather than aspartic acid occurs in the protein molecule, but is quickly hydrolyzed into aspartic acid and ammonia during the process of protein cleavage.

Fig. 51. Aspartic acid.

l(+)-Glutamic Acid, C₅H₉O₄N (α-amino-glutaric acid).

Glutamic acid was discovered by Ritthausen in 1866. This acid, when obtained after the hydrolysis of the protein molecule, is largely a secondary product. The primary constituent of the protein molecule is undoubtedly glutamine, the amide of glutamic acid, which accounts for the greatest part of the total glutamic acid found after hydrolysis of the protein.

Glutamic acid is present in practically all proteins, usually in fairly large amounts, being present to the extent of 47 per cent in gliadin, a protein found in wheat, and to the extent of 23.3 per cent in casein. The sodium salt of glutamic acid is widely used commercially for flavoring soups, sauces, and food concentrates.

Glutamic acid crystallizes from water in rhombic tetrahedra which melt from 209° to 213°. It possesses two carboxyl groups and but one amino group and is therefore strongly acid toward litmus. The addition of HCl to the acid forms the hydrochloride which is soluble in dilute acid, but relatively insoluble in concentrated HCl. This property is employed in the isolation of glutamic acid.

Fig. 52. Glutamic acid. (Reproduced from a photomicrograph made by Prof. E. T. Reichert, of the University of Pennsylvania.)

Glutamic acid is found combined with glycine and cysteine in the glutathione molecule (Chapter 12). Glutathione has been shown to be a tripeptide, having the following structure:

EXPERIMENTS ON GLUTAMIC ACID

Preparation of Glutamic Acid: In a 500-ml. flask place 100 g. of gluten flour and 300 ml. of concentrated HCl. Heat on a water bath until the gluten has dissolved. Boil under a reflux condenser for 8 hours on a wire gauze. Cool, dilute with an equal volume of water, and filter. Evaporate to about one-fourth the volume in vacuo. Transfer the residue to a 250-ml. Erlenmeyer flask and saturate with HCl gas, then cool, seed, and place in the icebox for

2 to 3 days. By this time crystals of glutamic acid hydrochloride should have formed. Add an equal volume of ice-cold acetone and filter through a sintered glass funnel. Instead of recrystallizing the crystals, wash in the funnel with ice-cold acetone and ether.

In order to prepare the free glutamic acid from the glutamic acid hydrochloride, dissolve the crystals in the least possible amount of hot water, then add normal alkali until the solution no longer gives a blue coloration with Congo red, pH 3.2-3.3. Evaporate the solution to 60 ml. in vacuo at 40°. Allow this solution to remain in the icebox until crystallization is complete. Filter off the crystals, wash with a little cold water, and dry. Determine the melting point of the crystals. Examine microscopically (see Fig. 52).

l(-)-Histidine, C₆H₉O₂N₃ (β-imidazol-α-amino-propionic acid).

Histidine was discovered simultaneously by Hedin and by Kossel in 1896. It is found in small quantities in practically all proteins, but is present to the extent of 8 per cent in hemoglobin. It is soluble in hot

Fig. 53. Histidine dihydrochloride.

water. It is only slightly soluble in alcohol and crystallizes from a saturated alcoholic solution in thin platelets which melt at 250° to 255° C.

Histidine combines with a variety of substances, forming, for example, mono- and dihydrochlorides, also compounds or double salts with platinum chloride or silver nitrate which are particularly valuable for obtaining a pure crystalline compound. It also forms characteristic compounds with picric acid, phosphotungstic acid, nitrobenzoyl chloride, 2,5-dichlorobenzene sulfonic acid, etc.

l(+)-Arginine, $C_6H_{14}O_2N_4$ (δ -guanidino- α -amino-valeric acid).

Arginine was discovered by Schulze and Steiger in 1866. It is present in all proteins. Optically active arginine crystallizes in rosettelike formations. It reacts strongly alkaline, decomposes at 205° to 207°, and is easily soluble in water but almost insoluble in alcohol. It is almost specifically precipitated from dilute acid solution by flavianic acid.

In the presence of the enzyme arginase, found in the liver, arginine is hydrolyzed into urea and the amino acid ornithine $(\alpha, \delta$ -diamino-valeric acid):

This reaction is thought to be of major importance in connection with the formation of urea by the body (see Chapter 33 for a discussion of this and other metabolic relationships of arginine).

EXPERIMENTS ON ARGININE

1. Isolation of Arginine Flavianate (Kossel): Hydrolyze a 25-g. portion of gelatin by boiling with 250 ml. of 18 per cent hydrochloric acid under reflux for 18 hours. Remove the excess acid by repeated concentration in vacuo. Take up the residue in 250 ml. of hot water and decolorize with 5 g. of charcoal. Bring the filtrate to a volume of 250 ml. and add a saturated aqueous solution containing 200 g. of flavianic acid (2,4-dinitro-1-naphthol-7-sulfonic acid) at room temperature. Allow the precipitate to form in the cold for 5 days, stirring from time to time. Filter off the yellow precipitate and wash with a little cold water. Dissolve the washed precipitate in hot water with the aid of a minimal quantity of 4 per cent ammonia. While the solution is still hot add sufficient 20 per cent hydrochloric acid

to neutralize all the ammonia. Arginine flavianate crystallizes in shining yellow plates from the hot solution.

l(+)-Lysine, $C_6H_{14}O_2N_2$ (α - ϵ -diamino-caproic acid).

Lysine was discovered by Drechsel in 1889. It is one of the basic amino acids, possessing a predominance of amino groups over acidic or carboxyl groups. Histidine, arginine, and lysine were at one time called "the hexone bases."

Fig. 54. Lysine picrate.

Lysine is present in most proteins of animal origin. It is notably absent from zein and present in rather small amounts in gliadin. Crystalline lysine was first prepared by Vickery and Leavenworth in 1928.

Citrulline, $C_6H_{12}O_2N_3$ (δ -carbamino- α -amino-valeric acid).

$$\begin{array}{c} \operatorname{NH_2} \\ \operatorname{NH_2-C-NH-CH_2-CH_2-CH_2-C-COOH} \\ \operatorname{O} \end{array}$$

Citrulline was obtained by Wada in 1930 from watermelon juice and its structure established by synthesis; in 1933 the same author isolated citrulline from an enzymatic digest of casein. Little is known concerning its distribution in other proteins. The melting point of citrulline is 220° to 222° C. It is readily soluble in water to give a neutral solution. It forms a difficultly soluble copper salt, a property used in its isolation. Free

citrulline is present in small amounts in liver and in blood. Interest in citrulline at the present time is based largely upon its possible relation to arginine and the processes of urea formation in the animal body (see Chapter 33).

Dispensable and Indispensable Amino Acids. For discussion see Chapter 33.

Proteins: Their Structure and General Reactions

The results of investigations on the hydrolysis of proteins indicate that the protein molecule is composed almost exclusively, if not entirely, of α -amino acids. Investigations of this type, which involve the complete tearing down of the protein molecule, yield the constituent amino acids but throw practically no light on the question as to the order in which these acids are linked together to form the intact protein molecule with its characteristic chemical, physicochemical, colloidal, and biological properties. In spite of this defect these researches are of the highest importance since they yield the actual "building stones" of the protein molecule.

In recent years emphasis has been placed on the study of the physicochemical behavior of the intact protein. The difficulty involved in the formulation of an acceptable theory for the structure of the protein molecule becomes apparent when we list the great number and variety of properties and reactions of proteins that such a theory is called upon to explain. Of these, we may mention especially the following: (1) The hydrolysis of proteins by acids, alkalies, and proteolytic enzymes into their constituent amino acids; (2) the small proportions of free amino and carboxyl groups in the intact molecule; (3) the large increase in both amino and carboxyl groups that accompanies the hydrolysis of the protein; (4) the combinations of proteins with acids, bases, and many other classes of compounds; (5) the large size and colloidal nature of the protein molecule, together with the complex colloidal behavior of protein solutions; (6) the complex solubility relationships of the various classes of proteins; (7) the sensitiveness of proteins to chemical and physical agents such as acids, alkalies, alcohol, heat, mechanical shaking, ultraviolet light, etc.; and (8) the immunological reactions of the proteins. In the following sections the modern conceptions of protein structure will be discussed briefly together with the more important reactions and properties of proteins which make them such vital constituents of living protoplasm.

Structure of Protein Molecule: Peptide Linkage. It was pointed out by Hofmeister, in 1902, that there are three conceivable types of linkage by which individual amino acids might be joined together in the protein molecule.

The first type of linkage involves direct union between carbon atoms:

This type of union is very unlikely since bonds between carbon atoms are

not attacked by proteolytic enzymes which hydrolyze native proteins. It is difficult, also, to understand how a molecule having such a structure could be broken down by hydrolytic agents into such definite structural units as the polypeptides and amino acids.

The second type of linkage that suggests itself is a linkage of carbon atoms by means of an oxygen atom, as in the ethers, esters, and anhydrides:

This type of union is also improbable since, taking into consideration its carboxyl groups, the protein molecule does not contain sufficient oxygen to account for a major linkage of that kind. Moreover, since such a linkage does not involve the amino groups, the latter should be much more abundant in the intact protein molecule than they actually are.

This leaves, as the final possibility, the linkage, of carbon atoms by means of a nitrogen atom:

Of the various possibilities for such a linkage, that resulting from the condensation of the amino group of one acid with the carboxyl group of another, which Fischer named the peptide linkage, is the only one which is in accord with the experimental facts. Fischer devised several ingenious methods for condensing amino acids in this manner and prepared a large number of di-, tri-, and polypeptides, some of them containing as many as 18 molecules of amino acids. Many of the synthetic polypeptides prepared by Fischer, Bergmann, and others are identical with polypeptides isolated from partially hydrolyzed proteins.

According to modern conceptions of protein structure the peptide bond is the predominant bond in the protein molecule. This point of view is based on a great mass of experimental evidence, of which only a brief review may be given here. The structural formula of the tetrapeptide given below indicates clearly that only those amino and carboxyl groups which are at the ends of chains are free. When the molecule contains diamino or dicarboxylic acids, the additional amino or carboxyl groups

cither may remain free or may be the starting points for side chains of various kinds. Analyses of proteins indicate that the number of free amino and carboxyl groups in the intact molecule, determined by Van Slyke's nitrous acid and Sørensen's formol titration methods, are substantially what would be expected of a molecule built up of amino acids joined together by means of peptide linkages. Furthermore, hydrolysis of proteins by acids or enzymes results in the liberation of equal numbers of amino and carboxyl groups, such as would arise during the hydrolysis of peptide bonds. The biuret reaction, which is characteristic of proteins and some of their decomposition products, is given by many of the synthetic polypeptides and disappears when all of these substances are completely hydrolyzed.

Relation of Structure to Properties of Proteins. The generally accepted theory of Hofmeister and Fischer that proteins consist of chains of amino acids joined to each other through their amino and carboxyl groups does not seem to explain by itself the unique chemical, physical, and biological differences among proteins in nature. Why are keratins so resistant to dilute acids and proteolytic enzymes? How does the muscle protein, myosin, function in the contraction of muscle? What is responsible for the immunological specificity of proteins, for the enzyme action of catalase and pepsin, for the toxicity of tobacco mosaic virus, and so forth? The hypotheses which are mentioned briefly below are attempts to answer some of these questions.

- A. Protamine Nucleus Hypothesis of Kossel and Siegfried. These investigators believed all proteins were built around a nucleus of the three amino acids arginine, histidine, and lysine, and that arginine was the most important member of this triad. Block has shown that one group of proteins, eukeratins, can be characterized by the relative constancy of the ratios of arginine to lysine to histidine. The location of these three amino acids or their mode of action in the formation of the eukeratins remains unknown. It should also be pointed out that no protein devoid of arginine has as yet been reported.
- B. DIKETOPIPERAZINE HYPOTHESIS OF ABBERHALDEN. Amino acid anhydrides (diketopiperazines, see p. 117) can be obtained from proteins under certain conditions. These compounds are readily formed by condensation of two amino acids or by cyclizing a dipeptide. Abderhalden suggested that proteins are composed of diketopiperazine-containing units which are held together by secondary valences. This structure was intended to account for certain properties of proteins, especially the hydrolysis to peptones by pepsin. Unfortunately for this theory, amino acid anhydrides are not hydrolyzed by proteolytic enzymes.
- C. Periodicity of Amino Acids in Peptide Chains (Bergmann). The observations on protamines of Kossel and others that amino acids appear to repeat themselves periodically in the peptide chain were extended by Bergmann and Niemann to all proteins. They said: "In every protein each amino acid residue is distributed throughout the entire peptide chain at constant intervals, i.e., each amino acid residue recurs with a characteristic whole number frequency." They believed that pro-

teins were composed of 288 amino acid residues or some simple multiple thereof. The evidence in favor of this interesting hypothesis is not adequate and it has been severely criticized by Neuberger, Bull, and others.

D. STEREOCHEMICAL ORGANIZATION OF THE PROTEIN MOLECULE (FOA, MEYER AND MARK, ASTBURY, NEURATH, WRINCH). The use of the x-ray to study the fine structure of proteins, especially in the hands of W. T. Astbury, has given us a much clearer insight into the organization of the peptide chains in the protein molecule. A short section of such a chain in the fully extended position is shown in Figs. 55 and 56. In general these peptide chains are pictured as either fully extended (silk

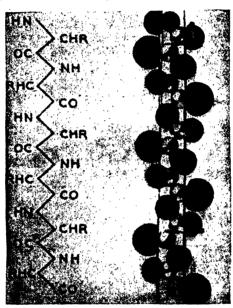

Fig. 55. Scaled model of a fully extended polypeptide chain, viewed from above. (Neurath: J. Phys. Chem., 44, 297 (1940).)

fibroin, or other denatured, mechanically elongated fibrous proteins) or folded chains of (native) insoluble fibrous and soluble globular proteins. In certain cases, such as hair and wool, the long axis of the peptide chain is parallel to the long axis of the fiber, and the strength, elasticity, and resistance to enzymatic hydrolysis can be definitely correlated to this structure. Thus hair keratin can be pictured as consisting of bundles of partially folded peptide chains which are cross-linked to each other through the —S—S— bonds of cystine. The tensile strength of hair is thus explained by the large number of similar peptide chains in parallel; the elasticity by the folding and unfolding of the chains; and the resistance to enzymes by the close packing of the parallel chains which are held together by the disulfide bonds of cystine.

The structure of the soluble proteins, especially those whose molecules

are essentially oval or globular in shape, is still largely unexplained, although the speculations of Wrinch and others concerning cagelike, spiral, or multiple discoid structures may be the clues to their ultimate solution. The closely knit structure of these highly organized soluble globular proteins is broken down by denaturing agents such as strong sodium hydroxide. The peptide chains then become a mass of disorganized fibrils in solution. If this alkaline protein solution is passed through a small capillary, these fibrils orient themselves with their long axes parallel to the direction of flow. If the alkaline solution is then extruded through a small orifice into an acid or other coagulating bath, the protein fibrils unite with each other parallel to their long axes and a typical macroscopic

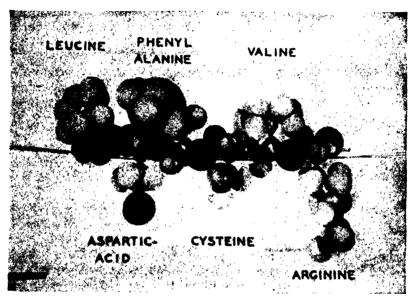

Fig. 56. Scaled model of a hypothetical fully extended polypeptide chain viewed from the side. (Neurath: J. Phys. Chem., 44, 299 (1940).)

thread is formed. This is the essence of the production of synthetic fiber, "wool," etc., from soluble globular proteins such as casein and soybean.

From this presentation it is apparent that the solution to the problems of protein structure and function has not yet been found, but that the Hofmeister-Fischer peptide theory, coupled with the known electrical and chemical properties of the peptide linkage (—NH—CO—CHR—) and of the specific side chains of the amino acids, offers a reasonable basis to account for many of the properties of natural and of isolated proteins.

Proteolytic Enzymes. The most convincing evidence that the peptide linkage is the principal one in the protein molecule comes from the fact that enzymes are able to hydrolyze synthetic polypeptides of known structure, liberating equal amounts of amino and carboxyl groups, just as they do when acting on native proteins. Our recent knowledge on the structural specificity of enzymes is due in large part to the brilliant

researches of Bergmann, Fruton, and their co-workers. The table given below illustrates the specificity of enzymes according to Bergmann.

ACTION OF PROTEOLYTIC ENZYMES (BERGMANN)

Enzyme	Requisite Peptide Chain	Requisite Amino Acid in Peptide Chain Tyrosine		
Pepsin	R —CONH—CH—CONH— HOH			
Cathepsin I	-CONH-CH-COOH + H ₂ N-	Phenylalanine		
Trypsin Cathepsin II Papain H ₂ S	Same as above except for R group	Lysine Arginine		
Leucylpeptidase	R			
Cathepsin III	H ₂ N-CH-CO NH- HO H R H ₂ N-CH-COOH + H ₂ N-	Leucine		
Carboxypeptidase	R —CO NH—CH—СООН НО Н	Tyrosine		
Cathepsin IV	-COOH + H ₂ N-CH-COOH	Phenylalanine		

Up to the time of these investigations it was believed that the size and not the amino acid composition of the protein or polypeptide was the controlling factor in enzymatic breakdown. Thus pepsin was thought to act on proteins of high molecular weight such as fibrin, casein, etc., but not on the smaller protamines, while trypsin split the smaller molecules such as the protamines and erepsin hydrolyzed peptides of still lower molecular weight. It is now evident that pepsin fails to hydrolyze protamines not because of their molecular size but because these proteins are deficient in tyrosine and phenylalanine, while the ample supply of arginine and lysine in protamines permits the action of trypsin. Likewise a mixture of polypeptides containing a relatively high proportion of free carboxyl groups would be split by carboxypeptidases (erepsin?) such as the "aromatic" carboxypeptidase shown in the table above. In each case, the ratio of carboxyl to amino groups liberated is unity.

Molecular Weights of Proteins. Many of the properties of protein solutions, especially those connected with their colloidal behavior, are intimately related to the size and molecular weight of the protein. The determination of the molecular weights of the proteins involves many difficulties due to the complex solubilities of the proteins and the colloidal nature of their solutions. Thus, for example, the ordinary physicochemical methods such as the raising of the boiling point or lowering of the freezing point are either inapplicable or yield misleading results when applied to proteins because of the effects of traces of salts and other impurities on determinations made by those methods. However, the minimal molecular weight can be obtained from chemical, especially amino acid, analyses. By assuming that the protein molecule contains one atom of an element or one molecule of the amino acid present in least amount, the minimal molecular weight may be calculated from the following relationship:

Minimal molecular weight of protein

On the other hand the relatively large particle size of most proteins has permitted the development of methods for estimating their size and molecular weight which could not be used for the average organic compound. These are:

- 1. Molecular weight from osmotic pressure (Sørensen, Roche, Adair, Greenberg, et al.)
- 2. Molecular weight from sedimentation equilibrium and from sedimentation rate and diffusion (Svedberg, Peterson).
- 3. Molecular weight from diffusion and viscosity (Northrop and Anson, Neurath, et al.).
- 4. Molecular size and shape from dielectric constant dispersion curves (Williams, Oncley).
 - 5. Molecular size from x-ray data (Crowfoot, Fankuchen).

The osmotic pressure method yields the mean molecular weight when carried out under suitable experimental conditions. This procedure, which can be carried out with ordinary laboratory equipment, suffers from the disadvantages that it gives no indication of homogeneity of the substance investigated and that it becomes increasingly insensitive with increasing molecular weights.

Every molecule in solution is subject to thermal forces which result in diffusion of the substance away from a center of high concentration toward one of lower concentration. In addition to these thermal forces the molecule is subject to gravitational forces which tend to cause the molecules to sediment. It is thus apparent that whether a substance will remain in solution or not is dependent upon the relative strengths of the gravitational (settling) and thermal diffusion forces. By increasing the speeds attainable in the ordinary laboratory centrifuge, Svedberg, Beams,

and others have constructed very high speed centrifuges (ultracentrifuges) which are able either just to balance the diffusion forces of a protein molecule in solution (sedimentation equilibrium) or actually overcome these thermal forces and cause the protein to sediment at a definite rate (sedimentation velocity).

If the concentration, diffusion constant, and approximate shape of the protein are known, the molecular weight or particle size of the protein or other colloid can be calculated either from sedimentation equilibrium or sedimentation velocity data. One significant contribution of this method is that it is capable of separating particles of different sizes and weights and thus indicating whether the protein under investigation

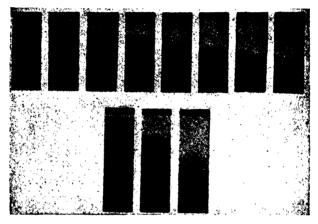

Fig. 57. Sedimentation in the ultracentrifuge of a monodisperse sol (hemocyanin) and a polydisperse sol (gold). (From Svedberg: "Colloid Chemistry," Reinhold Pub. Co., New York, 2d ed., 1928.)

is mono- or polydisperse. Many proteins which were previously considered to be monodisperse are now known to be mixtures of products varying widely in particle size. It should be recalled, however, that protein particles of the same size (monodisperse) may differ in amino acid composition, thus making the protein a mixture; on the other hand protein particles of different sizes (polydisperse) may have the same amino acid composition and thus be chemically pure. Analogies exist in organic chemistry; thus leucine admixed with a little isoleucine would be monodisperse, although impure; whereas acetic acid dissolved in benzene would be both monomeric and dimeric acetic acid (polydisperse) and yet be all the same compound.

Molecular weights of proteins have been calculated from diffusion and viscosity data. Both diffusion and viscosity are functions of the size, shape, and degree of hydration of the molecule.

Proteins, among other substances, can be oriented in an electric field. If the direction of the field is reversed the molecule will reorient in the opposite direction. As the rate of change of direction of the current is

increased (i.e., increasing frequency), more and more of the molecules fail to orient properly and the electrical properties of the solution change. The changes in the dielectric properties of a protein solution are also dependent upon the size, shape, and viscosity of the molecule as well as the alternating frequency. Such data have been used to calculate the molecular weight of some proteins.

The final method mentioned above for the estimation of molecular size is based upon the fact that a single protein crystal, when placed in the beam of an x-ray, will cause the beam to be somewhat deflected. From this, the dimensions for a "unit cell" are thus obtained and from the density of the protein its mass is computed. The molecular weight is calculated by dividing this mass by that of the hydrogen atom (1.66 \times 10^{-24}). The results indicate the molecular weight of the protein or some multiple thereof.

MOLECULAR WEIGHT* OF PROTEINS

	Method						
Protein	CHEM- ICAL	Ultracen- trifuge	Osmotic Pressure	Diffu-	Viscos-	X-ray	
Lactalbumin		17,400 15,600 16,900					
Gliadin		27,500 27,500	40,000	27,500			
Zein		40,000 42,000 30,000					
Insulin	35,000	35,000 37,000	36,000			37,000 53,000	
Ovalbumin \(\beta \text{-Lactoglobulin} \) Serum albumin		67,000	74,000	44,000 40,000 67,000	40,000 70,000	83,000

Tobacco mosaic virus		60,000,000					

^{*} Many values are averages from the literature.

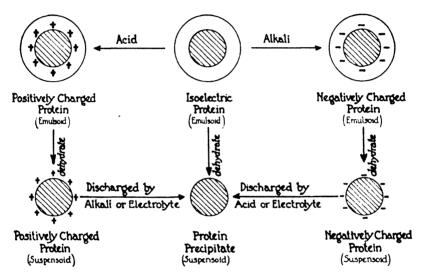

Nature of Protein Solutions. Studies of the behavior of the serum globulins led Sørensen, some years ago, to conclude that euglobulin and pseudoglobulin were reversibly combined in a loose chemical combination, $E_p P_q$, in which E and P represent euglobulin and pseudoglobulin complexes, respectively, combined in the relative proportions of p and q. Subjecting serum to such procedures as dialysis, or fractionation with

ammonium sulfate, results in a shifting of the proportions of E and P with the resultant formation of more soluble and less soluble complexes of the two proteins. Sørensen failed, even after repeated fractionations, to prepare samples of either euglobulin or pseudoglobulin that were completely free from the other protein. These results with the globulins led to a series of investigations of other proteins with the result that highly purified preparations of serum albumin, casein, and gliadin were each found to consist of mixtures of an unknown number of proteins of similar character combined in a reversible manner. Such proteins, according to Sørensen, represent "reversibly dissociable component systems" and may be represented by the formula A_xB_yC_x . . . , in which A, B, C, etc., represent components of a definite character and composition (e.g., polypeptides) while x, y, z, etc., indicate the number of such components in the more complex system. In each component, the atoms or groups of atoms, such as amino acids, are linked together by means of strong chemical bonds, whereas the complexes are formed by the union of these components through weak, residual valences. Chemical or physical agents that act on the chemical bonds produce irreversible changes in the protein molecule whereas the residual valences respond to changes in salt concentration, pH, or temperature in a reversible manner. Although the various fractions obtained by the fractionation methods employed possess the essential properties of the initial material, they exhibit variations in physical properties and chemical composition that are considered as being due to the varying amounts of the individual components in each fraction. In no case has Sørensen succeeded in isolating a component which could not be further fractionated by appropriate methods.

Applying these conceptions to biological systems, we find that not only may comparatively simple components combine with each other, by means of their residual valences, to form protein complexes, but these complexes may themselves combine to form still more complicated structures. In serum, for example, we probably have not only such component systems as albumins and globulins, which may be isolated by suitable methods, but also more complex systems in which these proteins are combined in varying proportions not only with each other but with other serum constituents, such as the lipids. In protoplasm, instead of relatively inert, independent substances, there are probably complex systems composed of protein, lipid, and carbohydrate in equilibrium with each other (orosins) and constantly shifting in response to changes in environment. The multiplicity and flexibility of such systems may be of profound importance in determining the adaptability of the organism to its environment.

If we accept Sørensen's views on proteins, we can understand the extraordinary difficulties encountered in the isolation of individual proteins from such complex materials as serum and egg white, and can explain results obtained in Svedberg's laboratory on these substances. Svedberg found, for example, that there was no substance in fresh egg white with a molecular weight corresponding to that of the crystallized ovalbumin, but that this substance appeared only after the egg white was treated with

ammonium sulfate, as in the crystallization method employed. Similarly, Svedberg found that half saturation of serum with ammonium sulfate precipitated a globulin fraction which was homogeneous and had a definite molecular weight, and that the euglobulin and pseudoglobulin appeared only after this substance was subjected to further fractionation processes. It thus appears that the proteins with which we are familiar exist in nature only as part of more complex systems, and that even these purified proteins may themselves be complexes formed by the union of several simpler components. The problem of determining the structure and properties of the protein molecule thus depends upon the development of suitable methods for the isolation, in pure form, of the comparatively simple components.

Frg. 58. Colloidal behavior of protein solutions.

Colloidal Behavior of Protein Solutions. The proteins form colloidal solutions of the type known as emulsoids, or hydrophilic colloids. One of the most characteristic properties of emulsoids, as pointed out in Chapter 1, is that such systems have two stability factors, charge and hydration, either of which is capable of keeping the particle in solution. Individual proteins show marked differences in the hydration of their particles. Most proteins are soluble in dilute acids and alkalies, the particles acquiring positive or negative charges depending upon the pH of the solution. For every protein, there is a definite characteristic pII, known as the isoelectric point, at which the particles are electrically neutral and cease to migrate to the poles of an electrical field. Although all proteins are least soluble at their isoelectric points, certain proteins such as gelatin or ovalbumin remain in solution when brought to their respective isoelectric points. On the other hand, less soluble proteins such as casein and edestin remain in solution only at acid or alkaline reaction and precipitate when their solutions are brought to the isoelectric point. Ovalbumin thus behaves as a typical emulsoid, forming stable solutions of neutral particles, while casein acts more like a suspensoid, the particles of which flocculate when their charges are neutralized. The effect of hydration and charge on the colloidal properties and stability of protein solutions is illustrated in Fig. 58, adapted from Kruyt.

The determination of the true nature of protein solutions is complicated by the fact that the proteins are unique colloids, since in addition to their typically colloidal properties they function as amphoteric electrolytes because of the free amino and carboxyl groups which their molecules contain. A great deal of confusion existed as to whether the reactions of proteins with acids and bases are chemical reactions, taking place in stoichiometric proportions, or colloidal reactions following various laws of adsorption. Much of this confusion is probably due to differences in the nature of the particles present in different protein solutions. The work of Pauli, of Sørensen and of Loeb, and more especially the fine work of Syedberg, discussed above, indicates that in solutions of such proteins as ovalbumin, hemoglobin, and edestin, the material is dispersed in the form of individual molecules of protein and not as molecular aggregates. Such proteins therefore form molecular solutions whose colloidal properties are due entirely to the comparatively large size of the individual molecules. Solutions of other proteins, such as gelatin and casein, probably contain molecular aggregates as well as individual molecules. This point of view is supported by the growing mass of evidence obtained from ultracentrifugal and ultrafiltration experiments as well as from numerous studies on the physicochemical properties of protein solutions.

Behavior of Proteins as Amphoteric Electrolytes: Isoelectric Points of Proteins. It is currently believed that proteins behave as molecular solutions of amphoteric electrolytes which exhibit typical colloidal properties because of the large size of the individual molecules. These large molecules contain reactive amino and carboxyl groups which are capable of entering into true chemical combination with acids and bases. In choosing between the chemical and colloidal interpretations of protein reactions, it is well to consider, as pointed out by Svedberg, that colloidal and chemical forces are fundamentally the same, since both are electrical in character and depend upon the attraction and repulsion of negative electrons and positive nuclei. It is quite probable that different proteins vary in their reactions because of the fact that solutions of certain proteins undoubtedly contain individual molecules, while others contain molecular aggregates of various sizes. In the present state of our knowledge of protein chemistry we may assume that the proteins exhibit both chemical and colloidal properties, the former being due to the presence of reactive groups in the protein molecule and the latter being dependent upon changes in the charge and hydration of the particles in solution. whether molecules or molecular aggregates.

Considered as amphoteric electrolytes, the proteins combine with acids and bases to form salts which ionize into a colloidal protein ion and one or more crystalloidal ions. According to the work of Loeb, Sørensen, Pauli. Michaelis, Cannan, and their co-workers, this combination takes place in

definite proportions in accordance with the laws of classical chemistry. A protein at its isoelectric point is either entirely without charge—i.e., completely un-ionized—or else, according to the zwitter-ion hypothesis of Bjerrum, carries equal numbers of positive and negative charges due to complete dissociation of equal numbers of acid and basic groups in the molecule. Isoelectric protein may thus be represented by the following

Isoelectric Protein

formulas, in which R stands for the nucleus of the protein molecule. The addition of acid to isoelectric protein results in the formation of a protein salt (e.g., protein chloride) which ionizes into a positive protein ion and a

COOH COOH
$$R + HCl \rightarrow R \rightleftharpoons \begin{bmatrix} COOH \\ R \end{bmatrix} + Cl$$

$$NH_{2} \qquad NH_{2} \qquad NII_{3}$$

negative acid ion. In the same way the addition of alkali to isoelectric protein results in the formation of a salt which ionizes into a positive

COOH COONa
$$\rightarrow$$
 R \rightarrow R \rightarrow R \rightarrow R \rightarrow R \rightarrow NH₂ \rightarrow NH₂ \rightarrow NH₂ \rightarrow NH₂ \rightarrow NH₂

metal ion and a negative protein ion. In solutions acid to their isoelectric points, therefore, the proteins exist as positively charged ions, capable of combining with negative ions to form salts, while in solutions alkaline to their isoelectric points proteins exist as negatively charged ions which can combine only with positive ions. Loeb added solutions of silver nitrate and potassium ferrocyanide to powdered gelatin which had been previously brought to various hydrogen-ion concentrations by soaking in appropriate solutions of acid and alkali. He showed that gelatin combines with silver only when the solutions are on the alkaline side of its isoelectric point (pH > 4.7), and with ferrocyanide only on the acid side of its isoelectric point (pH < 4.7). At the isoelectric point gelatin behaves as though it were un-ionized, since it does not combine with either positive (cations) or negative (anions) ions.

¹ The above reactions make use of the older formula for isoelectric protein. The same products are formed according to the switter-ion hypothesis, the only difference being in the mechanism involved. (See section on amino acids, Chapter 4.)

The isoelectric points of the proteins are of especial significance in protein chemistry, because the properties of the proteins undergo unique changes at these points. It has already been pointed out that proteins are ionized and can enter into chemical combination only in solutions which are acid or alkaline with respect to their isoelectric points. The solubility of the proteins, especially those proteins which resemble the suspensoids in their colloidal behavior, is either negligible or at a minimum at the isoelectric points. Other physical properties of the proteins such as viscosity, osmotic pressure, swelling, etc., are also at a minimum at the isoelectric points. According to Loeb these properties are dependent upon a Donnan equilibrium set up between the particles and the surrounding dispersion medium. The isoelectric points of a number of the more common proteins are given in the following table.

ISOELECTRIC POINTS OF SOME COMMON PROTEINS

Protein	pII				
Ovalbumin Edestin Serum albumin Serum globulins Gelatin Casein Hemoglobin Gliadin Protamines Silk fibroin Myosin Pepsin (swine) \$\beta\$-Lactoglobulin Insulin	4.84- 4.90 5.5- 6.0 4.88 5- 7 4.80- 4.85 4.6 6.7- 6.8 6.5 12.0- 12.4 2.0- 2.4 5.4 <1.0 5.2 5.30- 5.35				

GENERAL REACTIONS OF PROTEINS

The proteins are characterized by the fact that they contain nitrogen, in addition to carbon, hydrogen, and oxygen, by the colloidal nature of their solutions, and by a series of color and precipitation reactions. In the following sections the technic and interpretation of these reactions will be discussed.

A. COMPOSITION TESTS

Since the proteins always contain nitrogen, a positive test for this element indicates the possibility that the material under examination is a protein. A negative test for nitrogen definitely eliminates the possibility of protein.

1. General Composition Test: Heat some powdered egg albumin in a dry test tube in which is suspended a strip of moistened red litmus paper and across the mouth of which is placed a piece of filter paper moistened with lead acetate solution. As the powder is heated it chars, indicating the

presence of carbon; the fumes of ammonia are evolved, turning the red litmus paper blue and indicating the presence of nitrogen and hydrogen; the lead acetate paper is blackened, indicating the presence of sulfur, and the deposition of moisture on the side of the tube indicates the presence of hydrogen. (Moisture indicates hydrogen only in case both the powder and the test tube are absolutely dry.)

2. Test for Organic Nitrogen—Lassaigne Test: Support a clean, dry test tube in a vertical position by means of a clamp placed near the open end. Drop in a small piece of freshly cut sodium (about a 3-mm. cube) which has been wiped free from oil with a piece of filter paper. Heat the bottom of the tube until a layer of sodium vapor about 1 cm. thick is formed. Drop a small amount of the material to be tested (enough to cover the end of a pen knife or small spatula) directly on top of the hot sodium, avoiding contact with the upper wall of the tube. Heat strongly until most of the sodium has vaporized or until thick fumes cease to come off. When cool add a few milliliters of distilled water. Heat the contents to boiling and filter. If the fusion with sodium has been carried out satisfactorily, the filtrate will be colorless. Otherwise it should be rejected and the fusion repeated.

Boil 2 ml. of the clear, colorless filtrate for about a minute with a few drops of 10 per cent sodium hydroxide and 1 or 2 (no more) drops of a freshly prepared, saturated solution of ferrous sulfate. Cool, add dilute HCl, drop by drop, until the solution becomes acid and the precipitate of ferrous hydroxide dissolves. The formation of a precipitate of prussian blue (ferric ferrocyanide) or of a blue or green color in the solution indicates the presence of organic nitrogen in the original material. If the solution remains colorless add a drop or two of ferric chloride solution. If nitrogen is present the solution will turn blue or green and a blue precipitate will usually form on standing.

The fusion of an organic compound containing nitrogen with sodium results in the formation of sodium cyanide. This, when heated with ferrous sulfate, in alkaline solution, forms sodium ferrocyanide. The sodium ferrocyanide reacts with the ferric ion usually present, or with the added ferric ion, to form the blue ferric ferrocyanide. An excess of acid is to be avoided since the formation of the ferric ferrocyanide is much more delicate in the presence of only a slight excess of acid. The reactions involved are as follows:

$$\begin{array}{c} Na+C+N=NaCN\\ 2NaCN+Fe(OH)_2=Fe(CN)_2+2NaOH\\ 4NaCN+Fe(CN)_2=Na_4Fe(CN)_6\\ 3Na_4Fe(CN)_6+4FeCl_3=Fe_4[Fe(CN)_6]_3+12NaCl \end{array}$$

An excess of ferrous sulfate must be avoided since, as these equations show, this would tend to stop the reaction at the $Fe(CN)_2$ stage and thus prevent the formation of the characteristic blue ferrocyanide.

- 3. Tests for Sulfur: A. Tests for Cystine and Cysteine Sulfur: (a) To equal volumes of KOH and egg albumin solutions in a test tube add 1 to 2 drops of lead acetate solution and boil the mixture. Cystine or cysteine sulfur is indicated by a darkening of the solution, the color deepening into a black if sufficient sulfur is present. Add hydrochloric acid and note the characteristic odor evolved from the solution. Write the reactions for this test. (b) Place equal volumes of KOH and egg albumin solutions in a test tube and boil the mixture vigorously. Cool, make acid with glacial acetic acid, and add 1 to 2 drops of lead acetate. A darkening indicates the presence of cysteine or cystine sulfur.
 - B. Test for Total Sulfur: (Cystine, Cysteine, and Methionine): Place the substance to be examined (powdered egg albumin) in a small porcelain crucible, add a suitable amount of solid fusion mixture (sodium carbonate

and potassium nitrate mixed in the proportion 2:1), and heat carefully until a colorless mixture results. (Sodium peroxide may be used in place of this fusion mixture if desired.) Cool, dissolve the cake in a little warm water, and filter. Acidify the filtrate with hydrochloric acid, heat it to the boiling point, and add a small amount of barium chloride solution. A white precipitate forms if sulfur is present. What is this precipitate?

As mentioned in the preceding chapter, sulfur is present in proteins as cystine, cysteine, or methionine. Cystine and cysteine sulfur was formerly termed unoxidized, loosely combined, mercaptan, or lead-blackening sulfur, while methionine sulfur because of its greater stability toward alkaline lead acetate was called oxidized or acid sulfur. These terms are generally misleading and, in the case of the term "oxidized," incorrect. The majority of proteins contain more methionine S than cystine + cysteine S. Exceptions are keratins, insulin, and certain serum albumins which contain all or almost all their sulfur in the form of cystine and cysteine. Silk fibroin and many protamines are devoid of sulfur.

B. COLOR REACTIONS OF PROTEINS

These color reactions are due to a reaction between some one or more of the constituent radicals or groups of the complex protein molecule and the chemical reagent or reagents used in any given test. Not all proteins contain the same amino acids and for this reason the various color tests will yield reactions varying in intensity of color according to the nature and amount of the groups contained in the particular protein under examination. Various substances not proteins respond to certain of these color reactions, and it is therefore essential to submit the material under examination to several tests before concluding definitely regarding its nature.

1. Millon's Reaction: To 5 ml. of a dilute solution of egg albumin² in a test tube, add 3 to 4 drops of Millon's reagent.³ Mix and bring the mixture gradually to the boiling point by heating over a small flame. Proteins like egg albumin, which are precipitated by strong mineral acids, yield a white precipitate which gradually turns red upon heating, whereas other proteins, like the secondary proteoses and peptones, yield only a red solution under the same conditions. If no color develops, add 2 to 3 more drops of the reagent and heat again. An excess of the reagent is however to be avoided since it may produce a yellow color which is not a positive reaction. Repeat the test, using a 0.1 per cent solution of phenol instead of the protein, and note the red color produced upon heating.

This test is a particularly satisfactory one for use on solid proteins. In this case, dilute some of the reagent with 3 to 4 volumes of distilled water, add the solid, and heat gently as above. The particles of undissolved protein will gradually turn red; if any of the protein dissolves the solution will also assume a red color.

² This egg albumin solution may be prepared by beating egg white with 6 to 10 volumes of water. The material is strained through cheesecloth to remove the precipitate of ovo-mucin formed, and then filtered through filter paper and the filtrate used in the tests. A 1 per cent solution may also be prepared from powdered or scale egg albumin by soaking the material in a small quantity of water (sufficient to thoroughly moisten it) for several hours, then diluting to volume, stirring until dissolved, and filtering.

⁸ See Appendix.

The reaction is due to the presence of the hydroxyphenyl group, —C₆H₄OH, in the protein molecule and any phenolic compound which is unsubstituted in the 3,5 position such as tyrosine, phenol (carbolic acid), and thymol will give the reaction. Inasmuch as the tyrosine grouping is the only hydroxyphenyl grouping which definitely has been proved to be present in the protein molecule, it is evident that proteins respond to Millon's reaction because of the presence of this amino acid. The test is not a very satisfactory one for use in solutions containing inorganic salts in large amount, since the mercury of the Millon's reagent is thus precipitated and the reagent rendered inert. This reagent is therefore never used for the detection of protein material in the urine. If the solution under examination is strongly alkaline it should be neutralized inasmuch as the alkali will precipitate yellow or black oxides of mercury.

 Millon-Nasse Reaction: This is an adaptation of the Millon test and can be used in the presence of considerable quantities of inorganic salts, especially NaCl.

To 5 ml. of a dilute solution of protein in a test tube, add 1 ml. of a 15 per cent solution of mercuric sulfate in 6 N sulfuric acid. Place the tube in a boiling water bath for 10 minutes, cool the contents in water for 5 to 10 minutes, and add 1 ml. of 1 per cent NaNO₂. A deep red color indicates tyrosine or other 3,5 unsubstituted phenol.

3. Xanthoproteic Reaction: To 2 to 3 ml. of egg albumin solution in a test tube add 1 ml. of concentrated nitric acid. A white precipitate forms, which upon heating turns yellow and finally dissolves, imparting to the solution a yellow color. Cool the solution and carefully add ammonium hydroxide or sodium hydroxide in excess. Note that the yellow color deepens into an orange. Repeat the test using a 0.1 per cent phenol solution instead of the protein, and note the production of the yellow and, later, the orange color.

This reaction is due to the presence in the protein molecule of the phenyl group, $-C_6H_5$, with which the nitric acid forms certain nitro modifications. The particular complexes of the protein molecule which are of especial importance in this connection are those of tyrosine and tryptophane. Phenylalanine does not respond to this test as it is ordinarily performed. The test is not a satisfactory one for use in urinary examination because of the color of the end reaction.

4. Glyoxylic Acid Reaction (Hopkins-Cole): Place 2 to 3 ml. of egg albumin solution and an equal volume of glyoxylic acid (CHO·COOH + H₂O or CH(OH)₂COOH) solution (Hopkins-Cole reagent⁴) in a test tube and mix thoroughly. Incline the tube and permit 5 to 6 ml. of concentrated sulfuric acid to flow slowly down the side of the tube, thus forming a sharp layer of acid beneath the protein mixture. When stratified in this manner a reddish-violet color forms at the zone of contact of the two fluids. If the color does not appear after standing for a few minutes, the tube may be rocked gently to cause a slight mixing of the liquids at the interface. If the two liquids are mixed by gentle stirring the precipitate of protein dissolves and the violet color spreads throughout the solution.

In performing the test on a solid substance employ the modification described on p. 173.

See Appendix.

This color is due to the presence of the tryptophane group (see p. 131). Gelatin does not respond to this test. Nitrates (NaNO₃ and KNO₃), chlorates, nitrites, or excess of chlorides prevent the reaction, but a trace of copper sulfate will increase its sensitivity. The sulfuric acid used must be pure.

5. Biuret Test: To 2 to 3 ml. of egg albumin solution in a test tube add an equal volume of 10 per cent sodium hydroxide solution, mix thoroughly, and add a 0.5 per cent copper sulfate solution drop by drop, mixing between drops, until a purplish-violet or pinkish-violet color is produced. (If too much copper sulfate is added the violet color may be obscured by the blue precipitate of copper hydroxide formed.) The color depends upon the nature of the protein; proteoses and peptones giving a decided pink, while the color produced with gelatin is not far removed from a blue.

Repeat the bluret test on some bluret, formed from urea as follows: Place about one-eighth inch of urea in a clean dry test tube and heat gently over a small flame. The urea melts, then effervesces, and the bluret formed appears as a white solid in the bottom of the tube. Note the odor of the gas given off during the heating. Allow the tube to cool, dissolve the bluret in 3 to 4 ml. of 10 per cent sodium hydroxide, and add 0.5 per cent copper sulfate solution, drop by drop, until the pink color appears.

The biuret test may also be carried out with a stable biuret reagent, prepared by adding 1 per cent copper sulfate solution, drop by drop, with constant stirring, to some 40 per cent sodium hydroxide solution until the mixture assumes a deep blue color. This reagent may be used in either of two ways. It may be added directly to the protein solution, a drop at a time, with mixing, until the solution assumes a violet color, or two or three drops of the reagent may be permitted to flow down the side of the inclined tube. In this case the reagent forms a layer beneath the protein solution and the violet color appears at the interface between the two liquids.

The biuret test is given by those substances whose molecules contain two carbamyl (—CONH₂) groups joined either directly together or through a single atom of nitrogen or carbon. Similar substances which contain, in place of the —CONH₂ group, —CSNH₂, —C(NH)NH₂, or —CH₂NH₂ also respond to the test. It follows from this fact that substances which are nonprotein in character but which contain the necessary groups will respond to the biuret test. As examples of such substances the following may be cited:

The test derives its name from the fact that biuret, which is formed on heating urea to 180° C., responds to the test. Proteins respond positively since there are pairs of CONH groups in the molecule.

According to Schiff the end reaction of the biuret test is dependent upon the formation of a copper-potassium-biuret compound (cupripotassium biuret or biuret potassium cupric hydroxide). This substance was

obtained by Schiff in the form of long red needles. It has the following formula:

If much magnesium sulfate is present a precipitate of magnesium hydroxide forms which interferes with the test. If much ammonium sulfate is present a large excess of alkali must be used.

6. The Triketohydrindene Hydrate (Ninhydrin) Reaction: To 5 ml. of dilute protein solution, which must be approximately neutral in reaction, add 0.5 ml. of a 0.1 per cent solution of triketohydrindene hydrate, heat to boiling for one to two minutes, and allow to cool. A blue color develops if the test is positive.

This test gives positive results with proteins, peptones, peptides, and amino acids which possess a free carboxyl and α -amino group. In a concentration of 1 per cent the ammonium salts of weak acids react positively, as do also the ammonium salts of strong acids in very high concentration. Certain amines also give the reaction. For further discussion see p. 116.

C. PRECIPITATION REACTIONS OF PROTEINS

The proteins are precipitated from solution by salts of the heavy metals (e.g., HgCl₂, AgNO₃, CuSO₄, Pb(C₂H₃O₂)₂, etc.), by certain acids some of which are called "alkaloidal reagents" (picric acid, phosphotungstic acid, tannic acid, metaphosphoric acid, etc.), by concentrated solutions of such salts as ammonium sulfate, sodium sulfate, and sodium chloride, and by ethyl and methyl alcohol. Although these reactions have been used for many years for the separation and characterization of proteins, there is still no definite evidence concerning the nature of the mechanisms involved. Some of this uncertainty is due to the experimental difficulties involved in the isolation of the pure products formed in these reactions. There is also a great deal of confusion due to attempts by various authors to interpret these reactions exclusively on either a chemical or a colloidal basis.

In the case of the acids, the evidence suggests that the protein combines with the acid radical to form insoluble salts such as protein tannate, protein phosphotungstate, etc. This is in agreement with the views of Loeb, who pointed out that proteins combine with negative, or acid, ions only on the acid side of their isoelectric points. In agreement also is the fact that if, instead of the free acids, the salts of these acids are added to neutral solutions of protein, no precipitates result until the solution is acidified. Some of the reactions obtained with the salts of the heavy metals are probably similar in character, precipitates of silver proteinate, for

example, being formed on the alkaline side of the isoelectric points. The reactions are, however, complicated by the fact that in some cases the first addition of salt causes the formation of a precipitate which dissolves in excess of salt and then reprecipitates when more salt is added. The difficulties involved in arriving at a rational explanation of these reactions are intensified by the fact that individual proteins show great differences in behavior, due, probably, to differences in the hydration and dispersion of the particles in solution, denaturation, etc. In general, precipitants of this class usually cause extensive intramolecular changes in the protein molecule.

The proteins, in common with other emulsoids, are precipitated by concentrated solutions of such salts as ammonium sulfate, sodium sulfate, sodium chloride, etc. In these cases, as discussed in Chapter 1, precipitation is apparently due to the neutralization and dehydration of the molecules and molecular aggregates in solution. The protein precipitated by these salting-out methods is unaltered (native) and usually redissolves when treated with fresh portions of the original solvent. The concentration of salt required for the precipitation of a protein depends on the particular protein and on the pH of the solution—i.e., on the charge on the protein complex. These variations will be considered in the next chapter in connection with the properties of the various classes of proteins.

The proteins are also precipitated by dehydrating agents, such as alcohols and acetone. The addition of alcohol to electrolyte-free solutions of proteins converts them into suspensoids, which flocculate upon the addition of a few drops of salt solution. Precipitation by alcohol is most effective at the isoelectric point of the protein. Besides precipitating proteins alcohol acts on certain proteins, such as egg albumin, to produce intramolecular changes which affect the solubility and other properties of the protein. This phenomenon, known as denaturation, will be discussed more fully in the next section. The denaturing effect of alcohol on some proteins may be minimized by the use of temperatures around 0° C. or below. Prolonged contact with alcohol (or any other denaturing agent, for that matter) produces an irreversible coagulation of the protein. The "fixing" of tissues for histological examination is an example of the coagulating action of alcohol on proteins.

Colloidal iron, kaolin, and alumina cream are frequently used for removing proteins from solution. These substances probably act by adsorption and their use has been adapted to various quantitative methods.

1. Effect of Strong Acid and Alkali: Place a few ml. of concentrated nitric acid in a test tube, incline the tube, and add dilute egg albumin slowly from a pipet, allowing the solution to run down the side of the tube and form a layer over the nitric acid. Note the appearance of a protein precipitate at the zone of contact between the two fluids. Now mix the contents of the tube thoroughly by careful shaking. Is protein precipitated by concentrated nitric acid?

Repeat the above experiment using concentrated sulfuric acid, concentrated hydrochloric acid, acetic acid, and concentrated sodium hydroxide. How do these various reagents differ in their action on proteins? Allow the tubes to stand overnight or longer and note any further changes.

The formation of a protein precipitate by layering the solution over nitric acid as described above is frequently used as a test for protein in urine and other fluids (Heller's test, see Chapter 29).

2. Precipitation by Metallic Salts: Prepare six tubes each containing 2 to 3 ml. of dilute egg albumin solution. To the first add mercuric chloride solution, drop by drop slowly, until an excess of the reagent has been added, noting any changes which may occur. If not added very gradually the formation of the precipitate may not be noted, due to its solubility in excess of the reagent. Repeat the experiment with lead acetate, silver nitrate, copper sulfate, ferric chloride, and barium chloride, using very dilute solutions.

Egg albumin is used as an antidote for lead or mercury poisoning. Why? Is it an equally good antidote for the other metallic salts tested?

- 3. Precipitation by Alkaloidal Reagents: Prepare six tubes each containing 2 to 3 ml. of dilute egg albumin solution. To the first add picric acid, drop by drop, until an excess of the reagent has been added, noting any changes which may occur. Repeat the experiment with trichloroacetic acid, tannic acid, phosphotungstic acid, phosphomolybdic acid, and potassio-mercuric iodide. Are these precipitates soluble in excess of the reagent? Acidify with hydrochloric acid before testing with the last three reagents.
- 4. Precipitation by Ferrocyanide: To 5 ml. of dilute egg albumin solution in a test tube add 5 to 10 drops of acetic acid. Mix well and add potassium ferrocyanide, drop by drop, until a precipitate forms. This reaction is very sensitive.
- 5. Fractional Precipitation of Proteins by Concentrated Salt Solutions: (a) Obtain some dilute egg-white solution which has been prepared by thoroughly mixing one volume of raw egg white with four volumes of 1 per cent sodium chloride solution and filtering. To a portion of the dilute eggwhite solution add an equal volume of a saturated solution of ammonium sulfate and mix. Does egg white contain a protein which is precipitated by half-saturated ammonium sulfate solution? Dilute a portion of the mixture with some distilled water. Is the precipitation reversible? To the remainder of the mixture add an excess of solid ammonium sulfate and stir until the solution is saturated with the salt. What happens? Again dilute a portion of the mixture with water. Is this precipitation reversible? Filter the remainder of the mixture and test a portion of the precipitate by the Millon test. Test the filtrate by the biuret test, using a saturated solution of ammonium sulfate as a control and adding the same amounts of alkali and copper sulfate solution to both control and filtrate. What are your conclusions?
 - (b) Repeat the above experiment, using sodium chloride instead of ammonium sulfate. How do the results differ from those obtained with ammonium sulfate? At the saturation point with sodium chloride, add 2 to 3 drops of acetic acid. What occurs?

All proteins except peptones are precipitated by saturating their solutions with ammonium sulfate. Most globulins are precipitated by half-saturation with ammonium sulfate or full saturation with sodium chloride. If the saturated sodium chloride solution is subsequently acidified, all proteins except peptones are precipitated.

Soaps may be salted-out in a similar manner (see p. 95).

6. Precipitation by Alcohol: (a) Influence of Electrolytes: Prepare an electrolyte-free solution of egg albumin as follows: Place the albumin solution in a dialyzing bag (see Chapter 1), add a drop of toluene as a preservative, and tie the mouth of the bag securely. Immerse in a large beaker of dis-

example, being formed on the alkaline side of the isoelectric points. The reactions are, however, complicated by the fact that in some cases the first addition of salt causes the formation of a precipitate which dissolves in excess of salt and then reprecipitates when more salt is added. The difficulties involved in arriving at a rational explanation of these reactions are intensified by the fact that individual proteins show great differences in behavior, due, probably, to differences in the hydration and dispersion of the particles in solution, denaturation, etc. In general, precipitants of this class usually cause extensive intramolecular changes in the protein molecule.

The proteins, in common with other emulsoids, are precipitated by concentrated solutions of such salts as ammonium sulfate, sodium sulfate, sodium chloride, etc. In these cases, as discussed in Chapter 1, precipitation is apparently due to the neutralization and dehydration of the molecules and molecular aggregates in solution. The protein precipitated by these salting-out methods is unaltered (native) and usually redissolves when treated with fresh portions of the original solvent. The concentration of salt required for the precipitation of a protein depends on the particular protein and on the pH of the solution—i.e., on the charge on the protein complex. These variations will be considered in the next chapter in connection with the properties of the various classes of proteins.

The proteins are also precipitated by dehydrating agents, such as alcohols and acetone. The addition of alcohol to electrolyte-free solutions of proteins converts them into suspensoids, which flocculate upon the addition of a few drops of salt solution. Precipitation by alcohol is most effective at the isoelectric point of the protein. Besides precipitating proteins alcohol acts on certain proteins, such as egg albumin, to produce intramolecular changes which affect the solubility and other properties of the protein. This phenomenon, known as denaturation, will be discussed more fully in the next section. The denaturing effect of alcohol on some proteins may be minimized by the use of temperatures around 0° C. or below. Prolonged contact with alcohol (or any other denaturing agent, for that matter) produces an irreversible coagulation of the protein. The "fixing" of tissues for histological examination is an example of the coagulating action of alcohol on proteins.

Colloidal iron, kaolin, and alumina cream are frequently used for removing proteins from solution. These substances probably act by adsorption and their use has been adapted to various quantitative methods.

1. Effect of Strong Acid and Alkali: Place a few mi. of concentrated nitric acid in a test tube, incline the tube, and add dilute egg albumin slowly from a pipet, allowing the solution to run down the side of the tube and form a layer over the nitric acid. Note the appearance of a protein precipitate at the zone of contact between the two fluids. Now mix the contents of the tube thoroughly by careful shaking. Is protein precipitated by concentrated nitric acid?

Repeat the above experiment using concentrated sulfuric acid, concentrated hydrochloric acid, acetic acid, and concentrated sodium hydroxide. How do these various reagents differ in their action on proteins? Allow the tubes to stand overnight or longer and note any further changes.

The formation of a protein precipitate by layering the solution over nitric acid as described above is frequently used as a test for protein in urine and other fluids (Heller's test, see Chapter 29).

2. Precipitation by Metallic Salts: Prepare six tubes each containing 2 to 3 ml. of dilute egg albumin solution. To the first add mercuric chloride solution, drop by drop slowly, until an excess of the reagent has been added, noting any changes which may occur. If not added very gradually the formation of the precipitate may not be noted, due to its solubility in excess of the reagent. Repeat the experiment with lead acetate, silver nitrate, copper sulfate, ferric chloride, and barium chloride, using very dilute solutions.

Egg albumin is used as an antidote for lead or mercury poisoning. Why? Is it an equally good antidote for the other metallic salts tested?

- 3. Precipitation by Alkaloidal Reagents: Prepare six tubes each containing 2 to 3 ml. of dilute egg albumin solution. To the first add picric acid, drop by drop, until an excess of the reagent has been added, noting any changes which may occur. Repeat the experiment with trichloroacetic acid, tannic acid, phosphotungstic acid, phosphomolybdic acid, and potassio-mercuric iodide. Are these precipitates soluble in excess of the reagent? Acidify with hydrochloric acid before testing with the last three reagents.
- 4. Precipitation by Ferrocyanide: To 5 ml. of dilute egg albumin solution in a test tube add 5 to 10 drops of acetic acid. Mix well and add potassium ferrocyanide, drop by drop, until a precipitate forms. This reaction is very sensitive.
- 5. Fractional Precipitation of Proteins by Concentrated Salt Solutions: (a) Obtain some dilute egg-white solution which has been prepared by thoroughly mixing one volume of raw egg white with four volumes of 1 per cent sodium chloride solution and filtering. To a portion of the dilute eggwhite solution add an equal volume of a saturated solution of ammonium sulfate and mix. Does egg white contain a protein which is precipitated by half-saturated ammonium sulfate solution? Dilute a portion of the mixture with some distilled water. Is the precipitation reversible? To the remainder of the mixture add an excess of solid ammonium sulfate and stir until the solution is saturated with the salt. What happens? Again dilute a portion of the mixture with water. Is this precipitation reversible? Filter the remainder of the mixture and test a portion of the precipitate by the Millon test. Test the filtrate by the bluret test, using a saturated solution of ammonium sulfate as a control and adding the same amounts of alkali and copper sulfate solution to both control and filtrate. What are your conclusions?
 - (b) Repeat the above experiment, using sodium chloride instead of ammonium sulfate. How do the results differ from those obtained with ammonium sulfate? At the saturation point with sodium chloride, add 2 to 3 drops of acetic acid. What occurs?

All proteins except peptones are precipitated by saturating their solutions with ammonium sulfate. Most globulins are precipitated by half-saturation with ammonium sulfate or full saturation with sodium chloride. If the saturated sodium chloride solution is subsequently acidified, all proteins except peptones are precipitated.

Soaps may be salted-out in a similar manner (see p. 95).

6. Precipitation by Alcohol: (a) Influence of Electrolytes: Prepare an electrolyte-free solution of egg albumin as follows: Place the albumin solution in a dialyzing bag (see Chapter 1), add a drop of toluene as a preservative, and tie the mouth of the bag securely. Immerse in a large beaker of dis-

tilled water and allow to stand for several days, changing the water at intervals. Remove the albumin solution from the bag and filter. Test the filtrate for chloride. It should be negative; if not, the dialysis must be repeated.

Place a 5-ml. portion of the salt-free albumin solution in each of two test tubes and add 10 ml. of 95 per cent alcohol to each tube. Mix. Now to one tube add a pinch or two of solid sodium chloride and again mix. Compare results in the two tubes. What is the effect of alcohol on protein in the absence of electrolytes? What is the effect of added electrolyte? Explain. Dilute some of the suspension with water. Does the precipitated protein redissolve?

(b) Influence of Isoelectric Point: See Exp. 2, below.

D. EXPERIMENTS ON ISOELECTRIC POINTS OF PROTEINS

Isoelectric Point and Solubility of Casein: Into a 50-ml. volumetric flask introduce 0.25 g. of pure casein. Add about 20 ml. of water and exactly 5 ml. of N NaOH. When solution is complete add exactly 5 ml of N acetic acid and dilute to 50 ml. Mix well. This is a solution of casein in 0.1 N sodium acetate. Set up a series of nine tubes as follows:

Tube No	 1	2	3	4	5	6	7	8	9
Distilled water ml	 8.38	7.75 1.25	8.75 0.25	8.5 0.5	8	7 2	5 4	1 8	7.4

To each tube add 1 ml. of the casein-sodium acetate solution, blowing it in from a pipet and shaking the tubes immediately. Note the turbidities just after mixing and after 10 and 30 minutes. Record the results as below, indicating no turbidity by 0, degrees of turbidity by + signs, and degrees of precipitation by \times .

Tube No	1	2	3	4	5	6	7	8	9
pH Turbidity, immediate Turbidity after 5 minutes	5.9	5.6	5.3	5.0	4.7	4.4	4.1	3.8	3.5
	0	0	+	++	+++	++	+	+	0
	0	0	+	+++	×××	××	++	+	0

The precipitation should be greatest in tube 5 which has a pH of 4.7, near the isoelectric point and point of least solubility of casein. The acidity in each tube may be actually determined by the electrometric method or may be calculated from the concentrations of sodium acetate and acetic acid by means of the Henderson-Hasselbalch equation (see Chapter 1).

Isoelectric Point and Precipitation of Gelatin by Alcohol: Gelatin and
many other proteins are quite soluble in water even at their isoelectric
points. They do, however, precipitate more readily at this point if some
precipitating agent such as alcohol is added.

Prenare	9	series	Ωf	test	tuhes	9.	follows:
riebate	a	961169	υı	LOST	LUDGE	ao	IOHOWS:

Tube No	1	2	3	4	5	6	7	8	9
0.1 N sodium acetate ml 0.1 N acetic acid ml				2	2 2	2 4	2.0	2.0	2.0
1.0 N acetic acid ml. Distilled water ml. 1% gelatin ml.	3.88	3.75	3.5	3 2	2 2	0 2	0.8 3.2 2.0	1.6 2.4 2.0	3.2 0.8 2.0

Mix the contents of the tubes well and add 95 per cent alcohol to tube 5 until a very faint cloudiness is produced (ordinarily about 8 ml. are required). Add the same amount of alcohol to each of the other tubes. Examine after 30 minutes. The results usually obtained, with approximate pH for each tube, are as follows:

Tube No	1	2	3	4	5	6	7	8	9
TurbiditypH.	6.0	5.6	5.3	++ 5.0	+++	± 4.4	4.1	3.8	- 3.5

The isoelectric point for gelatin is about pH 4.7.

3. Influence of Acid on Swelling of Gelatin: Proteins are least hydrated at their isoelectric points. The addition of acid, such as HCl, to gelatin causes it to swell, the process being one of increased hydration. Ions have a strong affinity for water and the addition of acid increases the ionization of the gelatin. In the case of HCl the H ion tends to increase the swelling and the Cl ion to depress it. In high concentrations the latter effect overcomes the former and decreased swelling results. The same result follows the addition of Cl ion as NaCl, which hence tends to decrease swelling. The influence of ions and other substances on the hydration of cell proteins is believed to be of great biological importance. Relatively slight changes in pH greatly influence protein swelling.

Prepare a series of test tubes as follows:

Tube No	1	2	3	4	5	6	7	8	9	10
1.0 N HCl ml	16 4	8 12	4 16	20 0	10 10	5 15	2.5 17.5	1.25 18.75	0.62 19.38	0.31 19.69

Cut strips as nearly the same size as possible (5 cm. \times 0.5 cm.) from a sheet of gelatin at least 1 mm. thick. Put a strip in each tube. After 24 hours measure the length of the strips. Results similar to the following may be obtained.

Tube No	1	2	3	4	5	6	7	8	9	10
Length (cm.)	6.4	6.6	6.7	7.4	8.3	8.3	7.6	7.0	6.1	5.3

The greatest degree of swelling will usually be found in tubes containing from 0.025 to 0.05 N HCl corresponding to pH values of 1.3 to 1.6. The reaction within the gelatin particles themselves at the point of maximum swelling is, however, about pH 3.2. This difference in reaction within and without the gel is a consequence of the Donnan equilibrium (see p. 11) which must be considered in all such cases involving the relations of protein ions to other ions in solution. Instead of gelatin strips, 1-g. portions of powdered gelatin (between 30 and 50 mesh) may be placed in 100-ml. graduated cylinders containing suitable solutions and the relative degree of swelling measured. The actual pH of the gel in any case may be determined electrometrically.

4. Influence of Acidity on Solidification of Gelatin: The isoelectric point for gelatin (pH 4.7) is the point of minimum viscosity of its solutions and the point at which the gelatin most readily solidifies. This is because at this point the gelatin is least soluble in the more liquid (water) phase and hence imparts less viscosity to it. For the same reason there is a greater tendency for the more solid phase (gelatin) to form the supporting network believed to be the basis of a jelly. Viscosity determinations must of course be made on the liquefied gelatin solution.

Prepare a series of test tubes as follows:

Tube No	1	2	3	4	õ	6	7
0.1 N sodium acetate ml		1.00 0.06	1.00 0.25	1.0	1.0	1.0	1.0
1.0 N acetic acid ml	0.05					1.6	6.4
Water ml		5.60	5.00	4.6	3.0	3.4	2.8

To each tube add 3 ml. of a warm 10 per cent solution of gelatin and mix. Place all the tubes in water at 50° C. for a few minutes, then transfer to a large beaker of water at room temperature, noting the time at this point. After a few minutes in the beaker, the tubes may be removed and placed in a rack to facilitate observation. Note the time required for solidification of the gelatin in each tube which may be established by tilting the tube and observing whether or not the fluid will flow. Results similar to the following should be obtained.

Tube No	1	2	3	4	5	6	7
Time required for solidification (min.)	19	17	16	14	19	25	very long

Observations may be repeated by remelting the jellies. Note also the much greater opacity of the gelatin at the isoelectric point, indicating that most of the gelatin is in the solid phase.

E. PROTEIN DENATURATION AND ITS REVERSAL

A protein is called a native protein if its amino acid composition and stereochemical structure are unchanged from the natural state. These properties control all the functions of a protein whether they be solubility in dilute salt solutions, proteolytic activity, oxygen-carrying capacity, etc. Chemical and physical agents which bring about changes in the composition or structure of a protein are called denaturing agents and the process is called denaturation.

It is to be expected that proteins will vary widely in their ease of denaturation. Certain proteins, especially those which in solution are fibrous or highly elongated molecules such as the muscle protein myosin, are easily denatured; while others such as the carbohydrate-rich glycoproteins (ovomucoid, for example) seem to be quite resistant to the usual physical agents causing denaturation.

Chemicals which denature proteins include acids, alkalies, salts of heavy metals, ureas, guanidines, detergents, water-miscible solvents such as alcohol and acetone, etc. Proteins may also be denatured by drying, wet and dry heat, ultrasonic vibrations, ultraviolet light, x-rays, high pressures, and the rapid formation and dissolution of interface (e.g., shaking an aqueous protein solution with air, amyl alcohol, or chloroform).

If the above rather specific definition of denaturation is used, then protein denaturation must have an all-or-none character. However, denaturation seldom is completed in one step but consists in a series of chemical and structural deviations from the original native protein. If these changes are not too extensive, many, and some authorities believe all, of the properties possessed by the native protein may be restored. This is called reversal of denaturation or protein regeneration. Thus pensing can be denatured and so lose its proteculation properties by warming to the proper temperature; when the solution is cooled, the proteolytic activity of the protein is restored—i.e., denaturation is reversed. Likewise the oxygen carrying capacity of hemoglobin can be destroyed by denaturing with salicylate; on reversal the restored hemoglobin is not distinguishable from untreated hemoglobin. Although many of the properties of the native protein can be restored by reversal regeneration, it is still questionable whether the reversed protein is identical with the original native protein. Thus regenerated proteins may simulate many characteristic properties of the native materials from which they were derived. but still be denatured proteins.

It is thus apparent that knowledge of the extent of denaturation and its reversal is primarily a technical one, being dependent upon the methods used to measure denaturation. Probably the oldest means of denaturing a protein and one which is familiar to all is illustrated by the marked change in consistency of egg white on cooking, a process which results in extensive denaturation of the albumen proteins. What is seen when

egg white is cooked is only the end-result of denaturation, the matting together of the fibers of denatured protein to form a tightly adhering coagulum. Denaturation involving less deep-seated changes in protein structure requires more refined methods to detect. In recent years the studies of Roche, Neurath, and others have shown that denatured proteins which other investigators believed to have been entirely reversed to the native form were still denatured when more delicate methods of measurement were employed. All investigators agree, however, that once a protein has undergone extensive denaturation, these changes cannot be reversed.

In practice, then, denaturation consists of a series of changes in the protein molecule brought about by various chemical and physical agents. These changes often consist in the opening up and extension of the highly organized coiled polypeptide chains of the native protein, which affect the viscosity, particle size, solubility, resistance to proteolytic enzymes, formation or disappearance of sulfhydryl groups, and may even cause the loss of certain amino acids or peptides of relatively low molecular weight.

Denatured proteins, because of their reduced solubility, usually flocculate at or near the isoelectric point. This flocculation is ordinarily reversible at room temperature. However, if the suspension at the isoelectric point is heated, the floccules form relatively large tenacious masses of *coagulated protein* which are not easily re-dissolved by treatment with dilute acids or alkalies. Denaturation is the primary and important change; flocculation and coagulation, which were often confused with denaturation, are simply visible manifestations of the changes in the protein molecule brought about by denaturation.

1. Denaturation, Flocculation, and Coagulation of Egg Albumin: Place 9 ml. of a clear, salt-free solution of egg albumin into each of three test tubes. To the first add 1 ml. of 0.1 N HCl, to the second 1 ml. of a mixture of sodium acetate and acetic acid (pH 4.7), and to the third 1 ml. of 0.1 N NaOH. Heat all three tubes in a boiling water bath for 15 minutes. Cool and examine. To tubes 1 and 3 add 10 ml. of acetate buffer solution, pH 4.7. What happens? Filter off the precipitates in each tube and wash them on the filter papers with distilled water. Precipitates 1 and 3 are denatured egg albumin, while precipitate 2 is coagulated egg albumin.

Suspend each of the precipitates in about 10 ml. of distilled water and divide each suspension into three parts. To the first part add dilute HCl, drop by drop. Does the precipitate dissolve? Repeat with another part of the suspension, adding dilute NaOH. Heat the third parts of suspensions 1 and 3 in a boiling water bath for 15 minutes. Cool and test the solubility of the material in dilute acid and alkali. Does the material now dissolve?

The precipitates of denatured protein, formed by bringing their solutions to the isoelectric point, dissolve readily in a few drops of dilute acid or alkali. The coagulated protein remains insoluble under similar conditions. Heating the precipitate of denatured protein converts it into a coagulated protein, in which case it now exhibits the properties characteristic of that type of substance.

F. IMMUNOLOGICAL REACTIONS OF PROTEINS

Certain materials, when injected into a living animal under proper conditions, stimulate the animal to produce substances which have the power to react with the specific material injected. The substance injected is referred to as the antigen, while the specific substances appearing in the blood of the immunized animal are known as antibodies. In order to act as antigens the substances must be protein (or combinable with protein) or polysaccharide in nature, colloidal, and foreign to the blood stream of the animal injected. The antibodies are structurally and possibly chemically modified serum proteins, usually globulins, induced by the presence of the antigen in those organs in which the formation of serum proteins occurs. Their presence in the blood stream of the immunized animal is recognized by their action on antigens. The type of reaction which takes place between the antigen and antibody depends upon the nature of the antigen. If, for example, the antigen consists of a suspension of red blood corpuscles, the blood serum of the immunized animal, known as the antiserum, acquires the property of hemolyzing this particular type of corpuscle. If the antigen is a suspension of bacteria or other cells, the antiserum will cause these particular cells to clump together or agglutinate.

When the antigen is a soluble protein the antiserum is capable of forming a precipitate with this specific protein, when mixed under proper conditions. This reaction, known as the precipitin reaction, is remarkably delicate and specific. By means of the precipitin reaction it is possible, for example, to detect a specific protein in solutions containing as little as one part in ten million, or even in one hundred million. Furthermore this reaction is so specific that the antiserum prepared by injecting a solution of hen's egg albumin will precipitate hen's egg albumin but will give no reactions with egg albumins from other sources, or with any of the other proteins in egg white. The precipitin reaction is thus of great value in determining the identity and individuality of protein preparations. It permits us to detect differences between similar proteins from closely related sources which, in their chemical composition and properties, are practically indistinguishable. By means of this reaction it may be shown that certain proteins, such as the protein of crystalline lens, are the same in animals of widely differing species. It has been used to study relationships between various species of plants and of animals. Practically it is used in medicolegal work to distinguish specifically between human and other blood stains.

The technic involved in immunization and in carrying out precipitin reactions is illustrated in an experiment in Chapter 22.

Proteins: Their Classification and Properties

The classification of the proteins is a very difficult problem because, as outlined in Chapter 5, they are found in nature not as distinct chemical individuals but as parts of larger complexes formed by the union of various proteins with each other and with carbohydrates and lipids. The problem is further complicated by the fact that individual purified proteins may themselves be separated into components showing individual differences in composition and properties. Until these components are isolated in pure form and their exact structure determined, a classification of proteins based on molecular structure is impossible. The classification offered below is based upon the fact that under specified experimental conditions the proteins in biological materials (e.g., egg white or blood plasma) may be separated into groups which exhibit certain characteristic properties. It should be kept in mind, however, that these proteins probably do not exist as such in the native material, and that, furthermore, their composition and properties are dependent upon the methods used in their isolation. In spite of all its shortcomings such a classification permits the grouping together of proteins with similar properties into fairly definite classes, and must suffice until the information required for a more rigid classification is obtained.

CLASSIFICATION

I. SIMPLE PROTEINS

The simple proteins are proteins which may be isolated from biological materials by suitable methods. Although they are usually described as yielding only α -amino acids or their derivatives on hydrolysis, some members of this class (e.g., ovalbumin, serum albumin, serum globulin) also yield carbohydrates (see p. 107). Some of these proteins, such as egg albumin, pepsin, trypsin, insulin, hemoglobin, serum albumin, edestin, excelsin and other vegetable globulins, and Bence-Jones and other urinary proteins, may be obtained in crystalline form. By repeated crystallizations these proteins may thus be separated from other proteins present in the original materials. The simple proteins are further classified into albumins, globulins, glutelins, prolamins, albuminoids, histones, globins, and protamines on the basis of solubility and other characteristic properties, as follows.¹

¹ The subclasses defined are exemplified by proteins obtained from both plants and animals. Appropriate prefixes indicate the origin of the compounds, e.g., ovoglobulin, lactalbumin, etc.

Albumins. Soluble in salt-free water and coagulable by heat, e.g., ovalbumin from egg white, serum albumin from blood serum, lactalbumin from milk, vegetable albumins.

Globulins. Insoluble in salt-free water but soluble in neutral solutions of salts of strong bases with strong acids, such as NaCl; coagulable by heat; e.g., serum globulin, lactoglobulin, thyroglobulin, edestin from hemp seed, amandin from almond, and other vegetable globulins.

Glutelins. Simple proteins insoluble in all neutral solvents, but readily soluble in very dilute acids and alkalies, e.g., glutenin from wheat. These may be mixtures of denatured proteins.

Prolamins. Simple proteins soluble in 70 to 80 per cent alcohol, insoluble in water, absolute alcohol, and other neutral solvents, e.g., zein from corn, gliadin from wheat and rye, hordein from barley, and bynin from malt. Rice, kafir, and sorghum have also been shown to contain alcohol-soluble proteins. The name prolamins was suggested for these alcohol-soluble vegetable proteins by Osborne, since upon hydrolysis they yield large amounts of proline and ammonia.

Albuminoids (Scleroproteins). All fibrous proteins which have a supporting or protective function in the animal organism. In the plant kingdom the albuminoids are probably replaced by cellulose and similar substances.

- 1. Collagens, the principal supporting proteins of skin, tendons, and bones, are resistant to peptic and tryptic digestion. They are converted into the easily digested soluble proteins, the gelatins, by boiling with water, dilute acids, or alkalies.
- 2. ELASTINS, present in elastic tissues (tendons, arteries), are more readily digested by trypsin than by pepsin, are not convertable into gelatin, and give a negative color test for hydroxyproline.
- 3. Keratins are proteins resistant to digestion by pepsin and trypsin insoluble in dilute acids and alkalies, in water, and in organic solvents. Keratins have been divided into two classes: (a) Eukeratins (true keratins) are keratins which on hydrolysis yield histidine, lysine, and arginine in a molecular ratio of approximately 1:4:12; and (b) pseudokeratins (false keratins) are a heterogeneous group of insoluble proteins which are digestible with difficulty, and which do not yield histidine, lysine, and arginine in the molecular ratio of 1:4:12.

Histones. Soluble in water and insoluble in dilute ammonia, and, in the absence of ammonium salts, insoluble even in excess of ammonia; yield precipitates with solutions of other proteins and a coagulum on heating which is easily soluble in very dilute acids. On hydrolysis they yield a large number of amino acids among which arginine and lysine predominate. Histones contain tyrosine but appear to be lacking in tryptophane. In short, histones are basic proteins which stand between protamines and true proteins, e.g., scombrone from mackerel sperm, thymus histone.

Globins. Simple basic proteins which were at one time classed as histones because of similarities in solubility, etc. The globins differ from the histones, however, in isoelectric point, toxicity, and amino acid com-

position. While histones are high in arginine and isoleucine and contain only traces of tryptophane, globins contain average quantities of arginine and tryptophane and are unique in their high content of histidine and deficiency in isoleucine. Globins are usually found in nature as the protein portion of conjugated proteins, e.g., globin from hemoglobin.

Protamines. Simpler polypeptides than the proteins included in the preceding groups. They are soluble in water, uncoagulable by heat, have the property of precipitating aqueous solutions of other proteins, possess strong basic properties, and form stable salts with strong mineral acids. They yield comparatively few amino acids, among which the basic ones, especially arginine, predominate. They are the simplest natural proteins, e.g., salmine from salmon sperm, sturine from sturgeon sperm, clupeine from herring sperm, scombrine from mackerel sperm.

II. CONJUGATED PROTEINS

The conjugated proteins, like the simple proteins, are substances which may be isolated from biological materials by suitable methods. They differ from the simple proteins, however, in the fact that the intact molecule consists of protein combined with some nonprotein substance (the prosthetic group) in a manner which confers new and characteristic properties on the complex formed. They are classified according to the nature of the prosthetic group, as indicated below.

Nucleoproteins. Compounds of one or more protein molecules with nucleic acids. The nucleic acid of the cell nucleus appears to be desoxyribose nucleic acid which is united to the protamines, histones, and other basic proteins of the cell nucleus. The nucleoproteins of the cytoplasm yield ribose nucleic acid; the nature of the protein component awaits investigation.

Glycoproteins (after K. Meyer). Mucins contain a uronic acid (see Chapter 2) probably united in salt linkage to the basic groups of proteins. They are found in vitreous humor and in Wharton's jelly of the umbilical cord.

Mucoids do not contain a uronic acid but consist of protein firmly bound to a polysaccharide such as polymerized glucosamine-mannose. Examples: serum mucoid, ovomucoid.

Sulfomucins contain sulfuric acid, uronic acid, and either chondrosamine or glucosamine. They are found in cartilage, intestinal tissue, cornea, gastric mucosa.

Phosphoproteins. Compounds of the protein molecule with phosphoric acid other than a nucleic acid or lecithin,² e.g., casein from milk, ovovitellin from egg yolk, and other proteins associated with the feeding of the young.

Chromoproteins. Compounds of proteins with a metal-containing prosthetic group, e.g., the red iron-containing hemoglobins from vertebrate blood; the blue copper-containing hemocyanins from the blood of

² The accumulated chemical evidence distinctly points to the propriety of classifying the phosphoproteins as conjugated compounds, i.e., they are possibly esters of some phosphoric acid or acids and protein.

certain invertebrates; the green magnesium-containing chlorophyll proteins from plants, etc. The protein should not be regarded as a mere colloidal carrier of the prosthetic group, but as an integral portion of the chromoprotein molecule determining not only the magnitude but even the nature of the reaction it promotes. Thus one iron-containing prosthetic group combined with four different proteins gives rise to four different substances: methemoglobin, catalase, peroxidase, and a component of cytochrome.

Lipoproteins. Compounds of the protein molecule with lecithins,

cholesterol, etc.

III. DERIVED PROTEINS

PRIMARY PROTEIN DERIVATIVES

The primary protein derivatives are substances formed from some of the simple and conjugated proteins on denaturation. When these proteins are subjected to certain chemical and physical agents they undergo intramolecular changes which are accompanied by changes in the properties of the original material. Although the nature of these intramolecular changes is still unknown, they may be recognized by the characteristic properties of the substances formed, as indicated in the classification below.

Proteans. Insoluble products which apparently result from the incipient action of water, very dilute acids or enzymes—e.g., myosan from myosin, edestan from edestin. This is probably an early denaturation stage.

Metaproteins. Products of the action of dilute acids and alkalies whereby the molecule is so far altered as to form products soluble in weak acids and alkalies but insoluble at their isoelectric points, e.g., acid metaprotein (acid albuminate), alkali metaprotein (alkali albuminate).

Coagulated Proteins. Insoluble products which result when isoelectric solutions of the protein are denatured by (1) heat, (2) alcohol, (3) ultraviolet light, (4) mechanical shaking, etc.

SECONDARY PROTEIN DERIVATIVES³

The secondary protein derivatives are substances formed during the hydrolysis of the protein molecule. As hydrolysis proceeds the intact molecule is split up into a series of smaller and smaller fragments which are designated, respectively, as primary and secondary proteoses, peptones, and peptides. The substances in each group are not homogeneous chemical entities, but rather mixtures of fragments of the original protein which probably vary in both composition and size and which are grouped together merely because they exhibit certain characteristic properties in common. This classification has little modern significance and it is being gradually abandoned except for the peptides.

^{*}The term secondary protein derivatives is used because the formation of some of the primary derivatives may precede the formation of the secondary derivatives.

Primary Proteoses. Soluble in water, noncoagulable by heat, precipitated by concentrated nitric acid, and precipitated by half saturation with ammonium sulfate.

Secondary Proteoses. Soluble in water, noncoagulable by heat, and precipitated by saturating their solutions with ammonium sulfate.

Peptones. Soluble in water, noncoagulable by heat, and not precipitated by saturating their solutions with ammonium sulfate.

Peptides. Definitely characterized combinations of two or more amino acids, the carboxyl group of one being united with the amino group of the other with the elimination of a molecule of water, 4—e.g., dipeptides, tripeptides, tetrapeptides, pentapeptides, etc.

CONSIDERATION OF VARIOUS CLASSES OF PROTEINS

I. SIMPLE PROTEINS

A. ALBUMINS

Albumins constitute the first class of simple proteins and may be defined as simple proteins which are coagulable by heat and soluble in pure (salt-free) water. They are also soluble in salt solutions and those of animal origin are not precipitated upon saturating their solutions at 30° C. with sodium chloride or magnesium sulfate except in the vicinity of their isoelectric points. All albumins of animal origin are soluble in half-saturated ammonium sulfate solution⁵ but may be precipitated by increasing the salt concentration up to full saturation. They may also be thrown out of solution by the addition of a sufficient quantity of a mineral acid. Metallic salts also possess the property of precipitating albumins, some of the precipitates being soluble in excess of the reagent, whereas others are insoluble in such an excess. Many albumins have been obtained in crystalline form, notably egg and serum albumins from various species.

Experiments on Albumins

Besides the general protein color reactions and precipitation reactions described in the last chapter, the albumins have other properties which are used to identify proteins belonging to this class. Some of these properties are illustrated by the following experiments:

1. Solubility in Concentrated Salt Solutions: (a) Place 25 ml. of dilute egg albumin solution (prepared as described on p. 154) in a beaker and add 6.6 g. of solid ammonium sulfate. Stir until dissolved. The solution is now 2 M in ammonium sulfate, or approximately half-saturated. Is the albumin precipitated? Now add an excess of solid ammonium sulfate and stir to produce full saturation with the salt. What happens? Dilute a small portion of the mixture with distilled water. Is the effect of ammonium sulfate reversible? Filter the remainder of the mixture. Test the precipitate by Millon's test. Test the filtrate for protein by the biuret test, using saturated ammonium sulfate solution as a control. What are your conclusions?

⁴ The peptones are undoubtedly peptides or mixtures of peptides, the latter term being at present used to designate those of definite structure.

In this connection Osborne's observation that there are certain vegetable albumins which are precipitated by saturating their solutions with sodium chloride or magnesium sulfate or by half-saturating with ammonium sulfate, is of interest.

- (b) To a 25-ml, portion of egg albumin solution in a beaker add an excess of solid sodium chloride and stir until the solution is saturated with the salt. How does the result differ from that with ammonium sulfate? Add 2 to 3 drops of acetic acid. What occurs? Explain.
- 2. Heat Coagulation: Add 3 to 5 drops of acetic acid to 25 ml. of dilute egg albumin solution in a small evaporating dish and heat to boiling. What happens? Why is the acetic acid added? Test a portion of the coagulum by Millon's reaction. Explain.
- 3. Crystallization of Egg Albumin: Method of Kekwick and Cannan: "A solution of Na₂SO₄ was prepared by dissolving 400 g. of the anhydrous salt in 1 liter of warm water. This solution which contains 36.7 g. of salt in 100 ml. must be kept at a temperature above 30° to prevent crystallization. Having collected the whites of fresh eggs and broken up the membranes, the volume was measured and an equal volume of the salt solution added. The mixture was stirred for some time and then after 1 to 2 hours the precipitate was removed by filtration or in the centrifuge. A solution of 0.2 N H₂SO₄ was slowly added to the filtrate while the latter was stirred mechanically. Titration was continued until the pH was about 4.6 to 4.8. A test on a few drops of the mixture with bromocresol green proves sufficiently accurate. It was unusual for any permanent precipitate of protein to separate during the titration but, if it did do so, it was redissolved by cautious addition of water. After the desired pH had been attained stirring was continued and anhydrous Na2SO4 was added slowly until a permanent opalescence developed. When crystallization of the protein became clearly evident the mixture was decanted from any solid Na₂SO₄ which remained undissolved and placed on one side for a day or two. The whole of the process must be conducted in a room not cooler than 20° or it will be impossible to achieve a high enough concentration of salt to effect crystallization of the protein.

"The crystalline material was removed by filtration or in the centrifuge and redissolved in a volume of water about equal to the original volume of egg white. Recrystallization was then effected by addition of solid Na₂SO₄ accompanied by stirring. From 140 to 180 g. of the anhydrous salt were required for each liter of solution. After two further recrystallizations the final product was either brought into solution and dialyzed or converted into a dry powder. In the former case it was possible by extracting the crystalline mass with ice-cold water to obtain a concentrated solution of protein which contained only about 5 per cent of sodium sulfate.

"By spreading the mass of crystals and mother-liquor thinly in front of a fan in a warm room it was rapidly reduced to a dry powder."

- 4. Preparation of Powdered Egg Albumin: This may be prepared as follows: Ordinary egg white finely divided by means of a beater is treated with 4 volumes of water and filtered. The filtrate is evaporated on a water bath at about 50° C. and the residue powdered in a mortar.
- 5. Tests on Powdered Egg Albumin: With powdered albumin prepared as described above by yourself or furnished by the instructor, try the following tests:
 - a. Solubility: Test the solubility of the albumin in water, sodium chloride, dilute acid, and alkali.
 - b. Millon's Reaction.

⁶ The eggs should, if possible, be not more than 24 hours old. One rather stale egg will prevent crystallization or reduce the yield obtained from a large number of fresh eggs.

In carrying out solubility tests on dry proteins, a small amount of the material is piaced in a dry test tube and then treated with a few drops of the desired solvent—enough to moisten it thoroughly. After the protein has swelled, which may take from one-half to several hours (some proteins may require 24 hours, or longer), more of the same solvent is added, a little at a time, with gentle stirring. Since most proteins, when dried, seldom redissolve again completely, solubility is tested for by filtering the solution through a dry filter paper,

c. Glyoxylic Acid Reaction (Hopkins-Cole): When used to detect the presence of protein in solid form this reaction should be conducted as follows: Place 5 ml. of concentrated sulfuric acid in a test tube and add carefully,

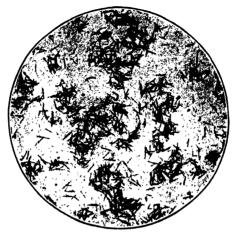

Fig. 59. Crystallized egg albumin. (Prepared and photographed by Dr. Arthur G. Cole, University of Illinois, College of Medicine, Chicago.)

Fig. 60. Horse serum albumin. (Crystals prepared by Drs. Wm. H. and D. H. Welker, University of Illinois, College of Medicine, Chicago.)

by means of a pipet, 3 to 5 ml. of Hopkins-Cole reagent. Introduce a small amount of the solid substance to be tested, agitate the tube slightly, and

or one moistened with the same solvent, and applying some color test, like the biuret, to the clear filtrate.

In preparing a solution of protein, the above procedure must be followed—i.e., the dry protein must be permitted to imbibe some of the solvent and swell before the main body of solvent is added.

- note that the suspended pieces assume a reddish-violet color, which is the characteristic end reaction of the Hopkins-Cole test; later the solution will also assume the reddish-violet color.
 - d. Coagulation Test: Immerse a dry test tube containing a little powdered egg albumin into boiling water for a few moments. Remove and test the solubility of the albumin according to the directions given under (a) above. It is still soluble. Why has it not been coagulated?

B. GLOBULINS

Globulins are simple proteins present in blood serum, muscle, and other animal tissues, and also present in many plant seeds. They give all the ordinary protein tests and are coagulable by heat. Globulins differ from the albumins in being insoluble in pure (salt-free) water. They are, however, soluble in neutral solutions of the salts of strong acids with strong bases, such as sodium chloride. The globulins require a certain concentration of salt in order that they may remain in solution, precipitating when the concentration of salt is lowered by such processes as dilution or dialysis. In general the globulins are precipitated by half saturation of their solutions with ammonium sulfate—i.e., by the addition to their solutions of an equal volume of saturated ammonium sulfate solution. Most globulins are also precipitated from their solutions by saturation with solid sodium chloride or magnesium sulfate.

Blood serum apparently contains a variety of globulins, characterized by differences in solubility, in precipitability by ammonium or sodium sulfate, and in rate of electrophoretic migration (Chapter 22). Blood globulins have not yet been crystallized but crystalline globulins have been obtained from milk (β -lactoglobulin), muscle (myosin), gastric juice (pepsin), and numerous plant seeds.

We have used an albumin of animal origin (egg albumin) for all the protein tests thus far, whereas the globulin to be studied will be prepared from a vegetable source. The vegetable globulin we shall study may be taken as a true type of all globulins, both animal and vegetable.

Experiments on Globulin

Preparation of Edestin: Extract 20 to 30 g. (a handful) of crushed hemp seed with about 150 ml. of 10 per cent sodium chloride solution for one-half hour at 60° C. Filter while hot through a filter paper moistened with 10 per cent sodium chloride solution into a 600-ml. beaker. To the warm filtrate, carefully add distilled water heated to 60° C. until the solution

* It is generally stated that globulins are precipitated from their solutions upon half saturation with ammonium sulfate and that albumins are precipitated upon complete saturation by this salt. Comparatively few exceptions were found to this rule until proteins of vegetable origin came to be more extensively studied. These studies, furthered especially oy Osborne and associates, have demonstrated very clearly that the characterization of a globulin as a protein which is precipitated by half saturation with ammonium sulfate can no longer hold. Certain vegetable globulins have been isolated which are not precipitated by this salt until a concentration is reached greater than that secured by half-saturation. As an example of an albumin which does not conform to the definition of an albumin as regards its precipitation by ammonium sulfate may be mentioned the leucosin of the wheat germ, which is precipitated from its solution upon half-saturation with ammonium sulfate. The limits of precipitation by ammonium sulfate, therefore, do not furnish a sufficiently accurate basis for the differentiation of globulins from albumins.

⁹ For the preparation of a globulin from ordinary garden peas, see Eleventh Edition of this book.

just becomes turbid (300 to 500 ml. of water are required, depending upon the concentration of the protein). Warm the solution in a water bath at 60° until it becomes clear and then permit both the solution and the water bath to cool spontaneously at room temperature. In 24 hours there settles out a precipitate of globulin which is almost entirely crystalline in form. This particular globulin in hemp seed is called edestin. It is soluble in warm 10 per cent sodium chloride solution and may be crystallized by cooling its solution, or by dialyzing the solution against distilled water. Addition of warm water, as above, increases the yield of crystals obtained by decreasing the solubility of the protein. Edestin crystallizes in several different forms, chiefly octahedra (see Fig. 61). (The crystalline form of excelsin, a protein obtained from the Brazil nut, is shown in Fig. 62. This vegetable protein crystallizes in the form of hexagonal plates.) Filter off the edestin and make the following tests on the crystalline material.

Fig. 61. Edestin.

Tests on Crystallized Edestin:

- 1. Microscopical Examination (see Fig. 61).
- 2. Solubility: Try the solubility in water, 1 per cent sodium chloride solution, dilute acid and alkali, and alcohol.
- 3. Millon's Reaction.
- 4. Coagulation Test: Place a small amount of the globulin in a test tube, add a little water, and boil. Now add hydrochloric acid and note that the protein no longer dissolves. It has been coagulated.

Dissolve the remainder of the edestin in about 50 ml. of 10 per cent sodium chloride solution, and make the following tests on this solution.

Tests on Edestin Solution:

- 1. Influence of Protein Precipitants: Try a few protein precipitants such as nitric acid, tannic acid, picric acid, and mercuric chloride. Compare with the results on egg albumin (p. 159). Can you distinguish between albumin and globulin by tests such as these?
- 2. Biuret Test.
- 3. Coagulation Test: Boil some of the solution in a test tube. What happens?
- 4. Saturation with Sodium Chloride: Saturate about 10 ml. of the solution with solid sodium chloride. How does this result differ from that obtained upon saturating egg albumin solution with solid sodium chloride?

5. Precipitation by Dilution: Add a few drops of the solution to a test tube filled with distilled water. Why does the globulin precipitate?

6. Precipitation by Dialysis: Place the remainder of the solution in a dialyzing bag and dialyze against about 500 ml. of distilled water. Why does the globulin precipitate? Examine the precipitate under the microscope.

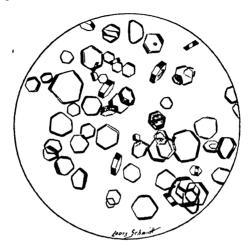

Fig. 62. Excelsin, the protein of the brazil nut. (Drawn from crystals furnished by the late Dr. Thomas B. Osborne.)

C. GLUTELINS

It has been repeatedly shown, particularly by Osborne, that after extracting the seeds of cereals with water, neutral salt solution, and strong alcohol, there still remains a residue which contains protein material which may be extracted by very dilute acid or alkali. These probably denatured proteins which are insoluble in all neutral solvents, but readily soluble in very dilute acids and alkalies, are called glutelins. The only member of the group which has yet received a name is the glutenin of wheat, ¹⁰ a mixture of proteins which constitute nearly 50 per cent of the gluten, the remainder being principally gliadin.

Gluten: Preparation and Tests: To about 50 g. of wheat ficur in a casserole or evaporating dish add a little water and mix thoroughly until a stiff dough results. Knead this dough thoroughly and permit it to stand for about a half hour. This is done in order that the maximum quantity of gluten may be obtained. Treat the dough with about 200 ml. of water and knead it thoroughly. Note the yellowish color of the dough and the milky appearance of the water due to suspended starch granules. (Place a drop of the suspension on a slide, cover with a cover slip, run underneath the slip a drop of iodine solution and observe the stained starch granules under the microscope.) Filter and apply a protein color reaction (see p. 154) to the filtrate. It should be positive, indicating that water-soluble proteins were

¹⁰ Work by Blish and Sandstedt indicates that glutenin prepared by extraction of gluten with dilute alkali is actually an irreversible alteration product of a more complex protein in the crude gluten.

present in the flour. Add fresh water to the dough and repeat the kneading process. Continue this procedure with fresh addition of water, or holding the gluten under the tap, until practically no starch granules are noted in suspension. To a small plece of the yellow, fibrous gluten apply Millon's reaction (p. 154). This test shows gluten to be protein material. Utilize the remainder of the gluten in the preparation of gliadin below.

Glutenin: Preparation and Tests: (In the preparation of gliadin below it is customary to remove this prolamin from the crude gluten by extracting with 70 per cent alcohol. Inasmuch as gluten consists chiefly of gliadin and glutenin the portion of the gluten remaining after the extraction of the alcohol-soluble protein gliadin may be utilized for the preparation of glutenin.)

To the finely divided residue from the preparation of gliadin below in a flask or bottle add about 250 ml. of 70 per cent alcohol. Allow to stand for about 48 hours with repeated shaking in order to remove any remaining gliadin. Crude glutenin remains. To purify the glutenin treat it in a mortar, with sufficient 0.2 per cent NaOH to dissolve it, and filter the liquid through a wet pleated filter. Neutralize the filtrate carefully, with 0.2 per cent HCl adding the acid drop by drop with thorough mixing after each addition. (The glutenin is soluble in excess of acid.) Filter off the glutenin precipitate and wash several times with 70 per cent alcohol and finally with water. Apply the following tests:

1. Solubility in water, 0.9 per cent NaCl solution, 0.2 per cent HCl, and 0.5 per cent Na₂CO₃.

2. Millon's Reaction.

D. PROLAMINS (ALCOHOL-SOLUBLE PROTEINS)

The term prolamin was proposed by Osborne for the group of plant proteins formerly termed "alcohol-soluble proteins." The name is very appropriate inasmuch as these proteins yield, upon hydrolysis, especially large amounts of proline and ammonia. The prolamins are simple proteins which are insoluble in water, absolute alcohol and other neutral solvents, but are soluble in 70 to 80 per cent alcohol and in dilute acids and alkalies. They occur widely distributed, particularly in the vegetable kingdom, and include zein of maize, hordein of barley, gliadin of wheat and rye, bynin of malt, and kafirin of kafir. Sorghum and rice also contain alcohol-soluble proteins. They yield relatively large amounts of glutamic acid on hydrolysis but little or no lysine. The largest percentage of glutamic acid (47 per cent) ever obtained as a decomposition product of a protein substance was obtained from the hydrolysis of the prolamin gliadin. This yield of glutamic acid is also the largest amount of any single decomposition product yet obtained from any protein except the 88.4 per cent of arginine obtained from salmin.

Gliadin: Preparation and Tests: Introduce the finely divided crude gluten as prepared on p. 176 into a flask or bottle, add about 250 ml. of 50 to 70 per cent alcohol, and allow the mixture to stand 24 hours with occasional shaking. Filter (retaining the undissolved portion for preparation of glutenin, above), and evaporate the filtrate to dryness in a porcelain dish over a water bath. Pulverize the dry material. Apply the following tests to this gliadin powder:

Solubility and Protein Tests: Test the solubility in alcohol (30 per cent, 50 per cent, and 70 per cent), water, 0.9 per cent NaCl, 0.2 per cent HCl, and 0.5 per cent Na₁CO₂. Shake each tube repeatedly and filter. To the filtrate

apply the coagulation test (p. 175) and the bluret test (p. 156),

E. ALBUMINOIDS (SCLEROPROTEINS)

The albuminoids yield hydrolytic products similar to those obtained from the other simple proteins already considered, thus indicating that they possess essentially the same chemical structure. They differ from all other proteins, whether simple, conjugated, or derived, in that they are insoluble in all neutral solvents. The albuminoids include "the principal organic constituents of the skeletal structure of animals as well as their external covering and its appendages." Some of the principal albuminoids are keratins from hair, horn, nails, feathers, etc.; elastins from arteries, ligaments; collagens from bone, skin, hoof, etc.; reticulin, spongin, and silk fibroin. Gelatin cannot be classed as an albuminoid although it is a transformation product of collagen. The various albuminoids differ from each other in certain fundamental characteristics (see p. 168). Experiments on albuminoids will be found in Chapter 9.

II. CONJUGATED PROTEINS

Conjugated proteins consist of a protein molecule united to some non-protein molecule or molecules otherwise than as a salt. Glycoproteins, nucleoproteins, chromoproteins, phosphoproteins, and lipoproteins are the five classes of conjugated proteins.

Glycoproteins. Glycoproteins may be considered as compounds of the protein molecule with a substance or substances containing a carbohydrate group other than a nucleic acid. They yield, upon decomposition, protein and carbohydrate derivatives, notably glucosamine, CH₂OH·(CHOH)₃·CH(NH₂)·CHO, galactosamine, and uronic acids. The principal glycoproteins are (1) mucoids, (2) mucins, and (3) sulfomucins. The elementary composition of typical mucoids is as follows:

	N	S	C	H	0
TendomucoidOsseomucoid	11.75	2.33	48.76	6.53	30.60
	12.22	2.32	47.43	6.63	31.40

(For the preparation of tendomucoid see Chapter 9; of salivary mucin, see Chapter 13.) Amyloid, 11 which appears pathologically in the spleen, liver, and kidneys, is also a glycoprotein.

Phosphoproteins. The phosphoproteins are considered to be compounds of the protein molecule and phosphoric acid. The percentage of phosphorus in phosphoproteins is very similar to that in nucleoproteins, but they differ from this latter class of proteins in that they do not yield any purine bases upon hydrolytic cleavage. Two of the common phosphoproteins are the casein of milk and the ovovitellin of egg yolk. The phosphorus in these proteins exists in phosphoric acid radicals bound in ester linkage to the hydroxy amino acids serine and threonine. For the preparation of a typical phosphoprotein (casein), see Chapter 8.

¹¹ Not to be confused with the substance amyloid, which may be formed from cellulose (see p. 80).

Chromoproteins. The chromoproteins are compounds of the protein molecule with a metalloporphyrin (see Chapter 22) or some similar substance. The principal members of the group are the hemoglobin of the blood and the chlorophyll proteins of plants. Upon hydrolytic cleavage hemoglobin yields a protein termed globin and a coloring matter which contains iron and is known as heme. Hemocyanin, another member of the class of chromoproteins, occurs in the blood of certain invertebrates, notably cephalopods, gasteropods, and crustacea. Hemocyanin generally contains either copper, manganese, or zinc, as contrasted to the iron of the hemoglobin molecule. For the preparation of hemoglobin in crystalline form, see Chapter 22.

Lipoproteins. The lipoproteins consist of a protein molecule joined to lecithin, cholesterol, and other fatty substances. They have been comparatively little studied and may possibly be mixtures of protein and lipid material. These unions are not split by treatment with ether but are by alcohol, especially after heat denaturation of the protein.

Nucleoproteins. For consideration of nucleoproteins, see Chapter 7.

III. DERIVED PROTEINS

A. PRIMARY PROTEIN DERIVATIVES

1. Proteans

Proteans are those insoluble, denatured protein substances which are produced from proteins originally soluble through the incipient action of water, enzymes, very dilute acids, etc. According to Osborne nearly all proteins may give rise to proteans, and the determining factor in the transformation is the hydrogen-ion concentration. The protean produced from the transformation of edestin is called edestan; that produced from myosin is called myosan, etc. The name protean was first given to this class of proteins by Osborne in 1900 in connection with his studies of edestin. It is but little used at present.

2. Metaproteins

The metaproteins are denatured proteins formed by the action of dilute acids and alkalies on some proteins, especially on the albumins and the globulins. The conversion of protein into metaprotein is accelerated by a rise in temperature, taking place almost immediately at the boiling point. There is, at present, no definite evidence concerning the exact nature of the changes which the protein molecule undergoes during this transformation. (See the section on Denaturation in the previous chapter.) The denatured protein behaves like a suspensoid, dissolving in dilute acids and alkalies—i.e., when the particles are electrically charged—and flocculating when the solutions are brought to the isoelectric point. The suspensoid character of the metaproteins is also indicated by their sensitivity to electrolytes, especially in the neighborhood of the isoelectric point. The metaproteins are precipitated by saturation of their solutions with ammonium sulfate and, when dissolved in acid, by full saturation

with sodium chloride. Boiling an isoelectric suspension of metaprotein converts it into coagulated protein, in which case the material is no longer soluble in dilute acids and alkalies.

The metaproteins are usually classified as (1) acid metaproteins, or so-called acid albuminates, and (2) alkali metaproteins, or alkali albuminates, depending upon whether they are formed by the action of acid or alkali on the native protein. Transformation products with similar physical properties are formed by the action of enzymes, ultraviolet light, etc., on native protein. It is unlikely that these procedures ever produce a homogeneous metaprotein.

EXPERIMENTS ON DENATURED PROTEINS (METAPROTEINS)

Acid Metaprotein (Acid Albuminate)

Preparation and Study: Take 25 g. of hashed lean beef washed free from the major portion of blood and inorganic matter, and place it in a medium-sized beaker with 100 ml. of 0.2 per cent HCl. Boil the mixture for one-half hour, filter, cool, and divide the filtrate into two parts. Neutralize the first part with 0.5 per cent NaOH solution, added drop by drop with stirring, until maximum precipitation occurs. Filter off the precipitate of acid metaprotein and make the following tests:

- 1. Solubility: Solubility in water, sodium chloride solution, dilute acid, and alkali.
- 2. Millon's Reaction.
- 3. Coagulation Test: Suspend a little of the metaprotein in water (neutral solution) and heat to boiling for a few moments. Now add 1 to 2 drops of dilute NaOH solution to the water and see if the metaprotein is still soluble in dilute alkali. What is the result and why?
- 4. Test for Cystine and Cysteine Sulfur (see p. 153).
- Subject the second part of the original solution to the following tests:
- 5. Coagulation Test: Heat some of the solution to boiling in a test tube. Does it coagulate?
- 6. Biuret Test.
- 7. Influence of Protein Precipitants: Try a few protein precipitants such as picric acid and mercuric chloride. How do the results obtained compare with those from the experiments on egg albumin? (See p. 159.)

Alkali Metaprotein (Alkali Albuminate)

Preparation and Study: Carefully separate the white from the volk of a hen's ess and place the former in an evaporating dish. Add 10 per cent sodium hydroxide solution, drop by drop, stirring continuously. The mass gradually thickens and finally assumes the consistency of jelly. This is solid alkali metaprotein or "Lieberkühn's jelly." Do not add an excess of sodium hydroxide or the jelly will dissolve. Cut it into small pieces, place a cloth or wire gauze over the dish, and by means of running water wash the pieces free from adherent alkali. Now add a small amount of water, which forms a weak alkaline solution with the alkali within the pieces, and dissolve the ielly by gentle heat. Cool the solution and divide it into two parts. Proceed as follows with the first part: Neutralize with dilute hydrochloric acid, noting the odor of the liberated hydrogen sulfide as the alkali metaprotein precipitates. Filter off the precipitate and test as for acid metaprotein (tests 1, 2, 3, and 4), above, noting particularly the sulfur test. How does this test compare with that given by the acid metaprotein? Make tests on the second part of the solution the same as for acid metaprotein (tests 5, 6, and 7) above.

3. Coagulated Proteins

Simple proteins, such as the albumins and globulins, are converted by heat, ultraviolet light, mechanical agitation, or long contact with alcohol, etc., into insoluble materials known as coagulated proteins, which probably consist of the matting together of the denatured protein fibrils similar to the formation of felt from short fibers of hair. (See the section on Denaturation in the previous chapter.) Coagulated proteins are insoluble in water, salt solutions, and dilute acids and alkalies. They are soluble in strong mineral acids and alkalies which hydrolyze the protein into simpler substances.

EXPERIMENTS ON COAGULATED PROTEIN

Ordinary coagulated egg white may be used in the following tests:

- 1. Solubility: Try the solubility of small pieces of coagulated protein in water 1 per cent sodium chloride, and dilute and concentrated acid and alkali.
- 2. Millon's Reaction.
- 3. Xanthoproteic Reaction: Partly dissolve a medium-sized piece of the protein in concentrated nitric acid. Cool the solution and carefully add an excess of ammonium hydroxide. Both the protein solution and the undissolved protein will be colored orange.
- 4. Biuret Test: Partly dissolve a medium-sized piece of the protein in concentrated sodium hydroxide solution. If the proper dilution of copper sulfate solution is now added the white coagulated protein, as well as the protein solution, will assume the characteristic purplish-violet color.
- 5. Glyoxylic Acid Reaction (Hopkins-Cole): Conduct this test according to the modification given on p. 173.

B. Secondary Protein Derivatives

1. Proteoses and Peptones

The proteoses and peptones are poorly defined intermediate products formed during the digestion of proteins by the proteolytic enzymes, as well as in the decomposition of proteins by hydrolysis and the putrefaction of proteins through the action of bacteria. As hydrolysis proceeds, the large, colloidal protein molecule is split up into a mixture of large and small fragments which were formerly designated as primary and secondary proteoses, peptones, and peptides. The larger fragments are constantly being broken down until, finally, only amino acids remain. It should be emphasized that the substances formerly known as proteoses and peptones are not homogeneous chemical entities, but rather mixtures of fragments of the original protein molecule which vary in composition and also in size, and which are grouped together merely because they exhibit certain characteristic properties in common. Those fragments which are precipitated when the solution is half saturated with ammonium sulfate were known as primary proteoses, while those precipitated when the solution is saturated with ammonium sulfate were called secondary proteoses. The peptones were not precipitated by ammonium sulfate. While the proteoses still exhibit colloidal properties, these properties become less pronounced and begin to disappear entirely by the time the breakdown of the protein molecule has reached the peptone stage. Thus, in addition to being nonprecipitable by ammonium sulfate, the peptones diffused through such membranes as collodion and failed to give some of the characteristic precipitation reactions of proteins.

Since the proteoses and peptones are both heterogeneous mixtures of fragments of the original protein molecules, different preparations of these substances will show variations in composition and properties depending upon the nature of the protein used as starting material, the method of hydrolysis employed, and the method used to separate the various products of hydrolysis. Thus the so-called peptones sold commercially vary not only in composition but also in the amounts of primary and secondary proteoses they contain. As a class the proteoses and peptones are a mixture of amino acids and peptides not coagulated by heat. Some are also soluble in dilute alcohol. Peptones differ from proteoses in being more diffusible, nonprecipitable by $(NH_4)_2SO_4$, and by their failure to give any reaction with potassium ferrocyanide and acetic acid, potassio-mercuric iodide and HCl, picric acid, and trichloroacetic acid. Peptones may be precipitated by phosphotungstic acid, phosphomolybdic acid, absolute alcohol, and tannic acid, but an excess of the precipitant may dissolve the precipitate. The so-called primary proteoses, being relatively large molecules, are precipitated by HNO₃ and are the only members of the proteose-peptone group which are so precipitated.

EXPERIMENTS ON PROTEOSES AND PEPTONES

Some of the more general characteristics of the proteose-peptone group may be noted by making the following simple tests on a proteose-peptone powder:

- 1. Solubility: Solubility in hot and cold water and sodium chloride solution.
- 2. Millon's Reaction.
- 3. Precipitation by Picric Acid: To 5 ml. of proteose-peptone solution in a test tube add picric acid until a permanent precipitate forms. The precipitate disappears on heating and returns on cooling.
- 4. Precipitation by a Mineral Acid: Try the precipitation by nitric acid.
- 5. Coagulation Test: Heat a little proteose-peptone solution to boiling. Does it coagulate like the other simple proteins studied?

Separation of Proteoses and Peptones¹²

Place 50 ml. of proteose-peptone solution in an evaporating dish or casserole, and half-saturate it with ammonium sulfate solution, which may be accomplished by adding an equal volume of saturated ammonium sulfate solution. At this point note the appearance of a precipitate of the primary proteoses. Now heat the half-saturated solution and its suspended precipitate to boiling and saturate the solution with solid ammonium sulfate. At full saturation the secondary proteoses are precipitated. The peptones remain in solution.

Proceed as follows with the precipitate of proteoses: Collect the sticky precipitate on a rubber-tipped stirring rod or remove it by means of a watch glass to a small evaporating dish and dissolve it in a little water. To remove the ammonium sulfate, which adhered to the precipitate and is now in

¹³ The separation of proteoses and peptones by means of fractional precipitation with ammonium sulfate does not possess the significance it was once supposed to possess inasmuch as the boundary between these substances and peptides is not well defined (see p. 101). For discussion of a quantitative method for determining protein and proteose based on their separation by trichloroscetic acid, see Seibert: J. Biol. Chem., 70, 265 (1926).

solution, add barium carbonate, boil, and filter off the precipitate of barium sulfate. Concentrate the proteose solution to a small volume¹³ and make the following tests:

Tests on Proteoses:

- 1. Biuret Test.
- 2. Precipitation by Nitric Acid: What would a precipitate at this point indicate?
- 3. Precipitation by Trichloroacetic Acid: This precipitate dissolves on heating and returns on cooling.
- 4. Precipitation by Picric Acid: This precipitate also disappears on heating and returns on cooling.
- 5. Precipitation by Potassio-mercuric Iodide and Hydrochloric Acid.
- 6. Coagulation Test: Boil a little in a test tube. Does it coagulate?
- 7. Precipitation by Acetic Acid and Potassium Ferrocyanide.

Tests on Peptones: The solution containing the peptones should be cooled and filtered, and the ammonium sulfate in solution removed by boiling with barium carbonate as described above. After filtering off the barium sulfate precipitate in the presence of a filter aid such as diatomaceous earth, concentrate the peptone filtrate to a small volume and repeat the tests as given under the proteose solution, above. Also try the precipitation by tannic acid. In the biuret test the solution should be made very strongly alkaline with solid potassium hydroxide.

2. Peptides

The peptides are "definitely characterized combinations of two or more amino acids, the carboxyl (COOH) group of one being united with the amino (NH₂) group of the other with the elimination of a molecule of water." These peptides are more fully discussed on pp. 101 and 140.

REVIEW OF PROTEINS

In order to facilitate the student's review of the proteins, the preparation of a chart similar to the model shown on page 185, is recommended. The signs + and - may be conveniently used to indicate positive and negative reactions.

13 If the proteoses are desired in powder form, this concentrated proteose solution may now be precipitated by alcohol, and this precipitate, after being washed with absolute alcohol and with ether, may be dried and powdered.

SCHEME FOR DETECTION OF PROTEINS

If the solution is acid or alkaline it should be approximately neutralized.

If a precipitate forms it should be filtered off. The neutralization need not necessarily proceed until an exact neutral reaction is obtained but should cease at the point where the largest precipitate is secured.

* Gelatin and protecee may also be differentiated by means of the Hopkins-Cole reaction (see p. 155). A positive reaction here would indicate protecte and a negative reaction gelatin.

Nucleic Acids and Nucleoproteins

THE NUCLEOPROTEINS

Nucleoproteins are combinations of highly polymerized nucleic acids (polynucleotides) with proteins. The proteins may have a preponderance of arginine, histidine, and lysine, and may be basic in reaction. There are two kinds of nucleic acids and consequently two types of nucleoproteins.

THE NUCLEIC ACIDS

The nucleic acids are difficultly soluble in cold water, more readily in hot water, insoluble in alcohol, but readily soluble in weak alkali with the formation of the alkali salt. If pure they do not give the protein color reactions. They are optically active. They are precipitated from their alkaline solutions by HCl, but only the ribose nucleic acid is precipitated by acetic acid. In weak acid solution they are precipitated by protein, the combination being considered a "nuclein." They form insoluble salts with alkaline earth and heavy metals. The sodium salt of desoxyribose nucleic acid in 2 per cent solution is liquid while warm but solidifies to a gelatinous mass on cooling. Ribose nucleic acid does not do this.

The nucleic acids on hydrolysis yield phosphoric acid, purine and pyrimidine bases, and a carbohydrate or carbohydrate derivative. The composition varies slightly with the type of nucleic acid.

Desoxyribose Nucleic Acid (Animal Nucleic Acid, Thymus Nucleic Acid, Chromonucleic Acid). Nucleic acid containing desoxyribose as the carbohydrate constituent was originally isolated from animal cells containing a relatively large proportion of nuclear material, such as the thymus gland. As this nucleic acid occurs in all cell nuclei whether of plant or animal origin, the terms thymus and animal nucleic acid are obviously misleading and should be eliminated. Because desoxyribose nucleic acid is normally restricted to the chromatin of the cell nucleus, Pollister and Mirsky have proposed that "chromonucleic" acid be used in place of the misleading term thymus nucleic acid.

Desoxyribose nucleic acid was shown, by the studies of Levene, Jones, and others, to consist of four principal components called nucleotides. Nucleic acid is, therefore, a tetranucleotide. On complete decomposition one molecule of chromonucleic acid yields four molecules of phosphoric acid, four molecules of desoxyribose CH₂OH·CHOH·CHOH·CH₂·CHO, two purines, adenine and guanine, and two pyrimidines, cytosine and thymine. Levene's formula for desoxyribose nucleic acid is as follows:

Desoxyribose nucleic acid (tetranucleotide), C39H51N15P4O25

According to this structure, the unit tetranucleotide molecule with a molecular weight of approximately 1200 contains four different bases in equimolecular proportions. As knowledge of nucleic acid chemistry increases, it is becoming apparent that such a tetranucleotide structure is an oversimplification of the picture. Nucleic acids have been studied which yield other than equimolecular amounts of the different bases on hydrolysis, as established by either actual isolation or chemical analysis. It is doubted by some that depolymerization by enzymatic or other means of the highly polymerized nucleic acid molecule has ever yielded a molecule as simple as that represented by the Levene formulation. Likewise, the nature of the phosphoric acid linkage between nucleotides may be considered an open question. It is perhaps best at the present time to regard the base-pentose-phosphoric nucleotide unit as a basal structural component of nucleic acid, just as the amino acids are so regarded with respect to proteins, without attempting to define too rigorously the precise composition of each unit or the nature of the union between these units which produces the nucleic acid molecule itself.

Desoxyribose Nucleoproteins. Chromonucleic acid seldom if ever occurs uncombined in nature. Its combination with proteins was elucidated by Miescher about 1870. Desoxyribose nucleic acid exists in chromatin as a highly polymerized threadlike molecule which when isolated has a molecular weight of approximately 1,000,000. These nucleic acid threads are united by easily dissociable salt linkages to parallel polypeptide chains of basic proteins such as the protamines and histones, although other proteins containing a greater variety of amino acids may also unite with polymerized nucleic acid to form nucleoproteins.

The desoxyribose nucleoproteins of the chromosome are readily disintegrated by trypsin, but only shrunk by the action of pepsin. This action is quite in accord with the specificity of these proteolytic enzymes

¹ Ensymes capable of depolymerizing nucleic acids are present in animal tissues.

according to Bergmann (p. 144), and suggests the presence in the chromosome of a protein containing the requisite aromatic side chains to permit some peptic proteolysis.

A characteristic common to all chromonucleoproteins is their solubility in 1 M NaCl and their insolubility in physiological saline. The insoluble material is highly fibrous so that it is readily wound around a stirring rod and can easily be separated from contaminating substances. The nucleic acid comprises from 25 to 60 per cent of the dry weight of the chromonucleoproteins.

In the normal cell nucleus desoxyribose nucleic acid is united with either the arginine-rich, tyrosine- and tryptophane-deficient protamines, the tyrosine-containing, tryptophane-deficient histones, or a more complex protein, chromosomin, which yields approximately 10 per cent of arginine, 5 per cent of histidine, 11 per cent of lysine, and relatively large quantities of the dicarboxylic amino acids and tryptophane.

The highly important self-propagating chromosomes are composed principally if not entirely of desoxyribose nucleoproteins. The part which these nucleoproteins must play in inheritance and other genetic phenomena is just beginning to be investigated by physiological chemists among whom Mirsky, Pollister, Stedman, Caspersson, Feulgen, Mazia, and Dische have made significant contributions. It seems at present that the desoxyribose nucleoproteins of the chromosomes are either the genes themselves or are intimately related to genes.

Ribosenucleic Acid (Plant Nucleic Acid, Yeast Nucleic Acid, Plasmonucleic Acid). The nucleic acid which was first isolated from plants, usually yeast cells, was shown by Jones, Levene, Bass, and others to also be a tetranucleotide differing only from chromonucleic acid in that its carbohydrate component consists of ribose CH₂OH·CHOH·CHOH·CHOH·CHO in the place of desoxyribose, and one of the nitrogenous constituents, uracil, is present in the pyrimidine portion of the molecule in place of thymine. Like desoxyribose nucleic acid, ribosenucleic acid is found in both plant and animal cells, and hence the terms plant or yeast nucleic acid for this substance should be abandoned. Ribosenucleic acid is not present in the cell nucleus, but is present in the nucleolus and in the cytoplasm. Because of this Pollister and Mirsky have suggested that ribosenucleic acid be called plasmonucleic acid.

Ribose Nucleoproteins. Like chromonucleic acid, plasmonucleic acid is combined in the cell with protein. This combination does not appear to be a simple salt linkage between basic protein and nucleic acid, but is in the nature of a nonpolar combination which migrates in an electrophoretic cell as a single entity (Sevag and Smolens).

The normal protein components of the ribose nucleoproteins are not well characterized. Tobacco mosaic virus is a typical ribose nucleoprotein, the protein of which is characterized by the absence of methionine and histidine, and the relative abundance of tryptophane. It is doubtful, however, if other viruses will be similarly characterized.

As to the constitution of the individual mononucleotides from plasmonucleic acid, the phosphoric acid appears to be combined with carbon atom 3 in the ribose molecule. In muscle adenylic acid, however, which also contains ribose, the combination is with the carbon atom 5. The combination of the purines with the sugar molecules appears to be through position 9 in the purines. In the pyrimidine nucleotides the combination seems to be with position 3 in the pyrimidines. Yeast adenylic acid has the following structure.

Yeast and muscle adenylic acids play important roles in yeast fermentation and in the carbohydrate metabolism of muscles (see Chapter 10).

9'-adenine-3-phosphoribofuranoside

The cleavage of the nucleic acid molecule into its corresponding nucleotides is brought about during digestion by enzymes present in the intestinal juice and intestinal mucosa. Enzymes of similar origin act further on the nucleotides thus formed and split off the phosphoric acid radicals together with carbohydrate-base compounds which are called nucleosides. The purine nucleosides may apparently be decomposed in the intestine but the pyrimidine nucleosides are apparently absorbed as such. Many tissues, however, contain nucleosidase. The purine bases may also be deaminized while still in combination as nucleosides and turther hydrolysis would then lead to the direct liberation of the oxypurines instead of their precursors, the amino purines.

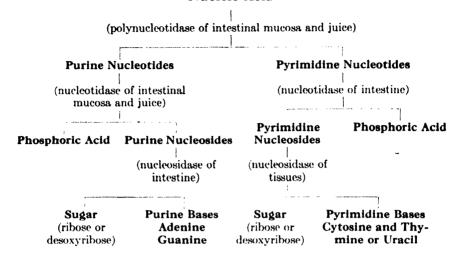

The relation between nucleotides and nucleosides may be indicated by the following diagram:

	Nucleotide	
Purine or	Ribose or	Phosphoric
Pyrimidine	Desoxyribose	Acid
Nucl	eoside	

The following outline will indicate the course of decomposition of a nucleic acid and the enzymes involved in the process.

DECOMPOSITION OF NUCLEIC ACID

Nucleic Acid

With regard to the fate of the various radicals of the nucleic acids in the body after absorption little is definitely known. The phosphoric acid may of course be built up into phosphorus-containing cell constituents such as nucleoproteins, phosphoproteins, or phosphatides, or be eliminated as phosphate in the urine. The carbohydrate portion may undergo the usual transformations of intermediary carbohydrate metabolism. The pyrimidine nucleosides appear to be ordinarily absorbed unchanged from the intestine and may be to a certain extent directly resynthesized in the animal body to nucleoprotein. The excess over body requirement must, however, be decomposed, although a certain portion may possibly be stored up in the individual cells or in certain organs. Enzymes capable of decomposing nucleic acids are found in most of the cells of the body. Pyrimidine nucleosides have been synthesized. Adenyl nucleoside has been used to stimulate bone marrow to increase the number of leukocytes. as well as for its effect on blood pressure. Guanine acts like histamine in producing a constriction of the pulmonary bronchioles. Thiouracil, chemically analogous synthetically to uracil except for the presence of sulfur instead of oxygen in the 2 position of the pyrimidine ring, has important clinical application in the treatment of certain diseases involving the thyroid gland.

The Purine Bases. As has been indicated, the basic substances present in nucleic acid belong to two classes: the purine and pyrimidine bases. The purine bases set free on the decomposition of nucleic acid are adenine and guanine belonging to the class of amino purines. The fate of the amino purines in the animal body is of considerable interest. It has been shown that certain tissues contain enzymes which transform these amino purines first to corresponding oxypurines known as hypoxanthine and xanthine and finally to uric acid. It is probable that different enzymes enter into

the various steps of these transformations leading to the formation of uric acid. Still another enzyme may carry the oxidation further with the formation of the compound allantoin. This enzyme is known as uricase. The purine enzymes are widely distributed in tissues. The transformations brought about are indicated in the following scheme.

N=C·NH₂

Uricacid
2-6-8-trloxypurine

All of the physiologically important purine bodies are precipitated by ammoniacal silver nitrate solution in the cold and by copper sulfate and sodium bisulfite in boiling solutions. Some of them are readily identified by their crystalline forms or the crystalline forms of certain of their salts. Uric acid differs from the other purines in being insoluble in dilute sulfuric acid. The purine bodies may be distinguished to a certain extent also by the reactions which they give when their solutions are evaporated with nitric acid and the residue treated with ammonia. Uric acid gives the characteristic formation of the purple murexide (ammonium purpurate). Potassium hydroxide changes this to a bluish-violet color which dis-

appears on heating. Xanthine and guanine form yellow compounds with nitric acid which turn purple or violet on treating with potassium hydroxide. The color in this case is not lost by heating. Adenine and hypoxanthine do not give a color reaction with nitric acid.

The keto-enol tautomerism which uric acid is known to possess is illustrated in the above formulas. The lactam form is less stable. Two series of salts of the lactim form result from substitution of the hydrogen atoms indicated in black-face type. The third enolic hydrogen is probably very slightly dissociated.

The Pyrimidine Bases. The pyrimidine bases entering into the composition of nucleic acid are thymine, cytosine, and uracil. Cytosine is found in both types of nucleic acid, while thymine is found only in chromonucleic acid and uracil only in plasmonucleic acid. They possess the following formulas.

2-6-dioxypyrimidine 5-methyl-2-6-dioxypyrimidine 6-amino-2-oxypyrimidine

With regard to the fate of pyrimidine bases in metabolism very little is known. Uracil and thymine are apparently converted into urea in metabolism. Cytosine and 5-methyl cytosine may be partly deaminized to uracil and thymine respectively. 4-5, Dihydroxyhydrothymine may be an intermediate product in the metabolism of thymine. Vitamin B_1 is a pyrimidine derivative (see Chapter 35).

EXPERIMENTS ON NUCLEOPROTEINS AND THEIR DERIVATIVES

1. Preparation of Chromonucleoprotein from Liver (Mirsky and Pollister):
Fresh liver is minced and thoroughly washed with physiological saline. The washed tissue is then extracted with 1 M NaCl. The suspension is centrifuged at high speed (10,000 to 12,000 r.p.m.) and the supernatant liquid containing the nucleoprotein is removed. This solution is poured into 6 volumes of water, in which the nucleoprotein precipitates as a fibrous mass. The supernatant liquid is decanted off and the nucleoprotein is purified by again dissolving in 1 M NaCl. The solution is centrifuged at high speed to remove any suspended material and the nucleoprotein is again precipitated by pouring into 6 volumes of water. If the mixture is stirred with a rod having a crook at its end, the fibrous material gen-

erally winds around the rod and adheres to it. The above precipitation should be repeated once more to obtain pure desoxyribose nucleoprotein.

- 2. Preparation of Nucleoprotein from Yeast:2 Place two small cakes of ordinary compressed yeast in a mortar. Sprinkle a small horn-spoonful of sand over the yeast, add 5 ml. of ether and 10 ml. of water and thoroughly triturate the mixture, grinding vigorously. The ether kills the yeast, in which condition the comminution of the cells with sand is more thoroughly effected. Occasionally during the trituration process add 1 or 2 ml of water until the mixture is comparatively fluid. The whole process of maceration can be completed in five minutes. Pour the thick liquid into a bottle, aiding the transfe, with enough 0.4 per cent NaOH to make a final volume of about 125 ml. The alkali extracts the nucleoprotein along with the water-soluble proteins of the yeast. Add a little toluene and allow to stand with frequent shaking for 12 to 24 hours. Filter through a wet, fluted filter. While thoroughly stirring add 1 drop at a time of 10 per cent HCl, cautiously continuing the addition as long as the milkiness of the mixture can be increased. Continue until the protein completely separates and the liquid is practically clear. Note that the solution is now acid in reaction. Excess of acid causes resolution. Filter on a wet. fluted filter. Retain the precipitate on the filter for nucleoprotein tests.
 - 3. Tests on Nucleoprotein: Try the following tests on the nucleoprotein prepared as above.
 - a. Try the xanthoproteic and Millon's tests.
 - b. Test the solubility in water, 10 per cent NaCl, 10 per cent HCl, dilute KOH, and alcohol.
 - c. Tests for Phosphorus in Organic Matter: Test for organically combined phosphorus by one of the following methods.
 - (1) Fusion Test: To a small amount of the substance in a crucible add about five times its bulk of fusion mixture (2 parts of sodium carbonate to 1 of potassium nitrate). Heat carefully until the resulting mixture is colorless. Cool, dissolve the mass in a little warm water, acidify with nitric acid, heat to about 65° C., and add a few ml. of molybdate solution. In the presence of phosphorus a yellow precipitate of ammonium phosphomolybdate is formed.

Instead of acidifying with nitric acid, the aqueous solution may be approximately neutralized with hydrochloric acid, a few ml. of magnesia mixture added, and then excess of ammonium hydroxide solution. A white precipitate of magnesium ammonium phosphate is formed.

- (2) Moist Ashing Procedure: Treat a small amount of the substance in a large test tube with about 1 ml. of concentrated sulfuric acid. Then add drop by drop an equal volume of concentrated nitric acid, and warm gently until a clear solution is obtained. A few more drops of nitric acid may be added if necessary. This treatment with sulfuric and nitric acids must be carried out with the greatest caution, particularly when fatty substances are present, otherwise an explosive reaction may take place. Dilute the acid solution with a little water, make slightly alkaline with ammonia, and then acid with nitric acid. Add molybdate solution and warm. A yellow precipitate is formed.
- d. Dissolve a little of the precipitate in very dilute KOH and then make slightly acid with acetic acid. Explain results.
- e. Mix a small portion of the nucleoprotein with 10 ml. of alcohol. Filter and wash free from HCl with more alcohol. (Freedom from HCl is indicated by absence of AgNO₂-chloride reaction in the filtrate.) Wash free from alcohol with a little water. Transfer small particles of the precipitate to moistened red and blue litmus paper on a microscopic slide. What is the reaction of nucleoprotein thus freed from adherent acid?

² All experiments on nucleoprotein of yeast have been taken from the laboratory notes of Prof. W. J. Giea, of the College of Physicians and Surgeons, New York.

- 4. To Show the Presence of Purine Base Radicals in Nucleoprotein: The nucleic acid portion of the protein molecule contains phosphoric acid. carbohydrate, and purine base radicals (see p. 190). Hence on the complete acid hydrolysis of nucleoprotein material these substances will be liberated as well as the decomposition products of the protein part of the molecule. To show their presence proceed as follows: Transfer the precipitate of nucleoprotein remaining from the previous experiment to a small flask and add 25 to 50 ml. of 5 per cent H2SO4. Boil for an hour or more to decompose. Maintain the original volume by adding water. The solution becomes brown due to the formation of melaninlike substances. The purine bases are set free. Retain one-fourth of the solution for the next experiment. Transfer the remainder to a casserole and add ammonia with thorough mixing, a little at a time, until the fluid is nearly neutral. Then make slightly alkaline with dilute ammonia and filter if not clear. Transfer to a beaker and add about 10 ml. of 5 per cent ammoniacal silver nitrate solution. Purine bases if present will yield a brown flocculent precipitate of their silver compounds. If a precipitate does not appear immediately, examine the solution after it has been allowed to stand for some time undisturbed.
- 5. To Show the Presence of Protein, Carbohydrate, and Phosphoric Acid Radicals in Nucleoprotein: Filter the greater portion of the acid liquid which was reserved from the preceding experiment. Apply the following tests to portions of it: (a) The biuret test, (b) the xanthoproteic test, (c) the Molisch test, (d) Benedict's test, and (e) the test for phosphate.
- 6. Preparation of Nucleoprotein from the Thymus: About 100 g. of fresh thymus gland (lymphatic glands may also be used), freed as nearly as possible from adherent fat, are run through a meat chopper. To this material in a flask add 300 ml. of 0.9 per cent NaCl and allow to stand 24 to 48 hours in the cold. A little chloroform and toluene should be added as preservatives, and the mixture shaken occasionally during this period. Filter. A milk-white liquid is obtained. Precipitate the nucleoprotein from solution by the careful addition of dilute acetic acid. Excess of the acid should be avoided. Ordinarily acetic acid to make a 1 per cent solution is sufficient. Filter off the precipitate. Wash with alcohol and then with ether and dry.
- 7. Experiments on Thymus Nucleoprotein: Repeat the experiments given under Yeast Nucleoprotein (p. 193).
- 8. Preparation of Ribose Nucleic Acid from Yeast: Dilute 50 ml. of 1 per cent NaOH with 250 ml. of water in a casserole and add to this solution 160 g. of compressed yeast cut in small pieces. Heat on the water bath for half an hour with occasional stirring. Remove from the bath and filter at once through a folded filter. To the cooled filtrate add acetic acid until faintly acid to litmus. Filter again. Evaporate the solution to 160 ml. or less, and filter if necessary. Allow to cool to 40° C. or below, then pour with vigorous stirring into 200 ml. of 95 per cent alcohol containing 2 ml. of concentrated HCl. Allow to settle and wash the precipitate by decantation in a tall vessel, twice with 95 per cent alcohol and twice with ether. Transfer to a filter paper. Allow to drain and dry at room temperature.
- Tests on Nucleic Acid from Yeast:² (a) Test the solubility of nucleic acid in cold and hot water, in alcohol, and in dilute acid and alkali. To the solution in alkali add dilute HCl drop by drop until the solution is acid, then add excess of concentrated HCl.

Does nucleic acid coagulate on boiling? Does the solution in hot water gelatinize on cooling?

(b) Try the xanthoproteic reaction and the biuret test.

 $^{^{9}}$ A satisfactory preparation of yeast nucleic acid may be obtained from Merck and Co., Rahway, N. J.

- (c) Dissolve a little nucleic acid in water with the aid of heat. Test the reaction of different portions of the solution with litmus, alizarin, and Congo red solution.
- (d) Boil a small portion of the nucleic acid with about 10 ml. of 10 per cent sulfuric acid for one to two minutes. Divide into three portions.

To one portion apply carbohydrate tests—e.g., the α -naphthol (Molisch) reaction and Tauber's test. What do these indicate?

To a second portion apply a test for purine bases. Add an excess of ammonia and then a little silver nitrate solution.

To the third portion apply the test for phosphate, adding ammonia in slight excess, then making acid with nitric acid, adding molybdate solution and warming.

- 10. Preparation of Chromonucleic Acid: Dissect 230 g. of thymus, pancreas, kidney, or spleen free from fat and grind in a chopping machine. Transfer to a casserole containing 300 ml. of 5 per cent sodium hydroxide. Boil for 35 minutes. Neutralize with acetic acid. Add 50 ml. of colloidal iron solution (Merck's 5 per cent). Filter and allow to stand over night. To the filtrate add two volumes of methyl alcohol, containing 2 per cent of hydrochloric acid. Filter and wash the precipitate with methyl alcohol until free from hydrochloric acid.
- 11. Tests on Chromonucleic Acid: (1-4) Repeat the experiments as given under yeast nucleic acid, above. (5) Make a 4 per cent solution of chromonucleic acid in hot water (0.4 g. to 10 ml.). Allow to cool. What happens? Divide into two portions. To one add a little NaOH solution; to the other add acetic acid. Then neutralize carefully in each case.

Both acetic acid and NaOH decrease the viscosity of the nucleate solution. It may be changed back and forth from the gelatinous to the fluid condition by the alternate addition of acid and alkali.

- 12. Tests on Purine Bases and Derivatives:
 - (a) Xanthine:
 - (1) Silver Nitrate Reaction: Dissolve a little xanthine in ammonia and add silver nitrate solution. Examine a little of the precipitate microscopically.
 - (2) Copper Sulfate Reaction: Dissolve a little of the substance in dilute alkali, make faintly acid with acetic acid. Heat to boiling. Add 1 ml. of 10 per cent CuSO₄, and then a few drops at a time of sodium bisulfite (saturated solution) until the precipitate becomes yellowish. All of the purines give this reaction.
 - (3) Nitric Acid Test: Place a small amount of the substance in a small evaporating dish, add a few drops of concentrated nitric acid, and evaporate to dryness very carefully on a water bath. The yellow residue upon moistening with caustic potash becomes red in color and upon further heating assumes a purplish-red hue. Now add a few drops of water and warm. A yellow solution results which yields a red residue upon evaporation. Compare with a similar reaction on other purine bases and uric acid. (See the murexide test, Chapter 28.)
 - (4) Weidel's Reaction: Bring a small amount of the substance into solution in bromine water. Evaporate to dryness on a water bath. Remove the stopper from an ammonia bottle and by blowing across the mouth of the bottle direct the fumes of ammonia so that they come into contact with the dry residue. Under these conditions the presence of xanthine is shown by the residue assuming a red color. A somewhat brighter color may be obtained by using a trace of nitric acid with the bromine water. By the use of this modification, however, we may get a positive reaction with bodies other than xanthine.
 - (b) Hypoxanthine:
 - (1) Repeat Exps. 1 and 3 under Xanthine. Examine the crystals of hypoxanthine silver nitrate under the microscope. (See Fig. 77.)
 - (2) Dissolve a little of the substance in a very small amount of hot 6 per cent nitric acid and allow to cool. Characteristic whetstone crystals

of hypoxanthine nitrate should be formed. Examine under the microscope. (See Fig. 78.)

(c) Adenine:

- (1) Warm a few crystals of adenine in a test tube with a little water. They should become cloudy at 53° C.
- (2) Dissolve a little adenine in hot water and add a few drops of picric acid. Examine the pale yellow crystals under the microscope. The picrate crystallizes as needle clusters.
- (3) Repeat Exp. 3 under Xanthine.
- (d) Guanine:
- (1) Dissolve a little substance in 20 to 25 times its weight of boiling 5 per cent alcohol. Allow to cool and examine the crystals microscopically.
- (2) Dissolve a little guanine in 20 to 25 times its weight of boiling 5 per cent hydrochloric acid. Allow to cool, and examine the crystals under the microscope. (See Fig. 63.)

(3) Perform Exp. 3 under Xanthine.

(e) Uric Acid: On a small amount of uric acid try the test as given under Xanthine (3). This test on uric acid is called the murexide test. For other tests on uric acid see Chapter 28. Urine.

13. Isolation of Guanine and Adenine from Nucleic Acid (Method of Walter Jones): The amino purines may be isolated from yeast or thymus nucleic acid or from glandular tissue (such as the pancreas) after hydrolysis of the material with sulfuric acid.

Fig. 63. Guanine chloride. (Reproduced from crystals furnished by the late Prof. Walter Jones.)

Place 5 g. of yeast nucleic acid in a 200-ml. Erlenmeyer flask, add 100 ml. of boiling hot 5 per cent sulfuric acid and heat carefully over a small flame to bring the nucleic acid into solution. During this heating which lasts only a minute, the contents of the flask should be kept constantly in motion to avoid burning the undissolved nucleic acid. Close the flask with a soft cork bored with one hole into which is inserted a condensing tube, immerse in a boiling water bath so that the surface of the liquid in the flask is not below the level of the water in the water bath, and allow to heat for about an hour. Disconnect the flask and while its contents are still hot add concentrated ammonia a drop at a time until the fluid is roughly alkaline and then add 5 ml. of concentrated ammonia in

excess. Guanine is thus precipitated in granular form and can be easily filtered off, while all of the other products including phosphoric acid and adenine remain in the ammoniacal solution.

After several hours filter off the precipitate of guanine and wash it with 1 per cent ammonia. Dissolve in as small an amount of 20 per cent sulfuric acid as possible, add a little animal charcoal, and boil. Filter, heat to boiling, and precipitate with excess of ammonia. Filter, dry the precipitate at 40° C., and dissolve it in about 20 parts of boiling 5 per cent hydrochloric acid. As the solution cools guanine chloride separates out as needle-shaped crystals. (See Fig. 63.) Filter off, wash with very dilute hydrochloric acid, and dry in the air (do not put in desiccator). Perform the nitric acid test on the product.

Combine the ammoniacal filtrates obtained in the isolation and purification of guanine. Filter if necessary. The ammonia may then be boiled off and an excess of picric acid added, in which case a yellow precipitate of adenine picrate is produced which is filtered off and dried. It is better, however, to neutralize the ammonia of the combined filtrates and make faintly acid with sulfuric acid. Then precipitate the adenine as its copper compound, decomposing this with hydrogen sulfide and evaporating the filtrate from the copper sulfide to dryness on the water bath. Dissolve the residue in hot 5 per cent sulfuric acid and allow to crystallize out. If necessary dissolve in hot water, decolorize with a little charcoal, and allow to crystallize out again. The compound has the formula $(C_1H_1N_2)_{2^{-1}}H_2SO_4$ 2 H_2O . Apply the picric acid and nitric acid tests as given for adenine (p. 196).

14. The Pyrimidine Derivatives. The pyrimidine derivatives—cytosine, thymine, and uracil—are separated from nucleic acid with some difficulty. The following tests may be made on their solutions.

Reactions for Uracil, Cytosine, and Thymine: Treat the aqueous solution with an excess of bromine. Remove the excess by boiling the solution. Add barium hydroxide in excess. A purple color indicates cytosine or uracil and is due to the purple barium salt of dialuric acid (2-6-8-oxy-7-hydroxy-pyrimidine.

Reflux for a few minutes and distill. If thymine is present, CO₂, urea, and acetol (CH₂COCH₂OH) are formed, and the acetol distills over. Make strongly alkaline with NaOH. Add several drops of o-aminobenzaldehyde. Evaporate over a flame to half the volume. Cool. Make distinctly acid with HCl and then alkaline with NaHCO₂. Filter. A blue fluorescence of 3-oxyquinaldine indicates acetol and the original presence of thymine.

'Mix 3 g. of crystalline o-nitrobensaldehyde with 50 g. of crystalline ferrous sulfate. Add 75 ml. of concentrated ammonia. Heat on a steam bath for one hour. Distill off the o-aminobensaldehyde with steam, The mixture before distillation will keep for two weeks.

8

Milk

COMPOSITION

Milk is the only material elaborated specifically as a food for mammals after birth and is nutritionally an almost complete natural food. It contains protein, fat, and carbohydrate, and inorganic salts are adequate with the exception of iron and copper, which are low. Milk is rich in vitamins A and B₂ and contains B₁, C, D, and niacin in smaller amounts. The dietary efficiency of milk is illustrated in Fig. 64, showing its effect as a supplement to a cereal diet. Its special value here lies in the high content of calcium, riboflavin (vitamin B₂), and vitamin A, and in the satisfactory nature of its protein, in which respects cereal diets are likely

Fig. 64. Dietary efficiency of milk. The rats were twin sisters. The first received bread and apple, the second bread and milk. The bread-and-milk diet led to rapid growth. The bread-and-apple diet was deficient in protein, calcium, phosphorus, and vitamin A. (Sherman, Rouse, Allen, and Woods: J. Biol. Chem., 46, 503 (1921).) See experiment on Dietary Efficiency of Milk, Chapter 33.

to be defective. Muscle meats could furnish the protein but they are low in calcium and vitamin A. Milk is therefore a valuable protective food for the growing child and the adult. It is not, however, satisfactory as a sole food after the age of six months because of its fluid bulk, its iron deficiency, and its rather low content of vitamins E, K, and particularly C and D. Even in the case of infants the latter vitamins are commonly added as supplements to the milk diet.

Although milk is, in general, man's best food, certain individuals are allergic to it. Milk is a specific product of the secretory activity of the mammary gland. The fat appears to arise from the phospholipids of the blood, the lactose from the glucose of the blood, and the casein from amino acids carried by the blood to the mammary gland. The calcium also arises from the blood, the bone acting as a reserve supply of this element.

MILK 199

The milk fat contains glycerides of the higher fatty acids (oleic, palmitic, myristic, and stearic) and of the lower fatty acids (butyric, caproic, caprylic, capric, and lauric). Also present are small amounts of cholesterol, lecithin, cephalin, free fatty acids, and the fat-soluble vitamins. The proteins include casein, lactalbumin, and lactoglobulin. The carbohydrate is lactose. It contains phosphates, citrates and chlorides of calcium, sodium, potassium, and magnesium. Present also are traces of iron, copper, zinc, aluminum, manganese, and iodine, and of the excretory products, urea, creatinine, etc. Normal, unheated milk contains various enzymes including protease, lactase, diastase, lipase, phosphatase, and certain oxidases.

The principal factors influencing the composition of cow milk are breed, ration, phase of lactation period, duration of and intervals between milkings, exercise, and disease. Average milk from Guernsey, Jersey, Ayrshire, Holstein, and Shorthorn cows varies in diminishing order from 5.2 to 3.6 per cent in fat content and from 4.0 to 3.3 per cent in protein; lactose and ash are quite uniform. The fat content of milk tends to increase during milking.

The mammary gland acts as a semipermeable membrane to some blood constituents, while to others there is selectivity. The molar ratios of concentration in milk compared to blood are fat 20, sugar 40, K 7, Ca 14. Mg 4, PO₄ 7, protein 0.5, Cl 0.25, and Na 0.13. The nonprotein nitrogenous constituents are present in about the same concentration in blood and milk.

GENERAL PROPERTIES

Fresh milk, both human and cow, has a reaction of pH 6.6 (and, by coincidence, an osmotic pressure of 6.6 atmospheres). The acidity is believed to be due in part at least to soluble acid phosphates. Milk has a decided buffer action due to the proteins, phosphates, citrates, and bicarbonates it contains. It requires about 30 ml. of N/10 HCl per 100 ml. to change the reaction to pH 5.4 and about 20 ml. of N/10 NaOH to bring the pH to 8.4. Upon standing for a sufficiently long time, unsterilized milk sours; i.e., it becomes strongly acid in reaction to litmus due to the production of the optically inactive lactic acid of fermentation, CH₂-CHOH-COOH, from the lactose contained in it. This is brought about through bacterial activity. The white color is imparted to the milk partly through the fine emulsion of the fat and partly through the medium of the casein in colloidal solution. The specific gravity of milk varies somewhat, the average being about 1.030. Its freezing point is about -0.56° C.

This lactic acid fermentation may be brought about by Streptococcus lactis and other microörganisms. E. coli and certain other bacteria in the human intestines may also cause lactic acid fermentation. The chemical changes in lactic acid fermentation may be indicated by the following equations, the breakdown of the monosaccharides presumably occurring in somewhat the same general way as in the production of lactic acid ir the animal body (see Chapter 10, Muscular Tissue).

 $\begin{array}{cccc} C_{12}H_{23}O_{11} + H_2O \rightarrow C_6H_{12}O_6 + C_6H_{12}O_6 \\ \text{Lactose} & \text{Galactose} & \text{Glucose} \\ C_6H_{12}O_6 \rightarrow 2 \text{ CH}_3 \cdot \text{CO} \cdot \text{CHO} + 2 \text{ H}_2O \rightarrow 2C_2H_6O_3 \\ \text{Galactose} & \text{Methyl glyoxal} & \text{Lactic acid or glucose} \end{array}$

Among the principal preservatives of milk are formaldehyde, hydrogen peroxide, boric acid, borates, benzoic acid, salicylic acid, and salicylates. The use of milk preservatives is illegal in most states.

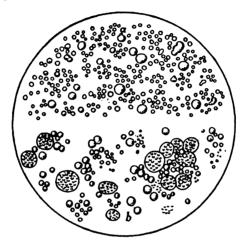

Fig. 65. Normal milk and colostrum:
(a) Normal milk; (b) colostrum.

Fresh milk does not coagulate on being boiled but a film consisting of a combination of casein and calcium salts forms on the surface. If the film be removed, thus allowing a fresh surface to come into contact with the air, a new film will form indefinitely upon the application of heat. Surface evaporation and the presence of fat facilitate the formation of the film, but are not essential. A similar film will form on heating any protein solution containing fat or paraffin. If the milk is of a pronounced acid reaction, through the inception of lactic acid fermentation, or from any other cause, no film will form when heat is applied, but instead a true coagulation will occur. When milk is boiled certain changes occur in its odor and taste. These changes, according to Rettger, are due to a partial decomposition of the milk proteins and are accompanied by the liberation of a volatile sulfide, probably hydrogen sulfide.

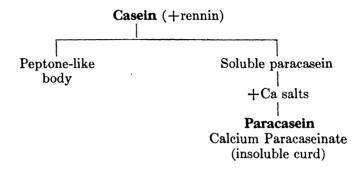

COAGULATION

The milk-curdling enzymes of the gastric and the pancreatic juices have the power of splitting the casein of the milk, through a process of hydrolytic cleavage, into soluble paracasein and a peptone-like body.¹

¹ Porcher: Chimie et industrie, 19,589, 809 (1928). Bosworth (Am. J. Diseases Children, 22, 193 (1921)), however, finds that the casein is split into two equal molecules of paracasein. According to another view the tetracalcium caseinate of milk is split into two molecules of dicalcium paracaseinate which then take up two more equivalents of Ca to form the

MILK 201

This soluble paracase in then forms a combination with the soluble calcium salts of the milk and an insoluble curd of paracase in results. The clear fluid surrounding the curd is known as whey. This action of rennin² may be represented by the following scheme:

There is still considerable confusion of terms when different authorities discuss milk proteins and the action of milk-curdling enzymes upon

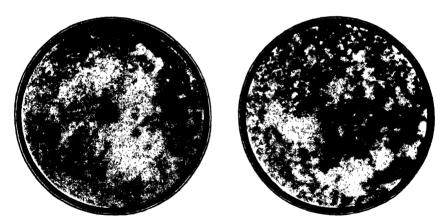

Fig. 66. (Left) Curd of human milk five minutes after ingestion of milk. (Beginning of curd formation.) (One-half actual size.)

Fig. 67. (Right) Curd of human milk ten minutes after ingestion of milk. (Maximum curd formation.) (One-half actual size.)

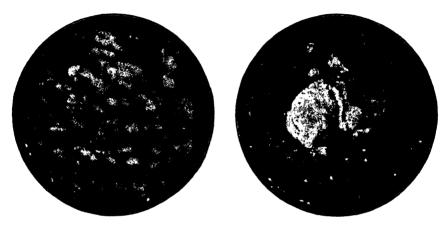

them. English scientists quite uniformly call the principal protein of milk caseinogen, whereas the insoluble curd formed by rennin is termed casein. On the other hand, the Germans and many Americans give the name casein to the milk protein and paracasein to the product of the action of rennin upon this protein.

insoluble paracasein curd. It is clear that the affinity for Ca is increased by the action of rennin, but Palmer considers that this cannot be accounted for by the hydrolysis taking place, but must involve molecular rearrangements or changes in colloidal state.

² For further discussion of rennin action, see Chapter 14.

DIFFERENCES BETWEEN HUMAN AND COW MILK

The most important difference between human milk and cow milk is in the protein content, although there are also differences in the carbohydrate and ash and likewise striking biological differences difficult to define chemically. It has been shown that the casein of human milk differs from the casein of cow milk in being more difficult to precipitate by acid or coagulate by gastric rennin. The casein curd (paracasein) also forms in much looser and more flocculent manner than that in cow milk and is for this reason much more easily digested than the latter.

Frg. 68. (Left) Curd of cow milk regurgitated 10 minutes after ingestion of 500 ml. of whole milk. (One-half actual size.)

Fig. 69. (Right) Curd of cow milk regurgitated 25 minutes after ingestion of 500 ml. of whole milk. (One-half actual size.)

The relative composition of human and cow milk is shown in the following table.

AVERAGE COMPOSITION OF HUMAN AND COW MILK

Constituent	Cow (Per Cent)	Human (Per Cent)
Water	87.0	87.5
Solids	13.0	12.5
Protein (N × 6.38)	3.0-4.0	1.0-1.5
Fat	3.5-5.0	3.0-4.0
Sugar	4.5-4.9	7.0-7.5
Ash	0.7	0.2

In human milk the nitrogen is about equally divided between casein, proteins other than casein, and nonprotein nitrogen; in cow milk three-fourths of the nitrogen is present as casein, about one-fifth as proteins other than casein, and the balance in nonprotein forms.

The composition of goat milk resembles that of cow milk (Holstein) in percentage of water, protein, fat, and sugar.³

Human milk contains less protein, more sugar, and much less ash than cow milk. The percentage composition of human milk at different periods is represented in the following table.

PERCENTAGE COMPOSITION OF HUMAN MILK BY PERIODS

Period	Fat	Sugar	Protein	Casein	Albumin	Ash	Total Solids
Colostrum (1-12 days)	2.83	7.59	2.25			0.31	13.4
Transition (12-30 days)	4.37	7.74	1.56			0.24	13.4
Mature (1-9 mos.)	3.26	7.50	1.15	0.43	0.72	0.21	12.2
Late (10-20 mos.)	3.16	7.47	1.07	0.32	0.75	0.20	12.2

The composition of the ash of milk varies in certain respects during the period of lactation. The following table was reported by Holt, Courtney, and Fales.

PERCENTAGE COMPOSITION OF ASH OF MILK

	Са	Mg	P	Na	K	Cı
Human milk	16.7	2.2	7.3	5.3	23.5	16.5
Cow milk	16.8	1.7	11.6	5 3	20.7	13.6

It will be observed that the composition of the ash of the two varieties of milk is about the same except for phosphorus. The higher phosphorus content in the case of cow milk is due principally to the fact that the milk contains a higher percentage of casein or phosphoprotein. It should be borne in mind that average cow milk contains over three times as much ash as human milk. Therefore unless cow milk has been diluted with more than twice its volume of water there is still present as high a concentration of the inorganic constituents as are present in normal human milk. Hence there is no necessity for the addition of any of these constituents in infant feeding.

Modification of cow milk to resemble more nearly human milk for the purpose of infant feeding usually involves dilution of the milk to reduce

^a U. S. Dept. Ag., Bul. 671.

the content of protein and of inorganic salts, and the addition of sugar (lactose, dextrimaltose, or glucose) to bring up the sugar content to that of human milk. Various means such as heating or acidification with lactic acid are employed to assist in the formation of a softer curd in the infant's stomach. Acidification also increases the proportion of diffusible calcium.

Interesting data relative to the composition of milk from various sources may be gathered from the following table, which was compiled mainly from the results of investigations by Pröscher and by Abderhalden in Bunge's laboratory. It will be noted that the composition of the milk varies directly with the length of time needed for the young of the particular species to double in weight.

	Days Required	100 Parts of Milk Contain					
Species	Birth Weight	Proteins	Ash	Calcium	Phos phorus		
Man		1.6	0.2	0.033	0.015		
Horse		$\frac{2.0}{3.5}$	$0.4 \\ 0.7$	0.124	0.041		
Goat	22.0	3.7	0.8	0.197	0.090		
Sheep Pig		$\frac{4.9}{5.2}$	$0.8 \\ 0.8$	0.245 0.249	0.093		
Cat	9.5	7.0	1.0				
Dog Rabbit		7.4 10.4	$egin{array}{c} 1.3 \ 2.5 \end{array}$	0.455 0.891	0.161		

The secretion of the mammary glands of the newborn of both sexes is called "witches' milk." This secretion is brought about by the passage of prolactin (the hormone of lactation) from the blood of the mother to the fetus.

Fig. 70. Lactose.

MILK 205

Lactose is the principal carbohydrate constituent of milk, and an important member of the disaccharide group. It occurs only in milk, except as it is found in the urine of women during the nursing period, and soon after weaning; it also occurs in the urine of normal persons after the ingestion of a very large amount of lactose in the food. It is not derived directly from the blood, but is a specific product of the cellular activity of the mammary gland. It has strong reducing power, is dextrorotatory, and forms an osazone with phenylhydrazine. Lactose is not fermentable by the ordinary baker's yeast. For changes which lactose undergoes in lactic acid fermentation, see p. 200. The crystalline form of lactose is shown in Fig. 70.

Proteins. Casein is the principal protein constituent of milk, and belongs to the group of phosphoproteins since it contains 0.7 per cent of phosphorus. The sulfur content of casein is rather low; viz., about 0.75 per cent. It is similar to other proteins in its ability to form salts with both acids and bases. Its isoelectric point is about pH 4.7. It is probably present in cow milk in the form of neutral calcium caseinate (Casein Ca₄), and in human milk mainly as potassium caseinate. It is not coagulable upon boiling and is precipitated from its neutral solution by certain metallic salts as well as upon saturation with sodium chloride or magnesium sulfate. Its acid solution is precipitated by mineral acid. By treatment with 0.25 N NaOH for 24 hours at 37° casein may be "dephosphorized," with the loss of some amide nitrogen also.

While casein has generally been considered to be an individual substance, evidence to the contrary has been adduced. Purified casein may apparently be separated by treatment with slightly acidified 60 per cent alcohol into fractions differing in their content of phosphorus and of certain amino acids. The existence of an alcohol-soluble protein distinct from casein has also been suggested.

Casein, serving as it does a similar purpose in all species of animals, is apparently very similar in composition in different species. It is a very weak antigen.

Lactalbumin and lactoglobulin are the other important protein constituents of milk. Whereas the casein of cow milk averages about 3 per cent, albumin makes up about 0.5 per cent and lactoglobulin from 0.05 to 0.25 per cent according to different investigators. In human milk the casein is about equal in amount to the combined albumin and globulin. Of the globulin fraction of milk one component, β -lactoglobulin, has been isolated in pure form and its molecular weight and amino acid distribution determined (pp. 109 and 147). The albumin fraction is likewise composite in nature, as from it has been separated a crystalline fraction insoluble in water, thus having globulin characteristics, also in small amounts a crystalline protein high in carbohydrate consisting of galactose and mannose.

The comparative amino acid composition of the total proteins of human milk, colostral and mature, and cow milk is shown in the following table:

PERCENTAGE OF	AMINO	ACIDS IN	HIMAN	AND COM	MILE	PROTEIN*

	Human Colostrum	Human Milk	Cow Milk
Nitrogen		(16.0)	(16.0)
Sulfur	1	1.6	
Arginine	5.5	4.3	3.8
Histidine		2.9	2.6
Lysine	6.5	6.8	6.6
Tyrosine		5.4	6.4
Tryptophane	2.0	1.7	1.4
Phenylalanine	5.9	5.6	5.7
Cystine		2.1	0.7
Methionine		2.4	3.7
Threonine		4.5	4.5
Leucine	7.9	10.1	10.6
Isoleucine	1	7.5	8.5
Valine		9.5	8.4

^{*} The values in this table are calculated on the assumption, made purely for practical purposes, that 16 g. of total nitrogen represent 100 g. of protein.

It will be seen that human milk is somewhat lower than cow milk in tryosine, methionine, and isoleucine, but is distinctly higher in cystine and possibly valine.

The Fat of Cow and Human Milk. Butterfat has been estimated to contain fatty acids as follows: oleic 31.9, palmitic 15.2, myristic 19.8, stearic 14.9, linolenic 0.1, linoleic 0.2, lauric 5.8, butyric 2.9, caproic 1.9, capric 1.6, and caprylic 0.8 per cent of the total fatty acid. Cow milk fat contains all of the saturated fatty acids with an even number of carbon atoms from butyric to stearic, and is relatively rich in fatty acids of low molecular weight. About 36 per cent of the fat has been found to be of the oleo-disaturated type and the rest of the dioleo-monosaturated type. Thus butter contains little triolein and no tributyrin, but consists of such compounds as butyrodiolein, butyropalmitolein, and oleodipalmitin. When butter becomes rancid through the cleavage of certain of its constituent fats by bacteria the odors of caproic and butyric acids develop.

The principal fatty acids of human milk fat, expressed in percentage of total fat, are oleic 30–37, palmitic 22–24, unsaturated C_{18} diethenoid acids (including linoleic) 7, unsaturated C_{20-22} acids 3–4, stearic 8–9, myristic 8–14, lauric 5–7, and decanoic 2–3. No acids of lower molecular weight than decanoic are present (distinction from cow milk fat). The fatty acid composition of human milk fat more closely resembles that of modern margarine than of butter fat (Hilditch).

The Pigments of Milk. The pigment of the fat of cow milk consists of carotene and small amounts of xanthophylls. The principal pigment is carotene, an unsaturated hydrocarbon pigment which is widely distributed in plants and is the precursor of vitamin A. Milk whey is rich

MILK 207

in riboflavin (vitamin B₂), an orange-red fluorescent pigment, formerly known, in this source, as lactoflavin. For a full discussion of these, and other vitamins of milk, see Chapter 35. Milk fat of the ewe, goat, buffalo, and camel is unpigmented. Fat of human milk may be colored.

Enzymes. Such enzymes as protease, lipase, amylase, galactase, catalase, peroxidases, and xanthine and aldehyde oxidase (Schardinger's enzyme) have been identified in milk, but not all of them in milk of the same species of animal. The ease of detection of phosphatase in raw cow milk has made it the basis of a test for efficiency of pasteurization since the enzyme is destroyed by heating.

Colostrum. Colostrum is the name given to the product of the mammary gland secreted for a short time before parturition and during the early period of lactation (see Fig. 65). It is believed to result from partial equilibration of milk, retained in the alveoli before parturition, with blood since it can be produced during later stages of lactation by suspending milking for a long enough period. Colostrum is yellowish in color, contains more solid matter than ordinary milk, and has a higher specific gravity (1.040–1.080). The most striking difference between colostrum and ordinary milk is the high percentage of globulin in the former. This globulin appears to be identical with the euglobulin of blood serum and seems to furnish this protein to the blood of the infant, which blood at birth is very low in globulin. The protective antibodies of the blood are associated with this globulin fraction. This peculiarity in the protein content is responsible for the coagulation of colostrum upon boiling.

EXPERIMENTS ON MILK

- Reaction: Test the reaction of fresh cow milk to litmus or other suitable indicator paper.
- 2. Biuret Test: Make the biuret test according to the directions given on p. 156.
- Microscopical Examination: Examine fresh whole milk, skimmed or centrifuged milk, and colostrum under the microscope. Compare the microscopical appearance with Fig. 65.
- 4. Specific Gravity: Determine the specific gravity of both whole and skimmed milk (see p. 211). Which possesses the higher specific gravity? Explain why this is so.
- 5. Film Formation: Place 10 ml. of milk in a small beaker and boil a few minutes. Note the formation of a film. Remove the film and heat again. Does the film now form? Of what substance is this film composed? The biuret test was positive; why do we not get a coagulation here when we heat to boiling?
- 6. Coagulation Test: Place about 5 ml. of milk in a test tube, acidify slightly with dilute acetic acid, and heat to boiling. Do you get any coagulation? Why?
- 7. Guaiac Test: To about 5 ml. of water in a test tube add 3 drops of milk and enough alcoholic solution of guaiac (strength about 1:60) to cause turbidity. Thoroughly mix the fluids by shaking and observe any change which may gradually take place in the color of the mixture. If no blue color appears in a short time, heat the tube gently below 60° C. and observe whether the color reaction is hastened. In case a blue color does not appear in the course of a few minutes, add hydrogen peroxide or

old turpentine, drop by drop, until the color is observed. (Fresh milk will frequently give this blue color when treated with an alcoholic solution of guaiac without the addition of hydrogen peroxide or old turpentine. Those milks which respond positively, fail to do so after boiling 15 to 20 seconds. What substances besides milk respond to this test? See the discussion in Chapter 22.)

- 8. Benzidine Peroxidase Reaction (Wilkinson and Peters): To 10 ml. of the milk to be tested add 2 ml. of a 4 per cent alcoholic solution of benzidine, sufficient acetic acid to coagulate the milk (usually 2 to 3 drops), and finally 2 ml. of a 3 per cent solution of hydrogen peroxide. Raw milk yields an immediate blue color. In adding the peroxide it is best to permit it to flow slowly down the wall of the vessel containing the mixture instead of allowing it to mix with the milk. Milk which has been heated to 78° C. or above remains unchanged. Paraphenylenediamine hydrochloride may be used in place of benzidine.
- 9. Phosphatase Test for Pasteurization (Kay-Graham Method, Modified4):
 Principle: The destructive effect of heat on the natural phosphatase in raw milk is used as the basis for testing the efficiency of pasteurization.
 Phosphatase activity is measured by the hydrolysis of disodium phenyl phosphate and colorimetric estimation of the released phenol by means of the Folin-Ciocalteu reagent (see Chapter 32).

Procedure: Buffer substrate is prepared by dissolving 11.54 g. of sodium diethyl barbiturate (sodium veronal) and 1.09 g. of disodium phenyl phosphate in water and diluting to one liter. A few ml. of chloroform are added, with shaking, and the solution is stored in a refrigerator.

To 10 ml. of the buffer substrate in each of five large test tubes add 0.5 ml. of each of the following samples: (a) Pasteurized milk to be tested, (b) raw milk (e.g., certified), (c) milk previously boiled 2 minutes and cooled, (d) sample c plus 0.05 mg. phenol, (e) sample c plus 0.1 mg. phenol. The phenol may be added with a micropipet, using 0.1 per cent phenol solution (0.1 ml. = 0.1 mg.).

Incubate all tubes at 37° C. overnight or at 47° C. for 10 minutes ("short test"). Cool and add 4.5 ml. of diluted Folin-Ciocalteu phenol reagent (1 part reagent (see Appendix) plus 2 parts water, diluted as needed). Mix, allow to stand 3 minutes, and filter (Whatman No. 40 is suitable). To 5 ml. of each filtrate in small test tubes add 1 ml. of 14 per cent sodium carbonate solution. Mix by rotation and heat in a boiling water bath for 5 minutes. Filter and cool. Compare the depth of the blue colors in tubes (a) and (b) with those in tubes (c), (d), and (e).

For more precise control work, standards may be prepared with graded additions of phenol, or artificial color standards may be employed. Blue or purple colors corresponding to phenol values greater than 0.05 mg. per 0.5 ml. of milk indicate progressively inadequate pasteurization. Lower values (pale blue) are regarded as indicative of heating for the equivalent of 30 minutes at 143° F., or more.

- 10. Influence of Gastric Rennin on Milk: Prepare a series of five tubes as follows:
 - a. 5 ml. of fresh milk + 0.2 per cent HCl (add drop by drop until a precipitate forms).
 - b. 5 ml. of fresh milk + 5 drops of rennin solution.
 - c. 5 ml. of fresh milk + 10 drops of 0.5 per cent Na₂CO₃.
 - d. 5 ml. of fresh milk + 10 drops of ammonium oxalate.
 - e. 5 ml. of fresh milk + 5 drops of 0.2 per cent HCl.

⁴ For various modifications of this procedure in practical milk control work, see "Standard Methods for the Examination of Dairy Products," 8th ed., New York, American Public Health Association, 1941.

⁵ Any commercial rennin or rennet preparation or an extract of the gastric mucosa of the pig may be employed.

Now to each of the tubes (c), (d), and (e) add 5 drops of rennin solution. Place the whole series of five tubes at 40° C. and after 10 to 15 minutes note what is occurring in the different tubes. Give a reason for each particular result.

- 11. Preparation of Casein: Into a 600-ml. beaker introduce 200 ml. of skimmed (or centrifuged) milk. Add an equal volume of water. Add from a pipet very carefully, drop by drop with thorough stirring, 10 per cent HCl until a flocculent precipitate forms. (Casein precipitates best at a point slightly more acid than its isoelectric point of pH 4.7.) From 3 to 5 ml. of acid are commonly required. In milk casein functions as an acid and exists as K and Ca caseinates from which compounds it is released by the acid. As the isoelectric point is passed, however, the casein begins to function as a base and go into solution as casein hydrochloride. Hence excess of acid must be avoided. If too much acid be added, run in, drop by drop, 10 per cent NaOH solution until precipitation occurs and a clear supernatant fluid is obtained. Allow the precipitate to settle, decant the supernatant fluid, and reserve it for use in later (12-14) experiments. Filter off the precipitate of casein and remove the excess of moisture by pressing it between filter papers. Transfer the casein to a small beaker, add enough 95 per cent alcohol to cover it, and stir for a few moments. Filter, and press the precipitate between filter papers to remove the alcohol. Repeat the extraction with alcohol, making sure that the casein is in a finely divided condition. Transfer the casein again to a small dry beaker, cover the precipitate with ether and heat on a water bath, with any flames turned out, for ten minutes, stirring continuously. Filter (reserve the filtrate), and press the precipitate as dry as possible between filter papers. Open the papers and allow the ether to evaporate spontaneously. Grind the precipitate to a powder in a mortar. Upon the casein prepared in this way make the following tests:
 - a. Solubility: Try the solubility in water, sodium chloride, dilute acid, and alkali.
 - b. Millon's Reaction: Make the test according to the directions given on p. 154.
 - c. Cystine and Cysteine Sulfur: Test for cystine and cysteine sulfur according to the directions given on p. 153.
 - d. Fusion Test for Phosphorus: Test for phosphorus by fusion according to the directions given on p. 193.
- 12. Coagulable Proteins of Milk: Place the filtrate from the original casein precipitate in a casserole and heat, on a wire gauze, over a free flame. As the solution concentrates, a coagulum consisting of lactalbumin and lactoglobulin will form. Continue to concentrate the solution until the volume is about one-half that of the original solution. Filter off the coagulable proteins (reserve the filtrate) and test them as follows:
 - a. Millon's Reaction: Make the test according to the directions given on p. 154.
 - b. Cystine and Cysteine Sulfur: Make the test according to the directions given on p. 153. Do the coagulable proteins differ from casein in their reaction to this test? Why?
- 13. Detection of Calcium Phosphate: Evaporate the filtrate from the coagulable proteins, on a water bath, until crystals begin to form. It may be necessary to concentrate to 15 ml. before any crystallization will be observed. Cool the solution, filter off the crystals (reserve the filtrate), and test them as follows:
 - a. Microscopical Examination: Examine the crystals and compare them with those in Fig. 71.
- ⁶ For the preparation of very pure case in it is better if the milk be centrifuged several times in a separator, then a small amount of dilute alkali added and the milk centrifuged several times more. Case in is also purified by repeated solution in dilute alkali and reprecipitation by acid.

- b. Dissolve the crystals in nitric acid. Test part of the acid solution for phosphates. Render the remainder of the solution slightly alkaline with ammonia, then acidify with acetic acid and add ammonium oxalate. Examine the crystals under the microscope and compare them with those in Fig. 241, Chapter 30.
- 14. Detection of Lactose: Concentrate the filtrate from the calcium phosphate until it is of a syruplike consistency, and pour into several volumes of acetone to precipitate the lactose in crystalline form.

Fig. 71. Calcium phosphate.

- a. Microscopical Examination: Examine the crystals and compare them with those in Fig. 70.
- b. Benedict's Test: Try Benedict's test upon the mother liquor.
- c. Phenylhydrazine Test: Apply the phenylhydrazine test to some of the mother liquor according to the directions given on p. 55.
- 15. Milk Fat: Evaporate the ether filtrate from the casein (Exp. 11) and observe the fatty residue. The milk fat was carried down with the precipitate of casein and was removed when the latter was treated with ether. If centrifuged

milk was used in the preparation of the casein the amount of fat in the ether filtrate may be very small.

- 16. Saponification of Butter: Dissolve a small amount of butter in alcohol made strongly alkaline with potassium hydroxide. Place the alcoholic-potash solution in a casserole, add about 100 ml. of water and boil for 10 to 15 minutes or until the odor of alcohol cannot be detected. Place the casserole in a hood and neutralize the solution with sulfuric acid. Note the odor of volatile fatty acids, particularly butyric acid. Under certain conditions the odor of ethyl butyrate may also be detected.
- 17. Detection of Preservatives. In these tests two controls should be run: one with pure milk and one with milk to which a very small amount of the preservative has been added.
- a. Formaldehyde: Leach's Hydrochloric Acid Test: In a porcelain dish or casserole mix 10 ml. of milk and 10 ml. of concentrated HCl containing about 1 ml. of 10 per cent ferric chloride solution to each 500 ml. of acid. Gradually raise the temperature of the mixture, on a water bath, nearly to the boiling point, with occasional stirring to break up the curd. If formaldehyde is present a violet color is produced, while a brown color develops in the absence of formaldehyde. In case of doubt the mixture, after having been heated nearly to the boiling point for about one minute, should be diluted with 50 to 75 ml. of water, and the color of the diluted fluid carefully noted, since the violet color if present will quickly disappear. Formaldehyde may be detected by this test when present in the proportion 1: 250,000.
- b. Salicylic Acid and Salicylates: Acidify 20 ml. of milk with 1 ml. of 10 per cent HCl, shake well to break up the curd, add 25 ml. of ether, mix thoroughly, and allow the mixture to stand. By means of a pipet or aspirator remove 5 ml. of the ethereal extract, evaporate it almost to dryness, boil the residue with 10 ml. of 40 per cent alcohol, and cool the alcoholic solution. Make the volume 10 ml., filter through a dry paper if necessary to remove the fat, and to 5 ml. of the filtrate, which represents 2 ml. of milk, add 2 ml. of a 2 per cent solution of neutral ferric chloride. The production of a purple or violet color indicates the presence of salicylic acid.

This test may form the basis of a quantitative colorimetric method by

MILK 211

diluting the final solution to 50 ml. and comparing this with standard solutions of salicylic acid.

- c. Hydrogen Peroxide: Add 2 to 3 drops of a 2 per cent aqueous solution of para-phenylenediamine hydrochloride to 10 to 15 ml. of milk. If hydrogen peroxide is present a blue color will be produced immediately upon shaking the mixture or after allowing it to stand for a few minutes. It is claimed that hydrogen peroxide may be detected by this test when present in the proportion 1:40,000.
- d. Boric Acid and Borates: Immerse a strip of turmeric paper into 15 ml. of milk previously acidified with 1 ml. of concentrated HCl. After about one minute remove it and allow it to dry in the air. The presence of boric acid is indicated by the production of a deep red color which changes to green or blue upon treatment with a dilute alkali. A confirmatory test may be conducted on the acid solution of the ash. (See Exp. 5, p. 213.)
- e. Benzoic Acid: Shake 5 ml. of strong HCl with 50 ml. of milk in a flask. Extract by gently shaking with successive portions of ether, avoiding the formation of an emulsion. Evaporate off the ether. Stir the residue with dilute ammonia. Pour off and evaporate to dryness on a water bath to remove free NH₂. Dissolve in 1 ml. of water and add a few drops of ferric chloride solution. A flesh-colored precipitate of ferric benzoate forms.

OUANTITATIVE ANALYSIS OF MILK⁷

1. Collection of Human Milk for Analysis. There are two methods of obtaining samples of breast milk for analysis.

First Method: Express all the milk from one breast and mix thoroughly. Second Method: Draw one ounce of milk before nursing and one ounce after nursing. Mix the two samples thoroughly. The best time for obtaining samples is 9 to 10 A.M.

2. Specific Gravity. This may be determined accurately by means of a pyknometer or more conveniently by means of a Soxhlet, Veith, or Quevenne lactometer. A lactometer reading of 32° denotes a specific gravity of 1.032. The determination should be made at about 60° F. (15.6° C.) and the lactometer reading corrected by adding or subtracting 0.1° for every degree F. above or below that temperature.

3. Fat:

a. Babcock's Centrifugal Method: Principle: This method involves the breaking of the emulsion of fat in milk by means of concentrated sulfuric acid, centrifugation of the acid solution in the special tube shown in Fig. 72, and the subsequent reading of the percentage of fat in the graduated neck. Larger Babcock bottles are commonly used for testing cow milk or cream; these are supplied with pipets calibrated to deliver 18- or 9-g. charges, respectively. The method is accurate to within 0.5 per cent.

Procedure: By means of a special narrow pipet introduce milk into the tube up to the 5-ml. mark. Now add sufficient sulfuric acid (sp. gr. 1,83-1,834) to fill the body of the tube and rotate the tube to secure a

'See "Standard Methods for the Examination of Dairy Products," New York, American Public Health Association, 8th ed., (1941); also "Official and Tentative Methods of Analysis," Association of Official Agricultural Chemists, Washington, D.C., 5th ed., (1940).

A modification of this method for use with sweetened dairy products (e.g., ice cream) and entailing the use of a different type of centrifuge tube has been proposed by Halverson. Another modification involving the use of mixtures of glacial acetic, sulfuric, and nitric acids instead of sulfuric acid alone has been proposed by Francis and Morgan. These authors use the regulation Babcock tube, and the method is applicable to the analysis of ice cream, and evaporated, malted, and dried milk.

homogeneous acid-milk solution. Fill the neck of the tube with an acidalcohol mixture. Centrifuge the tube and contents for one to two minutes and read off the percentage of fat by means of the graduated neck of the tube. If the top of the fat column is not at zero it may be brought there by the addition of hot water and a moment's recentrifugation.

In case very rich milk (over 5 per cent fat) is under examination, it may be diluted with an equal volume of water before examination and the fat percentage multiplied by 2. In the examination of cream it is

customary to dilute the sample with four volumes of water

and multiply the resultant fat value by 5.

b. Roese-Gottlieb Method: Principle: The milk is made alkaline and extracted repeatedly with petroleum benzin and the filtered extract evaporated to dryness in a tared flask. This method, together with the Babcock procedure, is "official" in the A.O.A.C. Book of Methods (see footnote 7, p. 211) and is adaptable to butter, ice cream, dried milk, etc.

Procedure: Transfer 10 g. of the sample to a Röhrig tube or a similar apparatus (Mojonnier flasks¹⁰ (Fig. 73) are widely used in dairy laboratories), add 1.25 ml. of NH₄OH (2 ml. if the sample is sour), and mix thoroughly. Add 10 ml. of 95 per cent alcohol and mix well. Add 25 ml. of ether, shake vigorously for 30 seconds, add 25 ml. of petroleum benzin (redistilled slowly at a temperature below 65°), and shake again for 30 seconds. Let stand 20 minutes, or until the upper liquid is practically clear. Draw off as much as possible of the ether-fat solution (usually 0.5 to 0.8 ml. will be left) into a flask through a small, quick-acting filter. Again extract the liquid remaining in the tube, this time with 15 ml. of each solvent; shake vigorously 30 seconds after each addition and allow to settle. Draw off the clear solution through the small filter into the same flask as before and wash the tip of the spigot, the funnel, and the filter with a few ml. of a mixture of the two solvents, in equal parts, free from suspended H₂O. To insure complete removal of the fat, a third extraction is necessary. (This third extraction yields less than 1 mg. of fat if the previous solutions have been drawn off closely.) Add a glass bead and evaporate the ethers slowly on a warm surface: then dry the fat in a boiling water oven to constant weight. Weigh the flask with a similar flask as a counterpoise. Do not wipe the flask immediately before weighing. Remove the fat completely with petroleum benzin. Deduct the weight of the dried flask with residue and bead to obtain the weight of fat. Finally, correct this weight by a blank determination on the reagents used.

- c. Soxhlet Method: This classical procedure is suitable for the determination of fat in solid materials such as dried milk. (Fig. 74.)
- 4. Total Solids: Introduce 2 to 5 g. of milk into a weighed flat-bottomed platinum dish¹¹ (which may, if desired, contain 15 to 20 g. of pure, dry sand spread over the bottom) and quickly ascertain the weight to milligrams. Expel the major portion of the water by heating the open dish on a water bath and continue the heating in an air bath or water oven at 97° to 100° C. until the weight is constant. (If platinum dishes are

^{*} This mixture consists of equal volumes of amyl alcohol and concentrated hydrochloric acid.

¹⁰ Obtained from Mojonnier Bros. Co., 4601 West Ohio St., Chicago 44, Ill.

¹¹ Lead or aluminum foil dishes which are much cheaper make a very satisfactory substitute for the platinum dishes.

213 MILK

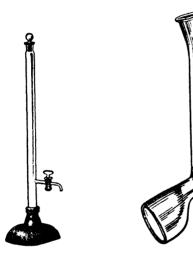

employed this residue may be used in the determination of ash according to the method described below.)

Calculation:12 Divide the weight of the residue, in grams, by the weight of milk used, in grams. The quotient multiplied by 100 gives the percentage of solids contained in the milk examined.

5. Ash: Heat the dry solids from 2 to 5 g. of milk, obtained according to the method just given, over a very low flame 13 until a white or light gray ash is obtained. If the determination is made directly on fluid milk, weigh quickly about 20 ml., add 6 ml. concentrated IINO3, evaporate,

and ignite as above. Cool the dish in a desiccator and weigh. (This ash may be used in testing for borates according to the directions given on p. 211.)

6. Proteins: Introduce a known weight of milk (5 to 10 g.) into a 500-ml. Kjeldahl digestion flask and add 20 ml. of concentrated sulfuric acid and about 0.2 g. of copper sulfate. Expel the major portion of the water by heating

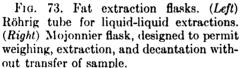

Fig. 74. Soxhlet apparatus.

over a low flame and finally use a full flame and allow the mixture to boil one to two hours. Complete the determination according to the directions given under the Kjeldahl Method, Chapter 32. If large amounts of milk are not available, a micro method may be used (see Chapter 32.) Calculation: Multiply the total nitrogen content by the factor 6.3814 to obtain the protein content of the milk examined.

12 The percentage of total solids may be calculated from the specific gravity and percentage of fat by means of the following formula:

$$S = 0.25 L + 1.2 F$$

S = total solids. L = lactometer reading (third and fourth decimal places of specific gravity). F = fat content.

18 Great care should be used in this ignition, the dish at no time being heated above a faint redness, as chlorides may volatilise.

16 The usual factor employed for the calculation of protein from the nitrogen content is 6.25 and is based on the assumption that proteins contain on the average 16 per cent of 7. Casein: To 10.5 ml. (or a weighed equivalent) of fresh milk in a beaker, add 90 ml. of warm water (40° to 42° C.) and 1.5 ml. of 10 per cent acetic acid and stir. After 5 minutes' standing decant on an acid-washed filter, and wash the precipitate by decantation several times with cold water. Transfer the precipitate to the filter and repeat the washing twice. The filtrate should be clear or very nearly so. If the first portions are not clear, repeat the filtration and complete the washing of the precipitate. Determine the nitrogen content in the washed precipitate and filter, as directed in Exp. 6.

Calculation: Total $N \times 6.38$ = case in content of aliquot.

8. Hart's Casein Method: Introduce 10.5 ml. of milk into a 200-ml. Erlenmeyer flask and add 75 ml. of distilled water and 1.0 to 1.5 ml. of 10 per cent acetic acid. 15 Mix the contents by giving the flask a vigorous rotary motion. The precipitated casein is now filtered off upon a 9- to 11-cm. filter paper. 16 Wash out the absorbed and loosely combined acetic acid by means of cold water. Continue the washing of both the casein on the filter and that adhering to the flask, until the wash water has reached a volume of at least 250 ml.

Now return the precipitate and paper to the original Erlenmeyer flask, add 75 to 80 ml. of neutral (carbon-dioxide free) water, 10 ml. of 0.1 N potassium hydroxide, and a few drops of phenolphthalein. Stopper the flask and shake it vigorously, by hand or machine, until the casein has been brought into solution.¹⁷ Rinse the stopper with neutral (carbon-dioxide free) water and titrate the alkaline casein solution at once with 0.1 N hydrochloric acid until there is a disappearance of all red color.¹⁸

Calculation: Subtract the corrected 18 acid reading from the 10 ml. of alkali used. The difference is the percentage of casein in the milk. For example, if it takes 6.7 ml. of 0.1 N hydrochloric acid to titrate the alkaline solution to the end-point and the check test was equivalent to 0.2 ml. of 0.1 N acid, the casein value would be obtained as follows:

$$10 - (6.7 + 0.2) = 3.1$$
 per cent casein

9. Lactalbumin: Exactly neutralize the filtrate obtained under Exp. 7 with 10 per cent NaOH solution, add 0.3 ml. of 10 per cent acetic acid, and heat on a steam bath until the albumin is completely precipitated. Collect the precipitate on an acid-washed filter, wash with cold H₂O, and determine the nitrogen as directed under Exp. 6.

Calculation: Multiply the total nitrogen by the factor 6.38 to obtain the lactalbumin content.¹⁹

10. Lactose: To about 350 ml. of water in a beaker add 20 g. of milk, mix thoroughly, acidify the fluid with about 2 ml. of 10 per cent acetic acid,

nitrogen. This special factor of 6.38 is used to calculate the protein content from the total nitrogen, since the total protein constituents of milk have a mean nitrogen content of about 15.7 per cent.

16 In general 1.5 ml. of acetic acid gives a clear solution which filters nicely, but occasionally, when the milk has a low casein value, it is advisable to use less acetic acid.

¹⁶ The process of filtration may be retarded through the packing of the casein mass upon the filter paper. In this case conduct a fine stream of cold water against the upper point of contact of filter paper and casein. By this means the casein precipitate is loosened and gathers in the apex of the filter. This procedure is very essential. It is not necessary to remove the casein which adheres to the interior of the flask.

¹⁷ Solution is indicated by the disappearance of the white casein particles which would otherwise settle to the bottom of the flask.

¹⁸ A check test should be run parallel with the entire determination. Even with special precautions as to neutrality, it is generally found that an acid check of 0.2 to 0.3 ml. will be obtained. This check titration should be *added* to the volume of acid used in titration.

¹⁹ This factor is probably somewhat high for true lactalbumin but it is the one officially adopted by the Association of Official Agricultural Chemists and the American Public Health Association.

MILK 215

and stir the acidified mixture continuously until a flocculent precipitate forms. At this point the reaction should be distinctly acid to litmus. Heat the solution to boiling for one-half hour, filter, rinse the beaker thoroughly, and wash the precipitated proteins and the adherent fat with hot water. Combine the filtrate and wash water and concentrate the mixture to about 150 ml. Cool the solution and dilute it to 200 ml. in a volumetric flask. Titrate this sugar solution according to directions given under Benedict's Method, Chapter 32.

Myers recommends the following procedure for the determination of lactose in milk. One part of milk is mixed with an equal volume of phosphotungstic acid solution (70.0 g. of acid and 200 ml. of concentrated HCl in 1 liter of water) and 2 to 3 parts of water. Mix well, filter until clear, and titrate the clear filtrate against Benedict's solution (25 ml. reduced by 67 mg. of lactose).

Bock's Method for Lactose in Milk: Pipet 20 ml. of milk into a 100-ml. volumetric flask. From a pipet or buret add 12 ml. of 10 per cent sodium tungstate and 12 ml. of $\frac{2}{3}$ N sulfuric acid. Mix by rotating the flask, dilute to the mark, and filter. Determine the lactose in the filtrate by titration with Benedict's solution.

Calculation: Make the calculation in the above titration methods, according to directions given under Benedict's Method, Chapter 32, bearing in mind that 25 ml. of Benedict's solution are completely reduced by 0.067 g. of lactose.

11. Micro Method for Lactose in Milk:

Principle: Lactose is determined on the protein-free filtrate of milk by a copper reduction method, following the method of Folin and Wu for blood sugar. This method is well suited to routine analyses.

Procedure: Introduce 1.0 ml. of milk into a 100-ml. volumetric flask, add 2 ml. of 10 per cent sodium tungstate. Add gradually 2 ml. of 23 N sulfuric acid (or 16 ml. of N/12 acid), mix well, and let stand 5 minutes. Dilute to the mark with water and filter. Into a Folin-Wu sugar tube introduce 1 ml. of the filtrate and 1 ml. of water. Into another tube place 2 ml. of standard lactose solution. 4 Add 2 ml. of the Folin-Wu alkaline copper solution (Chapter 23) to each tube, and heat in boiling water for 8 minutes. Cool and add 4 ml. of acid molybdate reagent (Chapter 23) to each tube. After 1 minute, add diluted acid molybdate solution (1:4) to the 25-ml. mark, mix, and compare in the colorimeter.

Calculation:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.6 \times \frac{100}{0.01} \times \frac{1}{1000} = \text{Per cent lactose}$$

³⁰ Prepare a stock standard solution by dissolving 1 g. of lactose in 0.2 per cent bensoic acid and making up to a volume of 100 ml. The working standard is prepared by diluting 3 ml. of the stock solution to 100 ml. with 0.2 per cent bensoic acid (2 ml. = 0.6 mg. lactose).

Epithelial and Connective Tissues, and Teeth

EPITHELIAL TISSUE (KERATIN)

The major portion of hair, horn, hoof, feathers, nails, and the epidermal layer of the skin is made up of albuminoid proteins called keratins. As a class the keratins are characterized by their extreme insolubility in the usual protein solvents, their lack of digestibility, and their high sulfur content, most of which is in the form of cystine. These characteristics are not unrelated; the keratin molecule is considered to consist of closely packed polypeptide chains which are held together by the disulfide bond of cystine, the resistance to solvents and enzymes being associated with the close packing of the chains. This view is supported by the fact that if wool, for example, is ground to a fine powder by mechanical means it becomes more soluble and more digestible.

According to Block the various keratins may be further characterized as eukeratins and pseudokeratins. The eukeratins contain, in addition to other amino acids, the amino acids histidine, lysine, and arginine in the definite proportion of 1:4:12, with from 3 to 5 per cent sulfur, nearly all of which is cystine. They are found largely in the hair, nails, feathers, horn, etc. The pseudokeratins, found chiefly in the skin and nervous tissue, contain less sulfur, from 1 to 3 per cent, and do not show the same histidine:lysine:arginine ratios as the eukeratins. It has been shown by x-ray crystallography that the intramolecular spatial arrangement of keratin can be modified under the influence of pressure or stretching. Such differences in molecular configuration of keratin may exist in the varied anatomic forms of epithelial tissue.

The keratins are not acted upon by the gastric or pancreatic juice. This is perhaps due more to lack of physical accessibility to the proteolytic enzymes than to lack of specific types of peptide linkages, since if keratin is reduced so that the disulfide bonds are broken and a sulfhydryl protein (kerateine) is formed, this latter is digestible by pepsin and trypsin. The keratins appear to be digestible by an enzyme in the intestine of the clothes moth at pH 9 in the presence of the reducing medium yielded by the H₂S liberated through bacterial action in the intestine.

The percentage composition of some typical keratins is given in the table as shown on p. 217.

The composition of human hair is influenced by its color and by the race, sex, age, and purity of breeding of the individual. It may be differentiated from all other animal hair or wool by its high content of cystine. Most of the S of hair is in the form of cystine, with some cysteine usually

present. Human hair contains from 9 to 17 per cent of cystine, sheep's wool 8 to 14 per cent, and feathers 7 to 12 per cent. It is claimed that the vitamins inositol, nicotinic acid, pantothenic acid and riboflavin are present in normal rat and human hair in about the same ratio as in other tissues.¹

	_	Percentage Composition					
	Source		Н	o	N	S	
Nails	3	51.0	6.9	21.8	17.5	2.8	
Horn		50.9	6.9			3.2	
	Indian	44.1	6.5	29.2	15.4	4.8	
Human Hair	Japanese	43.0	5.9	31.5	14.6	5.0	
	Negro	43.9	6.4	30.0	14.9	4.8	
Hum	Caucasian (adults)	44.5	6.4	28.7	15.8	5.2	
. , ,	Caucasian (children)	43.2	6.5	30.8	14.6	4.9	

From the analyses of the skin of the dog, rabbit, and man for mineral constituents, it has been shown that there is an individual variability in composition in the same species as well as distinct differences among different species. The addition of cystine to a diet deficient in this amino acid appears to favor the growth of hair to a greater extent than it affects the growth of body tissue as a whole.

EXPERIMENTS ON EPITHELIAL TISSUE (KERATIN)

Horn shavings or nail parings may be used in the experiments which follow:

- Solubility: Test the solubility of keratin in water, dilute and concentrated acid, and alkali.
- 2. Millon's Reaction.
- 3. Xanthoproteic Reaction.
- 4. Glyoxylic Acid Reaction (Hopkins-Cole).
- 5. Test for Cystine and Cysteine Sulfur.

What amino acids do these tests show to be present in keratin?

CONNECTIVE TISSUE

I. WHITE FIBROUS TISSUE

The principal solid constituent of white fibrous connective tissue is the albuminoid collagen. This substance is also found in smaller percentage in

¹ Novak and Bergeim: J. Biol. Chem., 155, 283 (1944).

cartilage, bone, and ligament, but the collagen from the various sources is not identical in composition. In common with the keratins, collagen is insoluble in the usual protein solvents, presumably because of the close packing of the polypeptide chains, as with the keratins. It differs from keratin in containing much less sulfur, and in amino acid composition. It has been estimated that glycine represents one-third of all the amino acid residues in the collagen molecule; a second third of the molecule is composed of proline and hydroxyproline, with the other amino acids making up the remainder of the molecule. It is digested slowly by pepsin-HCl but by trypsin only at temperatures above 40° C. or after previous action of pepsin. One of the chief characteristics of collagen is the property of being converted by boiling acid or water to gelatin. The process does not seem to be one of hydrolysis since there is no increase in amino nitrogen. Some intramolecular change may occur but the x-ray diagram does not change. This suggests that the alteration may be largely a physical one. The amino acid composition is essentially that of gelatin (see p. 109). ·

The form of white fibrous tissue most satisfactory for general experiments is the tendo achillis of the ox. The fresh tissue has the following composition:

Solids 37.1 Inorganic matter 0.5 Organic matter 36.6 Fatty substance (ether-soluble) 1.0 Coagulable protein 0.2 Mucoid 1.3 Elastin 1.6 Collagen 31.6 Extractives, etc 0.9	Water
Organic matter 36.6 Fatty substance (ether-soluble) 1.0 Coagulable protein 0.2 Mucoid 1.3 Elastin 1.6 Collagen 31.6	Solids 37.1
Fatty substance (ether-soluble) 1.0 Coagulable protein 0.2 Mucoid 1.3 Elastin 1.6 Collagen 31.6	Inorganic matter
Coagulable protein 0.2 Mucoid 1.3 Elastin 1.6 Collagen 31.6	Organic matter
Mucoid 1.3 Elastin 1.6 Collagen 31.6	Fatty substance (ether-soluble) 1.0
Elastin 1.6 Collagen 31.6	Coagulable protein 0.2
Collagen 31.6	Mucoid
	Elastin
Extractives, etc 0.9	Collagen 31.6
	Extractives, etc

The mucoid just mentioned is called tendomucoid and is a glycoprotein. It possesses properties similar to those of other connective-tissue mucoids, e.g., osseomucoid and chondromucoid.

Gelatin, the substance which results from the treatment of collagen with boiling water, is sometimes classed as an albuminoid. It is probably better to consider gelatin as a protein derivative not properly belonging to any of the recognized classes of proteins. Gelatin differs from the keratins and collagen in being easily soluble and digestible. Gelatin is not a complete protein from the nutritional point of view, since it is lacking in tryptophane and low or lacking in certain other amino acids (see p. 109). Thus it is not satisfactory as the sole dietary protein, but because of its ease of digestion and absorption it is used as an accessory protein in the diet, particularly in the case of convalescents. Attempts to remedy the dietary deficiencies of gelatin by supplementing the diet with the missing amino acids have not been successful; the reason is not known. Gelatin gives a negative Hopkins-Cole test because it is lacking in tryptophane. The low content of tyrosine and cystine usually results in a negative or at

the most a faintly positive reaction with Million's reagent and the leadblackening test. The isoelectric point of gelatin is about pH 4.7.

EXPERIMENTS ON WHITE FIBROUS TISSUE

The tendo achillis of the ox may be taken as a satisfactory type of the white fibrous connective tissue.

- 1. Preparation of Tendomucoid: Dissect away the fascia from about the tendon and cut the clean tendon into small pieces. Wash the pieces in running water, subjecting them to pressure in order to remove as much as possible of the soluble protein and inorganic salts. This washing is very important. Transfer the washed pieces of tendon to a flask and add 300 ml. of half-saturated lime water. Shake the flask at intervals for 24 hours. Filter off the pieces of tendon and precipitate the mucoid with dilute hydrochloric acid. Allow the mucoid precipitate to settle, decant the supernatant fluid, and filter the remainder. Test the mucoid as follows:
 - a. Solubility: Try the solubility in water, sodium chloride, dilute and concentrated acid, and alkali.
 - b. Biuret Test: First dissolve the mucoid in sodium hydroxide solution and then add a dilute solution of copper sulfate.
 - c. Test for Cystine and Cysteine Sulfur.
 - d. Hydrolysis of Tendomucoid: Place the remainder of the mucoid in a small beaker, add about 30 ml. of water and 2 ml. of dilute hydrochloric acid, and boil until the solution becomes dark brown. Cool the solution, neutralize it with concentrated sodium carbonate, and test by Benedict's test. With a reduction of Benedict's solution and a positive biuret test, what do you conclude regarding the nature of tendomucoid?
- 2. Collagen: This substance is present in the tendon to the extent of about 32 per cent. Therefore in making the following tests upon the pieces of tendon from which the mucoid, soluble protein, and inorganic salts were removed in the last experiment, we may consider the tests as being made upon collagen.
 - a. Solubility: Cut the collagen into very fine pieces and try its solubility in water and dilute and concentrated acid and alkali.
 - b. Millon's Reaction.
 - c. Bluret Test.
 - d. Xanthoproteic Reaction.
 - e. Glyoxylic Acid Reaction (Hopkins-Cole).
 - f. Test for Cystine and Cysteine Sulfur: Take a large piece of collagen in a test tube and add about 5 ml. of sodium hydroxide solution. Heat until the collagen is partly decomposed, then add 1 to 2 drops of lead acetate and again heat to boiling.
 - g. Formation of Gelatin from Collagen: Transfer the remainder of the pieces of collagen to a casserole, fill the vessel about two-thirds full of water, and boil for several hours, adding water at intervals as needed. By this means the collagen is transformed and gelatin is produced (see p. 218).
- 3. Gelatin: On the gelatin formed from the transformation of collagen in the above experiment (g), or on gelatin furnished by the instructor, make the following tests:
 - a. Solubility: Try the solubility in cold and hot water and in dilute acid and alkali.
 - b. Millon's Reaction.
 - c. Glyoxylic Acid Reaction (Hopkins-Cole): Conduct this test according to the modification given on p. 173.

- d. Test for Cystine and Cysteine Sulfur.
- Make the following tests upon a solution of gelatin in hot water:
- e. Precipitation by Mineral Acids: Is it precipitated by strong mineral acids such as concentrated hydrochloric acid?
- f. Salting-out Experiment: Saturate a little of the solution with solid ammonium sulfate. Is the gelatin precipitated? Repeat the experiment with sodium chloride. What is the result?
- g. Precipitation by Metallic Salts: Is it precipitated by metallic salts such as copper sulfate, mercuric chloride, and lead acetate?
- h. Coagulation Test. Does it coagulate upon boiling?
- i. Precipitation by Alkaloidal Reagents. Is it precipitated by such reagents as picric acid, tannic acid, and trichloroacetic acid?
- i. Biuret Test: Does it respond to the biuret test?
- k. Precipitation by Alcohol: Fill a test tube one-half full of 95 per cent alcohol and pour in a small amount of concentrated gelatin solution. Do you get a precipitate? How would you prepare pure gelatin from the tendo achillis of the ox?

II. YELLOW ELASTIC TISSUE (ELASTIN)

The ligamentum nuchae of the ox may be taken as a satisfactory type of the yellow elastic connective tissue. The principal solid constituent of this tissue is elastin, a member of the albuminoid group. In common with the keratins and collagen, elastin is an insoluble substance and gives the protein color reactions. It differs from keratin in the fact that it may be digested by enzymes and in amino acid composition (see p. 109). In this latter respect elastin is characterized by its low sulfur content and its high content of leucine plus isoleucine.

Yellow elastic tissue also contains mucoid and collagen but these are present in much smaller amount than in white fibrous tissue, as may be seen from the following percentage composition of the fresh ligamentum nuchae of the ox.

Water	t
Solids 42.4	
Inorganic matter 0.5	
Organic matter 41.9	
Fatty substance (ether-soluble)	
Coagulable protein 0.6	
Mucoid 0.5	
Elastin 31.7	
Collagen 7.2	
Extractives, etc	

EXPERIMENTS ON ELASTIN

1. Preparation of Elastin (Richards and Gies): Cut the ligament into fine strips, run it through a meat chopper, and wash the finely divided material in cold, running water for 24 to 48 hours. Add an excess of half-saturated lime water, and allow the hashed ligament to extract for 48 to 72 hours. Decant the lime water, remove all traces of alkali by washing in water, and then boil in water with repeated renewals until only traces of protein material can be detected in the wash water. Decant the fluid and boil the ligament in 10 per cent acetic acid for a few hours. Treat the pieces with 5 per cent hydrochloric acid at room temperature for a similar period, extract again in hot acetic acid and in cold hydrochloric acid. Wash out traces of acid by means of water and then thoroughly dehydrate

by boiling alcohol and boiling ether in turn. Dry in an air bath and grind to a powder in a mortar.

- 2. Solubility: Try the solubility of the finely divided elastin, prepared by yourself or furnished by the instructor, in the same solvents tried with collagen (p. 219). How does its solubility compare with that of collagen?
- 3. Millon's Reaction.
- 4. Xanthoproteic Reaction.
- 5. Biuret Test.
- Glyoxylic Acid Reaction (Hopkins-Cole): Conduct this test according to the modification given on p. 173.
- 7. Test for Cystine and Cysteine Sulfur.

III. CARTILAGE

The principal solid constituents of the matrix of cartilaginous tissue are chondromucoid, chondroalbumoid, and collagen. Chondromucoid on decomposition yields protein and chondroitin sulfuric acid which has the following formula:

On hydrolysis it loses sulfuric acid and forms chondroitin. The latter loses acetic acid to form chondrosin. Chondrosin on hydrolysis yields chondrosamine CH₂OH(CHOH)₃CHNH₂CHO and glucuronic acid COOH-(CHOH)₄CHO. Chondrosamine is apparently a galactosamine. The amino sugars are dealt with differently in metabolism from glucose or simple amino acids. They apparently do not form glycogen in the body. Chondromucoids in various tissues differ from each other in the character of the protein only. Chondroitin sulfuric acid differs from the mucoitin sulfuric acids found in the mucin of saliva, etc., in that the carbohydrate group in the latter is chitosamine (probably a glucosamine). It is of interest that chitin in the exoskeleton of certain lower animals is a polysaccharide containing chitosamine and acetic acid. Chondroitin sulfuric acid is found in tendomucoid and apparently also in osseomucoid which are thus closely related to chondromucoid.

Chondroalbumoid is similar in some respects to elastin and keratin. It differs from keratin in being soluble in gastric juice and in containing considerably less sulfur than any member of the keratin group. It gives the usual protein color reactions.

EXPERIMENTS ON CARTILAGE

1. Preparation of Chondroitin Sulfuric Acid from Chondromucoid: Free nasal septa of cattle from bone and other extraneous material. Run 200 g. of the material through a meat chopper. Add 400 ml. of 2 per cent NaOH. Let stand for 2 days. Strain through cloth. Treat the residue again with 200 ml. of NaOH for 2 days. Strain. Wash the residue once with water. Combine the extracts. Acidify with acetic acid and then add an excess of barium carbonate. Concentrate on the steam bath to half the volume. Pour off the clear liquid. Filter the remainder on a folded filter and add filtrate to the decanted solution. Acidify. Evaporate to about 80 ml. Centrifuge to remove protein and barium carbonate. Drop the clear yellow liquid into 8 volumes of glacial acetic acid kept vigorously agitated (preferably with a turbine). Filter off the acid potassium salt with suction. Wash with glacial acetic acid and then with alcohol and ether.

Dissolve 8 g. of the product which still gives a slight biuret test in 460 ml. of water, and while the solution is kept stirred drop in basic lead acetate solution to complete precipitation. Wash the precipitate several times by rubbing in a mortar with water and filtering with suction. Reserve a part of the lead salt for Exp. 2. Dissolve the rest of the precipitate in 10 per cent HCl. To the filtrate from the lead chloride add glacial acetic acid to precipitate all of the chondroitin sulfuric acid. Wash with glacial acetic acid, alcohol, and finally ether.

2. Preparation of Chondrosamine from Chondroitin Sulfuric Acid: To 8 g. of the dry lead salt (see Exp. 1) add 32 ml. of 20 per cent HCl, 8 g. of stannous chloride, and 2 g. of barium chloride. Heat over a free flame with reflux for 12 hours. Filter. Concentrate under diminished pressure to a thick syrup. Take up in 16 ml. of water. Remove the barium with sulfuric acid. Concentrate under diminished pressure to a thick syrup. Take up in about 2 ml. of methyl alcohol. Add acetone very cautiously until the sugar begins to crystallize. Let stand for 24 hours. Yield: about 6.7 g. of chondrosamine hydrochloride.

3. Preparation of Glucuronic Acid: This is most readily obtained pure from conjugated glucuronates of the urine. See Chapter 29.

4. To Show the Presence of Sulfuric Acid and of Reducing Sugars in Chondromucoid: Treat 50 g. of cartilage from nasal septum of the ox or cartilage rings from trachea of the ox with 100 ml. of 1 per cent NaOH and let stand over night. Pour off 50 ml. of fluid, add 5 ml. of concentrated HCl and boil for 30 minutes, bringing down to a low volume. To one portion add BaCl₂ solution and note the precipitate of BaSO₄. Neutralize another portion with sodium carbonate and apply Benedict's test to show the presence of a reducing carbohydrate group.

IV. OSSEOUS TISSUE (BONE)

Bone contains from 14 to 44 per cent water, depending upon the type of bone and its location in the body. Of the fat-free dry matter of bone, from 30 to 50 per cent is organic, and the remainder inorganic. Typical analyses of bone are given in Chapter 35 in connection with the discussion of rickets and vitamin D.

The organic portion of bone is similar in composition to cartilage. It contains collagen, osseoalbumoid, and osseomucoid. These proteins resemble the corresponding proteins in cartilage and tendon. Because of the collagen content gelatin is formed on boiling bone with dilute acid. The bone marrow also contains fat.

The inorganic material of bone consists chiefly of calcium, phosphate, and carbonate, with small amounts of magnesium, hydroxide, fluoride. and sulfate. These substances are present in amounts which correspond approximately to a mixture of 85 per cent Ca₃(PO₄)₂, 10 per cent CaCO₃, and 1.5 per cent Mg₂(PO₄)₂, but it is known that this does not represent the true structure of the bone crystal. Studies by x-ray crystallographic methods indicate that bone is similar in crystal structure to the substance hydroxyapatite, which is a member of the apatite group of minerals. The unit crystal of hydroxyapatite has the composition approximately represented by Ca(OH)₂·3Ca₂(PO₄)₂ or Ca₁₀(OH)₂(PO₄)₆; fluorapatite, a naturally occurring mineral of the apatite series which is reasonably pure, has the composition Ca₁₀F₂(PO₄)₆. These empirical formulas give no clue to the actual arrangement of the elements in the crystal lattice. It is believed that considerable substitution by different elements is possible in a given crystal lattice without significantly altering the crystal characteristics. According to Armstrong the mineral material of bone is essentially a hydroxyapatite in which a variable number of the calcium and phosphorus atoms may be replaced by carbon, the general structure being represented somewhat as follows: (OH)₂Ca₆[[(P, C)O₄]₆(Ca, C)₄]. Magnesium, sodium, and potassium may presumably replace calcium, and fluorine may replace OH. It should be pointed out that other views concerning the nature of bone are held; at the present time, the evidence is insufficient as to which viewpoint is the correct one.

Despite the possible variation in bone composition indicated in the above discussion, the inorganic material of bone is rather constant in composition. Observations on the constancy of composition of bone during fasting are of interest in this connection. The percentage composition of the dry fat-free femurs of two dogs, after the animals had fasted for 104 and 14 days respectively, was as follows:

Dog No.	Length of Fast	Ash	N	Са	Mg	P	
1	104 days	61.5	4.6	23.3	0.5	12.8	
2	14 days	61.7	4.1	23.2	0.5	12.9	

The marked uniformity in composition notwithstanding the wide variation in the fasting periods is significant. The tensile strength of the femur of the dog has been found to be at least 25,000 pounds to the square inch whereas that of oak is 10,000 and that of cast iron 20,000 pounds to the square inch.

The percentage compositions of normal human bone and of bone from a case of osteomalacia with respect to certain elements are given in the following table:

Garatii aat	Kind of Bone			
Constituent	Normal	Osteomalacia		
Calcium	20.2	10.8		
Magnesium	$0.1 \\ 8.6$	0.3 5.3		
PhosphorusSulfur	0.1	0.6		

Hammett has shown in the case of albino rats that there is an increase in calcium and a decrease in magnesium and phosphorus during the first 75 days of growth. Moreover the bones of the female have a higher calcium content than the bones of the male.

Chemistry of Ossification. Evidence from many sources indicates that there is an active metabolism in bone. The mineral matter of bone may be drawn upon in case of need elsewhere, as in the formation of milk by the lactating animal and in the formation of the bones of the fetus during pregnancy. This utilization of bone material should be regarded as a resorption of bone rather than a simple decalcification since both the organic and inorganic components of bone disappear during the process. Studies with radioactive phosphorus as a tracer² have shown that almost immediately after the introduction of radioactive phosphorus into the blood there is an appreciable uptake of the labeled phosphorus by the bones, indicating a "turnover" or metabolic interchange between the bone and plasma or lymph phosphorus. During a 50-day period in the life of the rabbit, for example, half the scapula may be replaced, with a 30 per cent turnover of the epiphyseal phosphorus; diaphyseal bone metabolism appears to be considerably slower. There are indications of a "labile" fraction of bone which is in equilibrium with the plasma and a "stable" fraction which is in equilibrium with the labile portion.

The chemistry of calcification is not yet clear. One mechanism which has been proposed involves a physicochemical process of precipitation of bone salt from a solution saturated with respect to the various ions concerned, chief of which appear here to be Ca⁺⁺, HPO₄⁻, and PO₄⁻. A major difficulty in establishing this theory lies in the inability to define the physicochemical equilibria concerned in precise terms. To avoid this,

² See Hevesy: Ann. Rev. Biochem., 9, 641 (1940); Cohn, Cohn, and Aub: Ann. Rev. Biochem., 11, 415 (1942).

McLean has proposed a biological index of saturation in terms of the ion concentrations associated with calcification of rachitic cartilage either in vivo or in vitro. According to McLean, findings on this basis appear to offer an adequate explanation of calcification in the growing (but not the adult) animal. A second theory, sponsored by Robison, is based on the presence of the enzyme phosphatase in calcifying bones. This enzyme splits phosphate from such compounds as hexosephosphate and glycerophosphate. The phosphate liberated may then react with calcium and be deposited as calcium phosphate. It is admitted that a local factor must also be involved here. According to Freeman and McLean, phosphatase is found not in the matrix of osteoid tissue awaiting calcification but rather in the osteoblasts surrounding growing bone.

Vitamin D promotes calcification, especially on rachitogenic diets. In some way it enables the body to use P more effectively for calcification, possibly by increasing the level of blood phosphate to the point where the Ca × P product is sufficiently high to enable calcification to occur. The finding of a high phosphatase content of the blood in osteitis deformans, rickets, and other generalized bone disorders, and a decrease of phosphatase in the tissues of the animals fed a diet high in vitamin D, are of interest in this connection. Calcium metabolism and deposition are also influenced by glands of internal secretion (see Chapter 26, Hormones).

Experiments on Osseous Tissue

- 1. Decalcification of Bone: Treat a strip of rib bone with dilute HNO₁ and permit it to soak for 6 to 8 days, renewing the acid every 1 to 2 days. After complete decalcification, wash the bone, split it, and remove the marrow. Now cut the bone into small pieces, wash it to remove acid, and boil the material in water for at least one hour. Filter, concentrate the filtrate, and permit it to cool. What is the characteristic of the cooled filtrate? What has been produced from the bone?
- 2. Qualitative Analysis of Bone Ash: Take 1 g. of bone ash in a small beaker and add a little dilute nitric acid. What does the effervescence indicate? Stir thoroughly, and when the major portion of the ash is dissolved add an equal volume of water and filter. To the acid filtrate add ammonium hydroxide to alkaline reaction. A heavy white precipitate of phosphates results. (What phosphates are precipitated here by the ammonia?) Filter and test the filtrate for chlorides, sulfates, phosphates, and calcium. Add dilute acetic acid to the precipitate on the paper and test a little of this filtrate for calcium and phosphates. Heat the remainder of the filtrate to boiling and add (NH₄)₂CO₃ and NH₄Cl slowly to this hot solution as long as a precipitate forms. Filter off the precipitate of CaCO₃ and wash with hot water until free from alkali. To the filtrate add a solution of Na₂HPO₄, make strongly alkaline with NH₄OH, and note the formation of a white precipitate of ammonium magnesium phosphate (NH₄MgPO₄). Examine the crystals under the microscope and compare with those shown in Fig. 236. To the precipitate on the filter paper, which was insoluble in acetic acid, add a little dilute hydrochloric acid and test this last filtrate for phosphates and iron.

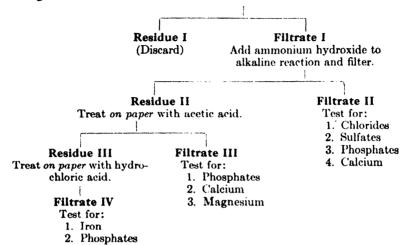

¹ Arch. Path., 32, 387 (1941).

^{*} Magnesium is not precipitated here because of precence of NH₆Cl.

Reference to the scheme below may facilitate the analysis.

BONE ASH

Add dilute nitric acid, stir thoroughly, and after the major portion of the ash has been brought into solution add a little distilled water and filter.

MICROESTIMATION OF THE INORGANIC CONSTITUENTS OF BONE. Sobel et al., have described a scheme for analysis of CO₃, Ca, P, and total base which is serial in operation and requires only one weighed specimen. The complete analysis can be performed on as little as 5 mg. of sample. For details, see the original article.

TEETH

Teeth are composed of four tissues: enamel, dentin, and cementum, which are highly calcified, and the dental pulp, which is uncalcified and is surrounded by the dentin. Enamel covers the dentin in the crown of the tooth. It is the hardest substance in the body and contains the smallest amount of water. Cementum contains about 30 per cent organic matter. It covers the dentin in the root of the tooth which is contained in the supporting structures known as the periodontal tissues.

The average elementary composition of human enamel and dentin is as follows:

	Enamel Dentin Per Cent on Dry Basis		
Calcium	35.8	26.5	
Magnesium	0.27	0.79	
Sodium	0.25	0.19	
Potassium	0.05	0.07	
Phosphorus	17.4	12.7	
Carbon dioxide (from carbonate)	2.97	3.06	
Chlorine	0.3	0.0	
Fluorine	0.0112	0.0204	
Iron	0.0218	0.0072	
Organic matter	1	25	

Sobel, Rockenmacher, and Kramer: J. Biol. Chem., 152, 255 (1944).

The following	values	have	been	reported	for	the	composition	of	whole
human teeth:									

	Per Cent on Dry, Fat-free Basis	Constituents in Mean Per Cent		
Calcium	26-30	29.7		
Magnesium		0.42		
Phosphorus	13-20	14.2		
Carbon dioxide (from carbonate)		2 .9		
Water		8.7		
Inorganic matter		84.7		
Organic matter		15.3		
_		•		

^{*}LeFevre and Hodge: J. Dental Research, 16, 279 (1937). In the last column the value for water represents the loss in weight after heating the teeth at 96° C. for seven days. The weight resulting is the dry weight. The values for inorganic and organic matter and those for the individual inorganic constituents represent the percentage of the dry weight.

X-ray diffraction pattern studies suggest that the inorganic matter of enamel and dentin is similar to that of bone (p. 223) and consists largely of hydroxyapatite, Ca₁₀(PO₄)₆·(OH)₂, which exists as submicroscopic crystallites. It is claimed that smaller amounts of carbonate-apatite, chlorapatite, and fluorapatite are present in enamel, and that dentin contains some fluorapatite. Enamel and dentin, on spectrographic examination, have been found to contain numerous trace elements.

The organic matter of enamel consists mainly of the protein keratin. Small amounts of cholesterol and phospholipid are also present. The albuminoids collagen and elastin are found in dentin, the former representing the major organic constituent of this tissue. A glycoprotein is present in dentin along with small amounts of cholesterol and phospholipid. Collagen is the main organic substance in cementum. Citrate has been identified as a constituent of human teeth, five to eight times more being present in dentin than in enamel.

Several investigations have been made in an attempt to ascertain whether differences in chemical composition exist between enamel of sound teeth and the intact enamel of carious teeth. No significant differences were found for the contents of calcium, magnesium, phosphorus, and carbonate. Similar studies on dentin have likewise given negative results. It has been reported that enamel from sound teeth contains more fluorine than does the sound enamel from carious teeth. However, this finding requires confirmation and should be taken with reservation. No difference was found in the ash, calcium, and phosphorus contents of the root dentin of teeth from pregnant and nonpregnant women, suggesting that there is no basis for the view that minerals are withdrawn from the teeth during pregnancy. Furthermore clinical investigation has shown that the incidence of caries in pregnant women is no greater than in non-pregnant women of corresponding age.

In studies dealing with the response of the dental tissues to systemic influences it is important to distinguish between the growing and the adult tooth, and between the dental tissues of limited growth as in humans and

those of continuous growth as the incisors of rats. A great deal of confusion has been caused by failure to recognize this distinction.

For the proper calcification of the teeth the diet must contain adequate quantities of calcium and phosphorus and certain vitamins. Some of the hormones likewise play a fundamental role.

The presence of vitamin A is essential to the process of tooth formation. Dietary deficiency of this vitamin during the period that the teeth are undergoing development causes the ameloblasts to atrophy, resulting in hypoplastic enamel which is imperfectly calcified. There is also atrophy of the odontoblasts, so that the dentin which is laid down is also incompletely calcified. It is claimed that the primary effect is on the enamel, irregularities in the development of the dentin being secondary to the enamel hypoplasia. Deficiency of vitamin A in rats has been found to produce an increase in the percentage of magnesium in the incisors in spite of the fact that the ash content was decreased. A characteristic effect of vitamin A deficiency—namely, the substitution of stratified keratinizing epithelium for normal epithelium—has been observed in the gingiva. Malformation of alveolar bone has been produced in dogs by feeding vitamin A-deficient diets.

Vitamin C is also important for the functional activity of the formative cells. Dietary deficiency in vitamin C during the period of tooth development causes impairment of the odontoblasts leading to defective calcification of the dentin, accompanied by hemorrhagic and degenerative lesions in the pulp tissue. The changes in the dentin and pulp have been attributed to an inability to produce and maintain intercellular substance. Defective enamel formation, which has also been observed, is said to be secondary to retarded dentin deposition. Pathological changes in gingival tissue have been demonstrated to be due to deficiency of vitamin C in the diet. These conditions, as well as those in the teeth themselves, have been shown to respond favorably to the addition of vitamin C.

The degree of mineralization of the teeth depends on the relative, as well as on the absolute, quantities of calcium and phosphorus in the diet, and also on the amount of vitamin D or exposure to ultraviolet rays. Even with optimal quantities of calcium and phosphorus the presence of vitamin D is essential to the development of perfect teeth. Hypoplastic defects in the enamel and imperfect calcification of the dentin have been found in rickets in children. It has been shown that an increase in the vitamin D intake brings about a reduction in the incidence of dental decay in children. Similar results have been produced in rats by adding vitamin D to a caries-producing diet.

Adult teeth of limited growth capacity are probably only slightly affected by systemic influences. That such effects may occur is suggested by studies in which radioactive isotopes have been used. For example it was shown that following the ingestion or injection of sodium phosphate containing radioactive phosphorus, small amounts of the isotope appeared in the enamel and dentin, but much smaller amounts were present in the former than in the latter. However, the slight extent to which this occurs is shown by the fact that after the ingestion of 900 mg. of sodium phos-

phate containing isotopic P by an individual 25 years of age, about 1/300,000 of the labeled P entered a single tooth. On the basis of such data it was calculated that the replacement of 1 per cent of the tooth P by that taken up in food would take about 250 days.

Although both teeth and bones are highly calcified tissues, metabolic effects do not necessarily parallel each other. For example, although the percentage of ash of the incisor teeth of rats fed a low-Ca, low-P diet was lower than that of animals on a normal diet, the absolute amount of ash on the deficient diet increased about 15 per cent during a period of nine weeks. In the normal animals there was an increase of 77 per cent. But. during this period there was a reduction of 16 per cent in the absolute amount of ash in the femurs of the animals on the deficient diet, while in the normal animals there was an increase of 38 per cent. Thus there was a continuous deposition of minerals in the incisors of the rats on the deficient diet, while bone underwent demineralization. Furthermore, although the percentage of ash, calcium, and phosphorus of the tibiae of rats may be reduced to about the same extent on a high-Ca, low-P rachitogenic diet, and on a low-Ca, high-P rachitogenic diet, the values for these constituents are unaffected in the incisors of the rats on the high-Ca diet, but are somewhat reduced on the low-Ca diet. These facts indicate that in some fundamental way there is a marked difference between the mineral metabolism of teeth and bones.

As to the relationship of the ingestion of fluoride and the topical application of fluoride on enamel to dental caries, several laboratories have reported beneficial effects. However there is no complete agreement as yet as to the value of fluoride as a prophylactic for dental caries.

Analysis of Teeth: Place a tooth in 25 ml. of dilute nitric acid and allow to stand over night. On the solution obtained run an analysis for inorganic elements according to the procedure given for bone ash (p. 225). Separate analyses may be made on dentin and enamel. Note the very slight amount of organic matter in enamel.

Quantitative Analysis of Teeth: Weigh a clean dry tooth on an analytical balance. Put in a beaker, add 25 ml. of dilute HCl, and let stand over night. Dilute to exactly 100 ml. and filter.

Determination of Calcium: Pipet 10-ml. portions of tooth solution into each of two 250-ml. beakers. Add to each 20 ml. of 2.5 per cent oxalic acid solution, 2 drops of methyl red (saturated alcoholic solution), about 70 ml. of distilled water, and then concentrated NH,OH drop by drop with vigorous stirring. When a precipitate of calcium oxalate begins to form add more ammonia very slowly until the color changes to an intermediate color between red and yellow. Let stand over night. Complete the determination according to directions in Chapter 32. Calculate the percentage of Ca in the tooth.

Determination of Phosphorus: Pipet 10 ml. of tooth solution into a 150-ml. beaker, add 2 drops of phenolphthalein solution and NaOH until the color just turns faint pink. Carry out a uranium acetate titration or determine colorimetrically according to the directions given in Chapter 32. Calculate the percentage of P.

Muscular Tissue

Muscular tissue constitutes about 40 per cent of the body weight, and is therefore the largest single tissue component of the body. Physiologically the muscular tissues are divided into (1) the voluntary (striated, skeletal), (2) the cardiac, and (3) the involuntary (nonstriated, smooth) types. In the chemical examination of muscular tissue either skeletal or cardiac muscle is usually employed; much more is therefore known concerning striated muscle than concerning smooth muscle. Striated muscle contains about 75 per cent water and about 25 per cent solids, of which four-fifths, or 20 per cent, consists of protein and the remainder is composed of "extractives" and inorganic salts.

PROTEINS OF MUSCLE

Microscopically the striated muscle fiber consists of a varying number of myofibrils imbedded in the sarcoplasm; the fibrils are approximately 1 micron in diameter and run parallel to the long axis of the fiber. The fibrils are believed to consist largely of protein. The striations are apparently due to alternate changes in the optical properties of the fibril, possibly associated with either variations in protein concentration or the arrangement of the protein molecules themselves. The light portion of the fibril is known as the I region (isotropic), the dark portion as the A region (anisotropic); this effect is reversed in polarized light. When muscle is extracted with dilute salt solutions the proteins of the fibrils, of the sarcoplasm, and of the stroma are found in the extract. By suitable fractionation of this extract a number of different proteins may be distinguished. Typical results of such fractionation are found in the following table:

PROTEINS OF MUSCLE (RABBIT) (IN PER CENT OF TOTAL PROTEIN)

	11	hite Muscle	Rcd Muscle		
	(Smith)	(Meyer and Weber)	(Meyer and Weber)		
Myosin	57	39	39		
	18	22	17		
MyogenStroma	9	22	17		
	16	17	27		

Myosin. Myosin is the most abundant protein in muscle, and is considered to be the major, if not the only, protein of the myofibril, the other

proteins of muscle presumably being found in the sarcoplasm and extracellularly. Myosin has been the most thoroughly studied of all the muscle proteins, the major interest in the part played by muscle proteins in muscular contraction having centered around this protein. Myosin is a typical globulin, insoluble in salt-free water or in the region of its isoelectric point but readily soluble in dilute salt solutions, particularly on the alkaline side of the isoelectric point, which is approximately pH 5.4. The insolubility of myosin around its isoelectric point has made the exact definition of this point a matter of some difficulty, and there is some disagreement in this respect. Myosin in solution is precipitated on dilution or dialysis, either as a flocculent mass or as a gel ("muscle clot"); the precipitated protein may be redissolved in salt solution and reprecipitated a number of times without alteration if the solution is kept cold. At room temperature or above the protein becomes denatured to form the insoluble myosan.

Myosin solutions exhibit the interesting property of double refraction of flow, or streaming birefringence; that is, the optical properties of a myosin solution with regard to the transmission of polarized light undergo change if the solution is flowing across the light path as compared to when the solution is at rest. This property is ascribed to the orientation of long molecules in the flowing solution, much as logs orient themselves in a flowing stream. By quantitative measurements based on double refraction of flow, it is possible to estimate the length of the myosin molecule, the values obtained ranging from about 800 to 1200 m μ . Thus the myosin molecule, which is believed to be arranged lengthwise in chains in the myofibril, is very long, having a length about equal to the width of the myofibril itself.

These observations concerning the nature of the myosin molecule are based upon studies of myosin preparations obtained by the usual process of extracting muscle with salt solution and precipitating the myosin by dilution or dialysis. Studies with the electron microscope (Schmitt) indicate that such myosin may not necessarily represent the state of myosin in the intact myofibril. X-ray and other data suggest that myosin is present in the cell as very thin, straight filaments, possibly only a few polypeptide chains in width. It is interesting to note that these filaments are as straight in contracted muscle as in uncontracted muscle, indicating that the filaments themselves shorten on contraction, rather than coiling up or folding.

Straub has isolated a protein from muscle called "actin" which appears able to combine with myosin to form complexes. According to Szent-Györgyi, ordinary myosin preparations consist of an actin-myosin complex ("myosin B"); in the presence of adenosine triphosphate (see below) this complex is dissociated to yield actin and "myosin A." The relation of these important findings to earlier work and to muscle contraction in general remains to be further studied.

Interest in the part played by myosin in muscle contraction has been considerably stimulated by the finding of Engelhardt and Liubimova, 18

¹ For review, see Kalckar: Ann. Rev. Biochem., 14, 283 (1945).

[&]quot; Nature, 144, 668 (1939). See also Engelhardt: Advances in Ensymology, 6, 147 (1946).

in 1939, that purified myosin preparations possess marked enzymatic properties; specifically, these investigators found myosin to catalyze the hydrolysis of the important compound adenosinetriphosphate ("ATP") into adenosinediphosphate ("ADP") and inorganic phosphate. Adenosinetriphosphate, or adenylic acid pyrophosphate as it is sometimes called, was discovered by Lohmann in muscle tissue and is believed to be of major importance in supplying the energy of muscular contraction, as discussed more in detail below. The structures of ATP, ADP, and related compounds are as follows:

Adenosine triphosphate

Adenosine diphosphate

Adenylic acid

The carbohydrate group is D(-)-ribose. The purine component is adenine, which, through loss of NH_3 , becomes hypoxanthine in inosinic acid. The phosphoric acid is linked to the 5 position of the ribofuranose; thus the adenylic acid of muscle may be called adenosine-5-phosphoric acid. Yeast adenylic acid is adenosine-3-phosphoric acid; the two compounds are biologically quite distinct from each other (see also Chapter 7).

The phosphate in adenylic acid and inosinic acid is in the usual type of ester linkage, hydrolysis by acid or phosphatase enzymes liberating about 3,000 calories per mole of phosphate set free. The additional phosphate linkages in ADP and ATP are of the pyrophosphate type, hydrolysis being accompanied by the liberation of about 10,000 calories per mole of phosphate set free. The pyrophosphate bond, and its equivalent found elsewhere as in phosphocreatine, phosphopyruvic acid, etc., has been called by Lipmann a "high energy phosphate bond," symbolized by ~ph, and it is known to play an important part not only in muscular contraction but also in many other processes of cell metabolism. The close association of ATP, containing this high energy phosphate, with the protein myosin, which is considered to be of major importance in the mechanism of muscular contraction, appears to be of considerable significance. Whether or not the myosin molecule is itself an enzyme is debatable. In this connection it has been shown² that highly purified myosin preparations may be obtained which possess at least two enzymatic properties in addition to that described by Engelhardt and Liubimova. One of these is an activity due to adsorption by myosin of the enzyme myokinase of Kalckar;3 this enzyme promotes the dismutation of two molecules of adenosinediphosphate into a molecule each of adenosinetriphosphate and adenylic acid.

2ADP → ATP + adenylic acid

Myokinase is strongly adsorbed by myosin at pH 8.0-8.5, but is readily eluted at pH 6.6-7.0. Myosin containing adsorbed myokinase therefore produces adenylic acid rather than adenosinediphosphate from ATP.

Another enzymatic property of myosin is a powerful deaminase activity, by which adenylic acid is converted into inosinic acid with the liberation of ammonia. This deaminase activity is similar to, if not identical with, that of the well-known muscle deaminase of Schmidt,⁴ which may be obtained in purified form free from myosin; however, the deaminase activity of myosin appears to be as firmly associated with the protein as is the pyrophosphatase activity described by Engelhardt and Liubimova. Finally, Kalckar⁵ has shown that an adenosinetriphosphatase obtained from sources other than muscle is readily adsorbed by myosin. Thus it would appear that the enzymatic activity of myosin is more

² Summerson and Meister: Read before the Division of Biological Chemistry of the American Chemical Society at the New York meeting, September, 1944.

³ J. Biol. Chem., 148, 127 (1943). ⁴ Z. physiol. Chem., 179, 243 (1928).

⁴ J. Birl Chem., 153, 355 (1944).

probably associated with the presence of strongly adsorbed enzymes than with the specific properties of the myosin molecule itself.⁵⁸.

The optimum pH for adenosine triphosphatase activity is approximately 9; calcium ions increase the enzymatic activity while magnesium ions inhibit it. Attempts to relate enzymatic activity with the presence of —SH groups have given contradictory results. There appears to be no direct relation between the optical and enzymatic properties of myosin.

OTHER MUSCLE PROTEINS

Globulin X. After the removal of myosin from a saline extract of muscle, a second globulin, globulin X, may be obtained in considerable amount. This is apparently a protein of the sarcoplasm. It has a coagulation temperature of approximately 50° C., and a molecular weight of around 160,000. Its function is unknown.

Myogen. Myogen is a protein with the general properties of an albumin and likewise appears to be a protein of the sarcoplasm. Two crystalline fractions have been obtained, myogens A and B, and enzymatic properties have been attributed to crystalline myogen A. Myogens appear to have a molecular weight of 80,000 to 90,000, and a coagulation temperature of about 52° C.

Myoglobin. Myoglobin is a heme pigment similar to hemoglobin. Its function is not known, although it appears able to combine with oxygen in a manner analogous to that of hemoglobin. The molecular weight of myoglobin is one-fourth that of hemoglobin; myoglobin may therefore represent a unit structure, of which four are combined to form the hemoglobin molecule (see Chapter 22). Myoglobin is found in the urine after crushing injury to the limbs; because of the small size of the molecule, myoglobin is apparently readily filterable from the plasma through the renal glomerular membrane.

A large number of enzymes are likewise found in muscle; some have been well characterized but most have not. Phosphorylase, the enzyme associated with glycogen synthesis and breakdown in muscle, has been crystallized. Muscle also contains a stable acetylphosphatase⁷ which catalyzes the hydrolysis of the highly labile compound acetylphosphate, CH₃COOPO₃H₂, into its components, acetic and phosphoric acids. In addition to the many glycolytic enzymes described later which are associated with carbohydrate breakdown and resynthesis in muscle, muscular tissue contains the various oxidation-reduction enzymes, such as succinic dehydrogenase, the cytochrome proteins, etc., which are described in Chapter 12, together with a number of other enzymes whose functions are as yet not well characterized.

Price and Cori (J. Biol. Chem., 162, 393 (1946)) report the successful separation of adenosinetriphosphatase from myosin and activation of the enzyme by creatine; the relationship of these interesting findings to the water-soluble adenosinetriphosphatase activity of muscle extracts, which is likewise activated by creatine (Liubimova and Engelhardt: Biokhimiya, 4, 716 (1939)) remains to be elucidated. See also Polis and Meyerhof: J. Biol. Chem., 163, 339 (1946).

⁶ Engelhardt: Yale J. Biol. Med., 15, 21 (1942); Taylor, Green and Cori: Fed. Proc., 5, 158 (1946).

^{&#}x27;Lipmann: Personal communication.

EXTRACTIVES OF MUSCLE

Under the name extractives we class a number of muscle constituents which occur in small amounts in the tissue and may be extracted by water. alcohol, or ether. There are two classes of these extractives, the nonnitrogenous extractives and the nitrogenous extractives. Grouped under the nonnitrogenous compounds we have glycogen, hexosephosphate, lactic acid, inositol, and fat. In the class of nitrogenous extractives we have creatine. creatine phosphate, purine bases (xanthine, hypoxanthine), uric acid. adenylic acid, inosinic acid, adenylic acid pyrophosphate, carnosine (ignotine), anserine and carnitine (novaine), All of these substances, and many more, have been obtained from dead muscle; there is considerable evidence that many of them (e.g., adenylic acid, lactic acid, etc.) are produced largely by postmortem reactions and are not present as such in significant amounts in living muscle. Other extractives besides those enumerated above have been described and there are undoubtedly still others whose presence remains undetermined. A detailed consideration would, however, be unprofitable in this place.

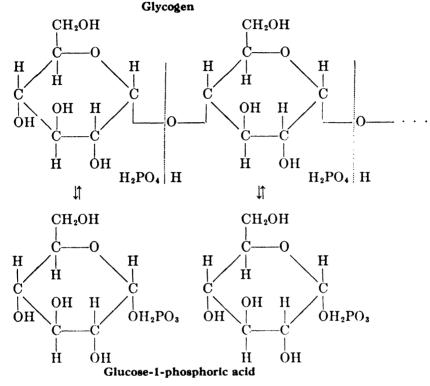

NONNITROGENOUS EXTRACTIVES

Glycogen. The chief carbohydrate of muscle is the polysaccharide glycogen. Glycogen is similar to starch and dextrin in that the molecule consists of a large number of glucose residues linked by 1,4 and 1,6 glycoside bonds; the glycogen molecule is smaller than the starch molecule, however, and is highly branched, in contrast to the relatively unbranched configuration of starch. On hydrolysis with acid, glycogen yields glucose; the amylolytic enzymes of the digestive tract and of the blood and urine yield maltose as an end-product. For structure of glycogen and further discussion see Chapter 2.

Pure glycogen is a colorless, tasteless, amorphous powder. It is easily soluble in water to form an opalescent solution, and gives a red color with iodine. It may be prepared from muscle or other tissue by extracting with boiling water and then precipitating the glycogen with alcohol. In common with other glycosides, glycogen is extremely resistant to the action of concentrated alkali; it is usually determined quantitatively in tissues by boiling the tissue with concentrated alkali to destroy interfering material, then precipitating the glycogen with alcohol, followed by hydrolysis by acid and final estimation as glucose. In addition to alcohol, other precipitants for glycogen include tannic acid, ammoniacal basic lead acetate, and saturation with ammonium sulfate. Glycogen does not reduce alkaline copper solutions.

The glycogen content of muscle varies and is markedly reduced by intense muscular activity. In contrast to liver, where glycogen is present apparently for storage purposes only, the glycogen of muscle is an important part of the system of muscular contraction and is not significantly depleted as the result of demand elsewhere in the body for carbohydrate, as is the case with liver glycogen. The initial stage in glycogen breakdown in muscle and other tissues was at one time thought to be a hydrolysis to

yield glucose; it is now known that this is not true, the process being a "phosphorolysis" (Cori), in which the elements of phosphoric acid are added at the glycoside bonds in the molecule to yield glucose-1-phosphate ("Cori ester"). This reaction may be visualized as follows:

This reaction is reversible, as shown, and is catalyzed by the enzyme phosphorylase which apparently contains adenylic acid as a prosthetic group. Glycogen has been prepared in vitro by the action of phosphorylase on glucose-1-phosphate, the synthetic glycogen (amylose?) resembling natural muscle glycogen except that a blue instead of a red color is given with iodine. This difference in color with iodine has been attributed to variation in the extent of chain branching. Phosphorylases from other tissues lead to the synthesis of glycogen giving red to purple colors with iodine. The role of glycogen in muscular contraction is discussed in detail below.

Hexosephosphate. The hexosephosphate of resting muscle is an equilibrium mixture of glucose-6-phosphate (80 per cent) and fructose-6-phosphate (20 per cent). The structures of these compounds are given on p. 242. Until the existence of a mixture was recognized, this was called the "Embden ester." These two hexose phosphates are the only intermediates in the breakdown of glycogen to lactic acid which accumulate in muscle; after a short tetanus as much as half of the glycogen which has disappeared may be accounted for as hexose phosphates, the remainder

of course being lactic acid. The lactic acid produced in muscular contraction is the l(+) variety (see p. 113).

Inositol. Inositol (C₆H₁₂O₆) is hexahydrohexahydroxybenzene. Inositol is found in most tissues. An inositol phosphatide has been isolated from brain tissue. Inositol forms octahedral crystals, is fairly soluble in water, but does not reduce Fehling's solution. It is found in plants as inositol phosphoric acid, the calcium magnesium salt of which is called phytin. In fresh muscle it appears also to be in combination; its function is not known. The functions of a vitamin have been attributed to inositol in the diet; this is discussed further in Chapter 35.

NITROGENOUS EXTRACTIVES

Creatine. Creatine is methylguanidoacetic acid:

It is found in varying amounts in the muscles of different species of animals, usually representing from about 0.3 to 0.5 per cent of the wet

Fig. 75. Creatine.

weight, the muscles of birds having shown the largest amount. It has also been found in relatively small amounts in the blood, in the brain, in transudates, and in the thyroid gland. The creatine of the body is derived largely by synthesis within the body, the amino acids glycine, arginine, and methionine being concerned. This synthesis presumably occurs in the liver. The mechanism of creatine synthesis is discussed in Chapter 33.

Creatine forms cclorless monoclinic prisms which are tasteless to some individuals but bitter to others and which decompose with marked effervescence at about 291° (corr.). It is soluble in warm water and practically insoluble in alcohol and ether. Upon boiling a solution of creatine with

dilute hydrochloric acid, it loses water and its anhydride, creatinine, is formed. Creatine exists in muscle largely if not entirely as the compound phosphocreatine (creatine phosphate, phosphagen).

The phosphoric acid is combined with the —NH₂ group of creatine to produce a "high energy phosphate bond" similar to the pyrophosphate bonds of ATP. The compound is unstable, readily decomposing into creatine and phosphate when muscle tissue is removed from the animal

unless the tissue is frozen immediately. Phosphocreatine is known to play an important part in the processes of muscular contraction, as discussed later.

The Purine Bases. The purine bases found in muscle are adenine, guanine, xanthine, and hypoxanthine. These substances have already been considered in Chapter 7, Nucleic Acids and Nucleoproteins. They exist in muscle at least in part as components of such compounds as ATP, ADP, etc., which have already been described.

Carnosine. Carnosine is β -alanylhistidine, i.e., a peptide of histidine and the β amino acid β -alanine.

Fig. 76. Xanthine. After the drawings of Horbaczewski, as represented in Neubauer and Vogel.

 β -Alanine is likewise found as a component of the vitamin pantothenic acid. Carnosine is dextrorotatory and soluble in water. Although found in significant amounts in muscle tissue, its function is not known. The formula for carnosine follows:

Anserine is methyl carnosine, the methyl group replacing the H of the —NH group in the ring. Invertebrate muscle contains neither carnosine nor creatine but arginine, free and as phosphoarginine, which appears to be here the biological equivalent of the phosphocreatine of the higher animals.

Carnitine. Carnitine is a betaine of the following structure:

$$(CH_{\delta})_{\delta} \equiv N - O \ | CH_{2}-CH_{2}-CH(OH)-CO$$

It gives trimethylamine on hydrolysis. Its function is not known.

INORGANIC SALTS

The predominating inorganic cation of muscle is potassium, followed by sodium, magnesium, and calcium; these two latter ions appear to function in part as activators and inhibitors of certain of the enzymes present. The anions include chloride, phosphate, and traces of sulfate. There is some doubt about the existence of large amounts of free inorganic phosphate in living muscle; that which is ordinarily found on analysis may have been produced by the decomposition of ATP and phosphocreatine.

The comparative composition of the ash of striated and nonstriated muscle and of blood serum for comparison is shown in the following table:

	Per 100 Parts of Fresh Substance							
	K	Na	Fe	Ca	Mg	Cl	P	H ₂ O
Muscle: Nonstriated (Mendel and Saiki) Skeletal (Katz) Blood serum (Abderhalden)	0.244	0.168	0.005	0.008	0.028	0.048	0.214	72.9

CHEMISTRY OF MUSCULAR CONTRACTION

Our present knowledge of the chemistry of muscular contraction is based upon the intensive studies of many investigators over a long period of time; perhaps no other single phase of animal biochemistry has so persistently attracted the attention of so many biochemists and physiologists. Muscles from both warm- and cold-blooded animals have been studied; skeletal, cardiac, and to a lesser extent smooth muscle have been used; and studies have been carried out on the isolated intact muscle, muscle extracts, and enzyme systems obtainable from these extracts. The discussion which follows is a summary of present knowledge, necessarily incomplete and subject to future revision, concerning the chemical processes associated with muscle contraction.

Four fundamental processes are known at the present time to be concerned in muscle contraction. These are: (1) Adenosine triphosphate \rightleftharpoons adenosinediphosphate + inorganic phosphate; (2) phosphocreatine \rightleftharpoons creatine + inorganic phosphate; (3) glycogen \rightleftharpoons lactic acid; and (4) carbohydrate + O₂ \rightarrow CO₂ and H₂O. Of these four reactions the first three are reversible as indicated and occur anaerobically. They pre-

sumably represent the sources of the immediate energy for muscular contraction under the anaerobic conditions which probably prevail during brief rapid muscular activity. These three reactions are thought to occur in the sequence indicated, each reaction being reversible at the expense of the succeeding reactions; thus muscular contraction will continue anaerobically until all of the energy represented by these three reactions is used up. In the presence of iodoacetic acid, as Lundsgaard found, lactic acid formation does not occur; contraction is still possible, however, until the energy of the first two reactions is dissipated.

The relative amounts of energy yielded by the various reactions are of interest. According to Lohmann the content of ATP, phosphocreatine, and glycogen in a gram of fresh frog muscle is such as to yield 0.04 calorie from reaction 1, 0.23 calorie from reaction 2, and 1.2 calorie from reaction 3. Continuous resynthesis of ATP and phosphocreatine will naturally increase the energy available from these sources; the total energy available anaerobically would appear to be limited to that supplied by the breakdown of glycogen to lactic acid. This is a minimal value, however, since reaction 4, the aerobic oxidation of carbohydrate, leads to the resynthesis of the components of the anaerobic reactions, furnishing from 30 to 60 calories per g. of fresh muscle. The extent to which this reaction contributes energy to the contracting muscle depends obviously upon the availability of oxygen and substrate; slowly contracting muscle in the presence of abundant oxygen is undoubtedly obtaining considerable energy from this source. The possibility that oxidation of fatty acids is also supplying energy here has not been excluded.

Evidence that the breakdown of adenosinetriphosphate is the primary reaction of muscle contraction is available from several sources. The close relation between the muscle protein myosin and adenosine triphosphate breakdown has already been discussed. Lohmann has further shown that in dialyzed muscle extracts the breakdown of phosphocreatine does not occur unless adenylic acid is present to accept the phosphate liberated. Since there is no free adenylic acid in resting muscle according to Meyerhof, the breakdown of ATP must precede that of phosphocreatine. Further evidence that this is so has been obtained by studying the changes in muscle pH associated with contraction. Of reactions 1 and 2, reaction 1 leads to acid production while reaction 2 produces a relative alkalinity. When muscle contracts there is an immediate slight lowering of the pH, followed by a pH rise. This would indicate that ATP breakdown is followed by phosphocreatine breakdown and ATP resynthesis. This sequence may be disputed, however. According to Lipmann there is no reason to distinguish between the "high energy phosphate bond" of ATP and of phosphocreatine, since both yield the same amount of energy, and studies with radioactive phosphorus have indicated that the "turnover" of the terminal phosphate of ATP and of phosphocreatine phosphate is approximately the same, indicating that energy liberation from these two sources is equivalent. Since the muscle protein myosin has no action on phosphocreatine while it does catalyze ATP breakdown, however, this latter process would appear to be closest to the actual conversion of chemical energy into work, with phosphocreatine serving as an accessory reservoir of energy, possibly at the same level as ATP but not subject to the direct control of myosin.

The inorganic phosphate liberated by ATP breakdown is apparently transferred to glycogen by the reaction of phosphorolysis described previously, to produce glucose-1-phosphate. This is the first step in the formation of lactic acid from glycogen in muscle, and is followed by a series of successive and interlinked reactions, all of which occur anaerobically and which lead ultimately to the production of lactic acid. In these reactions both ATP and coenzyme I (cozymase) are concerned, as will be shown. Knowledge concerning the intermediate stages in this process has been obtained largely on muscle extracts which have been treated with such substances as fluoride and iodoacetate, which block the series of steps at some point and thus lead to the accumulation of intermediates which can then be identified. The extent to which information gained in this way actually applies to the processes occurring in living muscle is naturally debatable; it is believed, however, that substantially a correct picture has been obtained.

After glucose-1-phosphate has been formed by the phosphorolysis reaction, this compound comes into a reversible equilibrium with two other hexose monophosphates, glucose-6-phosphate and fructose-6-phosphate, as indicated here:

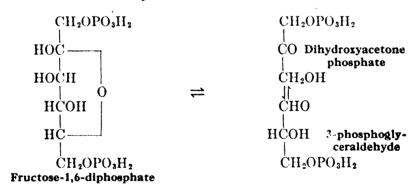

The enzymes concerned are as indicated; the various esters are frequently referred to under the name of the discoverer, as shown. Since these reactions are reversible, they may go in either direction depending upon existing conditions; however, the equilibrium point for a given reaction may be such as to preclude the presence of appreciable amounts of a particular component under ordinary conditions, as is the case with the Cori ester, which can be isolated from muscle preparations only if phosphoglucomutase activity is markedly diminished.

The next step of carbohydrate breakdown involves reaction between ATP and fructose-6-phosphate to form fructose-1,6-diphosphate. This compound is also known as the Harden-Young ester, and is of historical

interest since it was the first of the hexose phosphates to be isolated and characterized.

This reaction is also reversible, but in carbohydrate breakdown it obviously leads to a loss of ATP, which must be resynthesized if the reaction is to be continuously promoted. Energy and phosphate for the resynthesis of ATP from ADP are apparently derived from later stages in the breakdown, as will be shown; aerobic phosphorylations may also enter in here, to an extent as yet not clearly defined, as may myokinase.

The Harden-Young ester now undergoes scission into two triosephosphates, dihydroxyacetone phosphate and 3-phosphoglyceric aldehyde, which are isomers and in equilibrium with each other:

The enzyme which catalyzes this reaction is known as zymohexase or aldolase. It is this enzyme whose activity has been associated with crystalline myogen A of the muscle proteins.

Further reactions are considered to involve the glyceraldehyde isomer of the triosephosphates; since this compound is in equilibrium with the ketose triose, reactions involving the aldose must inevitably lead to disappearance of the ketose as well; side reactions directly involving the ketose may, however, occur under certain conditions. The aldose phosphate reacts with inorganic phosphate to form, according to Warburg, a 1,3-diphosphoglyceraldehyde, which in the presence of coenzyme I (see

Chapter 12) is oxidized by dehydrogenation to 1,3-diphosphoglyceric acid, the coenzyme being reduced in the process:

The unstable diphosphoglyceric acid containing a "high energy phosphate bond" on the carboxyl carbon, is now capable of transferring a molecule of phosphate to ADP, to form ATP and 3-phosphoglyceric acid; this latter undergoes isomeric phosphate shift to produce 2-phosphoglyceric acid:

$$\begin{array}{c|cccc} COOPO_3H_2 & COOH & COOH \\ \hline | & & & & & & & & \\ HCOH & + ADP \rightleftharpoons ATP + HCOH & \rightleftharpoons HCOPO_3H_2 \\ \hline | & & & & & & \\ CH_2OPO_3H_2 & & & & CH_2OPO_3H_2 \\ \hline | 1,3-diphosphogly- & & & & & \\ ceric acid & & & & & \\ ceric acid & & & & & \\ \hline \end{array}$$

These reactions involving triosephosphate, ADP, and coenzyme I deserve further comment. There is some dispute concerning the formation of the intermediary diphosphoglyceraldehyde in the process of formation of diphosphoglyceric acid; the other reactions are, however, generally accepted. It will be noted that an anaerobic oxidation has taken place. in which coenzyme I acts as the oxidizing agent, being reduced in the process; since reduced coenzyme I does not accumulate in muscle during lactic acid formation, it must be reoxidized by a subsequent reaction, as will be shown. This subsequent reaction, the reduction of pyruvic acid to lactic acid, is therefore coupled with the reactions being described. Furthermore the formation of ATP from ADP obviously must require as much energy as is liberated when ATP breaks down to ADP. This energy is apparently supplied by the "high energy phosphate bond" of the carboxyl phosphate group of 1,3-diphosphoglyceric acid, which in turn was derived from the energy of the coupled oxidation-reduction reaction involving coenzyme I. Thus we have here an example of a coupled oxidation-reduction reaction and phosphorylation; a type of reaction which is regarded as of fundamental importance in cell metabolism.

The 2-phosphoglyceric acid produced as described above readily loses water to yield the enol form of phosphopyruvic acid. This latter compound likewise contains a "high energy phosphate bond"; it is therefore capable of transferring its phosphate to ADP with the formation of ATP and pyruvic acid. These reactions may be illustrated as follows:

The pyruvic acid which is produced at this stage may be regarded as a keystone in the architecture of carbohydrate metabolism. Further reactions depend upon whether aerobic or anaerobic conditions prevail. A discussion of the ensuing steps in the aerobic metabolism of carbohydrate, and the part played by pyruvic acid, will be found in Chapter 33. Under anaerobic conditions such as prevail in muscle, pyruvic acid is reduced to lactic acid by reaction with reduced coenzyme I:

Thus the coenzyme I which was reduced in the formation of phosphoglyceric acid is reoxidized in the formation of lactic acid as the endproduct of the anaerobic breakdown of carbohydrate in muscle.

From the above presentation it will be noted that the apparently simple formation of lactic acid from glycogen in muscle in reality involves an interlocking of a series of complicated chemical reactions involving many different types of molecules, some of which are part of the machine and some of which are part of the fuel, and that the energy relationships at no point involve the participation of molecular oxidation but appear primarily to involve phosphate bond energy and the oxidation-reduction potentialities of coenzymes. One can only speculate as to the reason for such a complicated series of reactions; it has been suggested that control of the liberated energy is better accomplished if the energy is liberated in a series of steps than if it is liberated all at once.

The lactic acid which is produced as just described during the anaerobic phase of muscular contraction disappears under aerobic conditions; in fact, no lactic acid is found at all in a slowly contracting muscle in the presence of abundant oxygen. It was proposed by Hill and Meyerhof that the disappearance of lactic acid and the resynthesis of glycogen was at the expense of the complete oxidation of one-fifth of the lactic acid produced, the other four-fifths being resynthesized to glycogen. These conclusions were based upon studies using frog muscle; there is considerable doubt as to whether or not they are equally valid for mammalian muscle.

It will be noted that all of the reactions postulated as leading to the formation of lactic acid from glycogen are reversible. Thus these reactions could lead equally well to the synthesis of glycogen from intermediates.

There is good evidence that glycogen is formed in the animal body from lactate and pyruvate; this subject is discussed in detail in Chapter 33.

It is clear from the above discussion that the formation of glycogen from glucose necessarily involves the preliminary formation of glucose-1-phosphate or its equivalent. This phosphorylation is brought about by the enzyme hexokinase, found in most tissues, which catalyzes the transfer of phosphate from adenosinetriphosphate to glucose or fructose. The product of this action is either glucose-6-phosphate or fructose-6-phosphate, as the case may be; from this stage the further formation of glycogen or breakdown and oxidation may follow the pathways just described.

INFLUENCE OF VITAMINS AND DRUGS ON MUSCULAR EFFICIENCY

An increase in the daily ingestion of vitamin B₁ (thiamine) above that required to prevent deficiency symptoms (1 mg.) retards the onset of fatigue and brings about a higher degree of physical fitness and well being. The activity of isolated muscle is increased by vitamin C. However, that this vitamin has any definite influence upon the physical efficiency of man has not been conclusively shown. Of the drugs, caffeine is the only one which has been reported to cause an objective effect upon the work output in man.⁸ But even in the case of caffeine the increased work accomplished has been shown to be secured at the expense of accuracy.⁹ A number of well-controlled tests failed to verify the claim that the ingestion of gelatin increased the muscular strength of man.¹⁰

EXPERIMENTS ON MUSCULAR TISSUE

- 1. Preparation of Muscle Plasma: Wash out the blood vessels of a freshly killed rabbit with 0.9 per cent sodium chloride. This can best be done by opening the abdomen and inserting a cannula into the aorta. Now remove the skin from the lower limbs, cut away the muscles, and divide them into very small pieces by means of a meat chopper. Transfer the pieces of muscle to a mortar and grind them with clean sand and a little ice-cold 5 per cent magnesium sulfate. Place in an icebox over night. Filter off the salted muscle plasma and make the following tests:
 - a. Reaction: Test the reaction using suitable indicator paper. What is the approximate pH of this fresh muscle plasma?
 - b. Fractional Coagulation: Place a little muscle plasma in a test tube and place the tube in a beaker of distilled water. Raise the temperature very carefully from 30° C. and note any changes which may occur and the exact temperature at which such changes take place. When the first protein coagulates filter it off and then heat the clear filtrate as before, being careful to note the exact temperature at which the next coagulation occurs. There will probably be a preliminary opalescence in each case before the real coagulation occurs. Therefore do not mistake the real coagulation point and filter at the wrong time. What are the coagulation temperatures of these two proteins? Which protein was present in greater amount?

⁸ Folts, Ivy, and Barborka: Am. J. Physiol., 136, 79 (1942).

^{*} Hawk: Report before the 13th International Physiological Congress, Boston, 1929. (Abstr. in Am. J. Physiol., Oct., 1929.)

¹⁶ King, Kennedy, and Klumpp: J. Am. Med. Assoc., 118, 594 (1942).

- c. Formation of Myosin Clot: Dilute a portion of the plasma with three or four times its volume of water and place it on a water bath or in an incubator at 35° C. for several hours. A typical myosin clot should form. Note the muscle serum surrounding the clot. Now test the reaction. Has the reaction changed, and if so to what is the change due? Make a test for lactic acid. What do you conclude?
- 2. "Fuchsin-frog" Experiment: Inject a saturated aqueous solution of Fuchsin "S" into the lymph spaces of a frog two or three times daily for one or two days, in this way thoroughly saturating the tissues with the dye. Pith the animal (insert a heavy wire or blunt needle through the occipitoatlantoid membrane), remove the skin from both hind legs, and expose the sciatic nerve in one of them. Insert a small wire hook through the jaws of the frog and suspend the animal from an ordinary clamp or iron ring. Pass electrodes under the exposed sciatic nerve, and after tying the other leg to prevent any muscular movement, stimulate the exposed nerve by means of make and break shocks from an induction coil. The stimulated leg responds by pronounced muscular contractions, whereas the tied leg remains inactive. Continue the stimulation until the muscles are fatigued. The muscular activity has caused the production of lactic acid and this in turn has reacted with the injected fuchsin to cause a pink or red color to develop. The muscles of the inactive leg still remain unchanged in color.

The color of the Fuchsin "S" when injected was red; this substance acts as a pH indicator, however, and is colorless at the pH of normal tissues. Upon stimulating the muscles, as explained above, lactic acid was formed and the resultant lowering of pH regenerated the original color of the dye.

3. Preparation of Adenosinetriphosphate from Muscle: Into the peritoneal cavity of a rabbit inject a solution containing 25 per cent anhydrous magnesium sulfate in the proportion of 5 ml. per kilogram of body weight. When the animal is unconscious, slit its throat and bleed it as thoroughly as possible, then remove the skin and pack the carcass in ice for an hour or so to chill thoroughly. Excise the muscle tissue of the legs and back and grind in a chilled meat-grinder. (All of the remaining steps should be carried out in a cold room or with thorough chilling of reagents, containers, etc., by ice.) Mix the minced muscle with an equal weight of ice-cold 10 per cent trichloroacetic acid, and after thorough mixing, filter by suction. Extract the residue with an equal weight of 4 per cent trichloroacetic acid and filter as above. Neutralize the combined filtrates to pH 6.8 with 40 per cent sodium hydroxide solution. Add 50 per cent barium acetate solution to complete precipitation, and allow the precipitate to settle. Decant the supernatant, centrifuge down the precipitate, and wash it once with water.

Treat the precipitate with 0.2 N nitric acid, with stirring, to 2 pH of 3, or to the first blue with Congo red paper. Centrifuge and pour off the supernatant, rejecting the insoluble material. Add to the supernatant 3 to 5 ml. of Lohmann's reagent¹¹ for every kilogram of muscle used. Allow to stand at 0° for 15 minutes and centrifuge. Suspend the precipitate in water made faintly acid with nitric acid, treat for 1 hour with hydrogen sulfide to decompose the mercury salt, and filter. Aerate the filtrate to remove excess hydrogen sulfide, then neutralize the filtrate to pH 6.8 with dilute sodium hydroxide solution. Add 25 per cent barium acetate solution to complete precipitation, avoiding an excess. Filter off the precipitate by suction and wash it successively with 1 per cent barium acetate solution, 50 per cent alcohol, 75 per cent alcohol, 95 per cent alcohol, and ether. Dry the product in air and store well-stoppered in the cold. The yield is roughly 3 g. of the barium salt pes kilogram of muscle used.

¹¹ To prepare Lohmann's reagent, add 25 ml. of concentrated nitric acid to 100 g. of mercuric nitrate octahydrate, followed by 25 ml. of water. Warm to dissolve.

This product usually contains some inorganic phosphate; it may be further purified, with a lower yield, by redissolving in cold 0.1 N hydrochloric acid, neutralizing to pH 6.8 as above, and filtering off the precipitated barium ATP which is then washed with alcohol and ether and dried as above. The pure salt has the empirical formula $C_{10}H_{12}O_{13}N_0P_1Ba_2 + xH_2O$, the water content depending upon the extent of drying. Purity is usually established by the following criteria: (1) The molecular ratio of nitrogen to phosphorus, as established by total N and total P analyses, should be 5:3; (2) the inorganic phosphate content should be very low; (3) the "labile phosphate" (see below) should be two-thirds of the total phosphate after correcting the latter for any inorganic phosphate present.

Conversion of Barium ATP to Sodium ATP: Dissolve 200 mg. of the barium salt in 6 ml. of ice-cold 0.1 N hydrochloric acid in a centrifuge tube. Add 60 mg. of anhydrous sodium sulfate dissolved in a little water, stir, and centrifuge. Decant the supernatant and wash the precipitated barium sulfate several times with small portions of cold water containing a trace of hydrochloric acid. Neutralize the combined supernatant and washings to pH 7.5-8.5 as desired, analyze an aliquot for inorganic and labile phosphate, and on the basis of this analysis dilute to the desired concentration of sodium ATP. This solution is relatively stable for some weeks in the cold, but undergoes slow hydrolysis, the extent of which should be established before use.

Analysis of Adenosinetriphosphate: Prepare a solution of adenosinetriphosphate in cold 0.1 N hydrochloric acid, containing approximately 1 mg. of the salt per ml. Analyze aliquots of this solution as follows: (1) Inorganic phosphate.¹² Dilute 1 ml. to 4 ml. with water, add 1 ml. of 5 N sulfuric acid, followed by 1 ml. of 2.5 per cent ammonium molybdate and 0.4 ml. of the Fiske-SubbaRow aminonaphtholsulfonic acid reagent (see Chapter 23). Dilute to 10 ml. with water, mix, allow to stand 10 minutes, and read in a photometer at 660 mu wavelength. Compare with a standard containing 0.05 mg. P, treated in the same way. (2) "Labile phosphate." Dilute 0.5 ml. of solution to 4 ml. with water, add 1 ml. of 5 N sulfuric acid, place in boiling water for 30 minutes. 13 Cool, make up to 5 ml. again, and continue with the addition of ammonium molybdate, etc., as described above. The phosphate content, corrected for the inorganic phosphate already present, represents the "labile phosphate" of ATP. It should be two-thirds of the total ATP phosphorus. (3) Total phosphorus. Transfer a 1 ml. portion of the ATP solution to a large test tube or microkjeldahl flask and add 2.5 ml. of 5 N sulfuric acid. Heat over a microburner until the water has boiled off and the residual fluid is brown or black. Add 1 drop of 30 per cent hydrogen peroxide and boil until clear. Cool, transfer to a 25-ml. graduated flask, with washings to about 18 ml. volume. Add 2.5 ml. of ammonium molybdate and 1 ml. of aminonaphthoisulfonic acid reagent. Dilute to 25 ml., mix, and allow to stand 10 minutes. Compare in a photometer against a standard containing 0.1 mg. P digested with acid, etc., just as was the unknown. A blank of water alone should also be run through the entire procedure, to correct for any phosphorus in the reagents. The total P of the sample, corrected for any inorganic P present, represents ATP phosphorus. (4) Total nitrogen. Determine by any suitable microkjeldahl method (see Chapters 23 and 32). A 4-ml. portion of the ATP solution described above will contain about 0.3 mg. of nitrogen. The N:P ratio on a molecular basis should be 5:3.

¹⁸ In this and subsequent analyses, if barium is present a precipitate of barium sulfate will form during the procedure. This is centrifuged down after color development and before reading.

¹⁸ According to Lohmann, the "labile phosphate" of ATP is liberated by 7 minutes' hydrolysis in N hydrochloric acid at 100° C. Fiske and others claim that 15 minutes are required. When N sulfurie acid is used, a 30-minute period has been found necessary.

- 4. Preparation of Enzymatically Active Myosin (Bailey): Kill a rabbit by stunning and bleed it thoroughly, either from the slit throat or the inferior vena cava. Ouickly remove the skin from the hind quarters and obtain about 100 g. of muscle from the hind legs and back. Mince the muscle in a chilled meat-chopper, and add the minced muscle to 5 volumes of an ice-cold solution containing 37.2 g. of potassium chloride and 3 g. of potassium bicarbonate per liter. (The following steps should be carried out in a cold room or with thorough chilling of reagents, containers, etc., by ice.) Adjust the pH to 7.0-7.5 by the addition of solid potassium bicarbonate and stir the mixture slowly for 1 hour, keeping the temperature at 0° C. Check the pH from time to time, adding more potassium bicarbonate if necessary to maintain the pH within the limits indicated above. Centrifuge down the bulk of the insoluble material and filter the supernatant fluid through paper pulp saturated with the salt solution. Pour the filtrate into 20 volumes of ice-cold water. Adjust the pH to 6.8-7.0 by adding dilute hydrochloric acid, and allow the precipitated myosin to settle. Decant the supernatant liquid and centrifuge down the precipitated myosin. Redissolve the myosin by addition of sufficient solid potassium chloride to make an 0.5 M solution (37 mg. per ml.), and adjust to pH 7 with solid potassium bicarbonate. Reprecipitate by dilution at pH 7 with 20 volumes of ice-cold water as above, redissolve the centrifuged myosin in potassium chloride at pH 7, and repeat the precipitation at least once more. Bring the final myosin precipitate into solution at pH 7 in 0.5 M potassium chloride, centrifuge or filter through pulp, and store in the ice-box in the presence of a trace of toluene. For quantitative studies the protein content of this stock solution should be established. If this is done by total nitrogen analysis, the per cent of nitrogen times 6 equals the per cent of protein. The enzymatic activity may be tested as described below. Six week's storage results in a decrease in enzymatic activity of about 50 per cent.
 - 5. Demonstration of Adenosinetriphosphatase Activity of Myosin: Place 2 ml. of myosin solution (diluted in 0.5 M potassium chloride so as to contain 1 to 2 mg. of protein) in each of two test tubes. Add 1 ml. of 4 per cent sodium bicarbonate solution and 0.5 ml. of 0.1 per cent anhydrous calcium chloride solution. To tube 1, which is a control, add 0.5 ml. of 20 per cent trichloroacetic acid solution. To each tube add 0.5 ml. of sodium ATP solution containing a known amount (0.1 to 0.2 mg.) of "labile phosphorus." Dijute the contents of the control tube immediately to 10 ml. with water, mix and filter. Allow the second tube to stand at room temperature for 30 minutes, then add 0.5 ml. of 20 per cent trichloroacetic acid solution, dilute to 10 ml., mix and filter. Determine the inorganic phosphate content of each filtrate as described above, using a 2-ml. aliquot. Correct for the value of the control by subtraction. What fraction of the labile phosphate of the ATP has been converted into inorganic phosphate by the myosin? If desired this experiment may be repeated at varying time intervals to establish the rate of enzyme action.
 - 6. Preparation of Adenylic Acid from Adenosinetriphosphate (Kerr): Dissolve 2.5 millimoles of barium adenosinetriphosphate (93 mg. of ATP phosphorus equals one millimole) in a flask containing about 100 ml. of 0.1 N hydrochloric acid, and add a few drops of phenolphthalein followed by sufficient barium hydroxide solution to produce a permanent pink color. Attach a reflux condenser to the flask and heat to boiling over a free flame. Boil for 30 minutes, maintaining the reaction just alkaline to phenolphthalein by the continuous addition of barium hydroxide solution in small portions through the condenser tube. Cool to room temperature, add sufficient N hydrochloric acid to the flask contents to dissolve the precipitate, and dilute to about 1,750 ml. with water. Again neutralize to phenolphthalein with barium hydroxide, and allow the precipitate

to settle. Remove the supernatant by decantation and filtration, discarding the precipitate. To the supernatant add sufficient acetic acid to make the final acid concentration 0.2 per cent, followed by 50 ml. of 20 per cent mercuric acetate solution per liter of fluid present. Allow the precipitate to settle overnight, separate it by decantation and centrifugation, and wash it once with 0.5 per cent mercuric acetate solution. Suspend the washed precipitate in about 50 ml. of water containing a few drops of 2 N sulfuric acid and treat with hydrogen sulfide for one hour. Filter off the precipitated mercuric sulfide and pass air through the filtrate to remove excess hydrogen sulfide. The volume at this point should not be over 25 ml. per millimole of starting material. Add acetone to the solution at 20° C. to the first permanent turbidity (not over 1.5 volumes). Allow to stand on ice overnight, filter and discard the precipitate. Bring the filtrate to room temperature and again add acetone to the point of turbidity. Again chill overnight. Separate the crystalline adenylic acid by centrifugation. Repeat the addition of acetone as described until a total of 3 volumes has been added. Drive off excess acetone from the separated adenylic acid by gentle warming. Recrystallize by dissolving in the minimal amount of hot water, filtering quickly, and allowing the filtrate to stand in the cold overnight. Centrifuge or filter off the crystals and repeat the recrystallization procedure five or six more times to obtain a final product which has the theoretical N: P ratio of 5: 1 and the correct melting point of 189° C. The final crystals are washed with a little alcohol and ether and dried. The mother liquors from the various recrystallizations may be saved. combined, and treated with 3 volumes of acetone, followed by recrystallization as above, to obtain more adenylic acid which is less pure.

7. Preparation of Glycogen: Grind a few fresh oysters in a mortar with sand. Transfer to an evaporating dish, add water, and boil for 29 minutes. At this point the volume of solution should have been reduced by about one-half. Note the opalescence of the solution. At the boiling point faintly acidify with acetic acid. Why is this acid added? Filter, and divide the filtrate into two parts.

Test one part of the filtrate as follows:

- a. Iodine Test: To 5 ml. of the solution in a test tube add 5 to 10 drops or more of Lugol's iodine solution, at the same time adding a similar amount of iodine to 5 ml. of water in another tube, this serving as a control. What do you observe? Is this similar to the iodine test upon any other compound with which we have had to deal?
- b. Reduction Test: Does the solution reduce Benedict's solution?
- c. Hydrolysis of Glycogen: Add 10 drops of concentrated hydrochloric acid to 10 ml. of the solution and boil for 10 minutes. Cool the solution, neutralize with solid sodium carbonate, and test with Benedict's solution. Does it still fail to reduce Benedict's solution? If you find a reduction how can you prove the identity of the reducing substance?
- d. Influence of Saliva: Place 5 ml. of the solution in a test tube, add 5 drops of saliva, and place in the water bath at 40° C. for 10 minutes. Does this now reduce Benedict's solution?

To the second part of the glycogen filtrate add 3 to 4 volumes of 95 per cent alcohol. Allow the glycogen precipitate to settle, decant the supernatant fluid, and filter the remainder. Transfer the glycogen to a watch-glass and heat on a water bath to remove the alcohol, then subject it to the following tests:

- a. Solubility: Try its solubility in cold and hot water, in alcohol, and ether.
- b. Iodine Test: Place a small amount of the glycogen in a depression of a test tablet and add 2 to 3 drops of dilute iodine solution. The same wine-red color is observed as in the iodine test upon the glycogen solution.

¹⁴ Glycogen may be readily obtained from the livers of well-fed rabbits which have been killed by the intraperitoneal injection of 5 ml. of 25 per cent anhydrous MgSO₄ per kg. The excised liver is quickly cut into small pieces and dropped into about 150 ml. of boiling water, continuing then as described above.

8. Testing for Inorganic Constituents:

a. Examination of Ash of Muscle: Incinerate a small amount of muscular tissue, dissolve the ash in dilute nitric acid. Test for potassium, phos-

phates, magnesium, calcium, and chlorides.

b. Demonstration of Phosphates and Magnesium in Muscle (Hürthle's Experiment): Tease a very small piece of frog's muscle on a microscope slide. Expose the slide to ammonia vapor for a few moments, then adjust a cover glass, and examine the muscle fibers under the microscope. Note the large number of crystals of ammonium magnesium phosphate, distributed everywhere throughout the muscle fiber, thus demonstrating the abundance of phosphates and magnesium in this type of muscle preparation (see Fig. 236).

SEPARATION OF EXTRACTIVES FROM MUSCLE

1. Creatine: Dissolve about 10 c. of a commercial extract of meat 15 in 200 ml. of warm water. (Test for protein by the biuret and coagulation tests; see Chapter 6.) Precipitate the inorganic constituents by neutral lead acetate, being careful not to add an excess of the reagent (30 ml. of a 20 per cent solution is about the right amount). Write the equations for the reactions taking place here. Allow the precipitate to settle, then filter and remove the excess of lead in the warm filtrate by hydrogen sulfide. Filter while the solution is yet warm, evaporate the clear filtrate to a syrup, and allow it to stand at least 48 hours in a cool place. Crystals of creatine should form at this point. Examine under the microscope (see Fig. 75). Treat the syrup with 25 ml. of 95 per cent ethyl alcohol, stir well with a glass rod to bring all soluble material into solution, and then filter. When the fluid has drained completely, use a further 10-ml. portion of 95 per cent alcohol to aid in transferring the residue in the beaker to the filter paper, and to wash the material on the filter paper. The purine bases have been dissolved and are in the filtrate, whereas the creatine crystals were insoluble in the alcohol and remain on the filter paper. Remove the crystals and bring them into solution in about 10 ml. of hot water. A little animal charcoal may be added to decolorize the solution. Filter and concentrate the filtrate to small volume. Allow the solution to cool and note the separation of colorless crystals of creatine.16

Make the following tests on the crystals:

a. Microscopical Examination: Examine some crystals under the microscope and compare the form with those reproduced in Fig. 75.

b. Transformation of Creatine into Creatinine: Dissolve a portion of the crystals in about 10 ml. of water. Divide into two equal portions. To one portion add 5 ml. of 2 N hydrochloric acid. Evaporate this acidified portion carefully over the free flame and finally to dryness on the water bath. The creatine has been changed into creatinine. Take up the residue in about 5 ml. of hot water, cool, and apply the tests for creatinine as given in Chapter 28 to this extract as well as to the original solution. What are your conclusions?

Diacetyl Reaction: To 5 ml. of a dilute creatine solution add an equal volume of saturated sodium carbonate solution and a few drops of a solution of diacetyl. A pink color should develop. This test has been made the basis of a method for the quantitative determination of creatine.

2. Hypoxanthine: Evaporate the alcoholic filtrate from the creatine to remove the alcohol. Make the solution ammoniacal and add ammoniacal silver nitrate until precipitation ceases. The precipitate consists principally of hypoxanthine silver and xanthine silver. Collect these silver salts on a

¹⁸ Commercial meat extracts vary considerably in their creatine content, and may be quite low in this respect. For class use, the meat extract should be analyzed to establish its creatine content, and if necessary "fortified" by the addition of sufficient creatine to render the isolation feasible.

¹⁶ For the preparation of pure creatine from creatinine, see Chapter 28, Urine: Physiological Constituents.

filter paper and wash them with water. Place the precipitate and paper in an evaporating dish and boil for one minute with nitric acid having a specific gravity of 1.1. Filter while hot through a double paper, wash with the same strength of nitric acid and allow the solution to cool. By

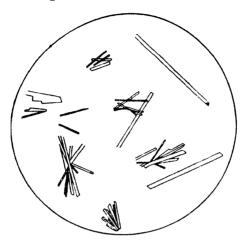

Fig. 77. Hypoxanthine silver nitrate. (Drawn from a student preparation by Dr. E. F. Hirsch.)

Fig. 78. Hypoxanthine Chloride. Hypoxanthine nitrate crystallizes in similar form. (Reproduced from crystals furnished by the late Prof. Walter Jones.)

this treatment with nitric acid hypoxanthine silver nitrate and xanthine silver nitrate have been formed. The former is insoluble in the cold solution and separates on standing. After standing several hours filter off the hypoxanthine silver nitrate and wash with water until the wash water is only alightly acid in reaction. Examine the crystals of hypo-

ranthine silver nitrate under the microscope and compare them with those in Fig. 77. Now wash the crystals from the paper into a beaker with a little water and warm the liquid. Remove the silver by hydrogen sulfide and filter. By this means hypoxanthine nitrate has been formed and is present in the filtrate. (For the crystalline form of hypoxanthine nitrate, see Fig. 78.) Concentrate on a water bath to drive off hydrogen sulfide, and render the solution slightly alkaline with ammonia. Warm for a time, to remove the free ammonia, filter, concentrate the filtrate to a small volume, and allow it to stand in a cool place. Hypoxanthine should crystallize in small colorless needles. Examine the crystals under the microscope.

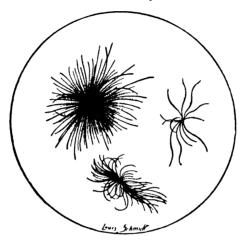

Fig. 79. Xanthine silver nitrate.

3. Xanthine: To the filtrate from the above experiment containing the xanthine silver nitrate add ammonia in excess. (The crystalline form of xanthine silver nitrate is shown in Fig. 79.) A brownish-red precipitate of xanthine silver forms. Filter off the precipitate, suspend in water, and treat with hydrogen sulfide (do not use an excess of hydrogen sulfide), then warm the mixture for a few moments and filter while hot. Concentrate the filtrate to a small volume and put away in a cool place for crystallization (Fig. 76). To obtain xanthine in crystalline form special precautions are generally necessary. Evaporate the solution to dryness and test according to the directions given in Chapter 7, Nucleic Acids and Nucleoproteins.

Nervous Tissue

In common with the other solid tissues of the body, nervous tissue contains a large amount of water. The percentage of water present depends upon the particular form of nervous tissue, but in all forms it is invariably greater in the gray matter than in the white. Embryonic nervous tissues also contain a larger percentage of water than the tissues of the adult. The gray matter of the brain of the fetus, for instance, contains about 92 per cent of water, whereas the gray matter of the brain of the adult contains but 83 to 84 per cent. Adult whole brain (mixed gray and white matter) has an average water content of 77 to 78 per cent; human spinal cord contains about 75 per cent of water.

The solids of nervous tissue include proteins, lipids, extractives, and inorganic salts. In adult whole brain the relative amounts of these various components, in percentage of the total solids, are approximately as follows: proteins 38 to 40 per cent, lipids 51 to 54 per cent, and extractives (including inorganic salts) 8 to 9 per cent. Other parts of the nervous system may show a somewhat different distribution.

The Proteins. The proteins of nervous tissue which have been fairly well characterized include several globulins, nucleoprotein, and the albuminoid neurokeratin. Two of the globulins coagulate at 47° C. and 70° to 75°C., respectively, while the nucleoprotein coagulates at 56° to 60°C. The relatively low coagulating temperature of one of the globulins of nervous tissue may be of importance in connection with the nervous manifestations of heat prostration.

The Lipids. Many types of lipids occur in nervous tissue. Among these are (1) phospholipids or phosphatides, (2) glycolipids or cerebrosides, (3) sulfolipids or sulfatides, (4) gangliosides, (5) aminolipids, and (6) cholesterol. Other types will doubtless be recognized as progress is continued in this field, It will be noted that the lipids are chiefly of the compound type; there is little or no true fat in nervous tissue. For example, of the 54 per cent of cerebrum solids which are composed of lipid material, the phosphatides constitute approximately 28 per cent, cholesterol 10 per cent, cerebrosides 7 per cent, and the remaining 9 per cent consists chiefly of sulfatides and other relatively poorly characterized and similar material. It has been shown that the relative amounts of certain of the lipids present in the brain may be influenced by age and sex.

PHOSPHOLIPIDS (PHOSPHATIDES). The phospholipids or phosphatides include (1) lecithins, (2) cephalins, and (3) sphingomyelin.

Lecithins. The lecithins are sometimes spoken of as "phosphorized fats." Their relationship to the fats is indicated by the formula of a typical lecithin.

This lecithin would be called olevl-stearyl-lecithin. On hydrolysis it would yield oleic acid, stearic acid, glycerol, phosphoric acid, and choline. There are different legithins depending on the character of the fatty acid radicals and also on whether the phosphoric acid-choline group is attached to the α (terminal) or β (middle) carbon of the glycerol group; in this latter instance these lecithins are known as α - and β -lecithins respectively. Apparently each lecithin contains one molecule each of unsaturated and saturated fatty acids. The saturated fatty acids found are palmitic and stearic. The unsaturated acids are oleic, linolic, linolenic, and arachidonic (see Chapter 3). The legithing are not confined to the nervous tissues but are found in nearly all animal and vegetable tissues, where they appear to be primary constituents of the cell. Lecithin is soluble in chloroform, ether, alcohol, benzene, and carbon disulfide. It may be precipitated from chloroform or alcohol-ether solution by acetone. Lecithin may be caused to crystallize in the form of small plates by cooling the alcoholic solution to a low temperature. It has the power of combining with acids, bases, and certain salts, such as cadmium chloride, and the hydrochloric acid salt has the power of forming a double salt with platinic chloride.

Pure lecithin is colorless; it readily turns brown on exposure to air, presumably because of oxidation of the unsaturated fatty acids present. The choline-phosphoric acid portion of the lecithin molecule is highly water-soluble; the fatty acid portion is insoluble in water but soluble in fats. Lecithin forms colloidal solutions in water which are of the hydrophilic or emulsoid type (see Chapter 1). If a portion of solid lecithin is placed in water and then observed under the microscope, the lecithin will be seen to diffuse out into the water in the form of long curving strands ("myelin forms") which bear a remarkable resemblance to the protoplasmic protuberances of lower forms of life. The hydrophilic nature of the lecithin molecule may be of importance in connection with the structure and properties of cell membranes.

Choline, as was indicated above, is one of the products of hydrolysis of lecithin. It is trimethyl-hydroxyethyl-ammonium hydroxide, and has the following structure:

Choline is a moderately strong base, and forms a crystalline double salt with platinic chloride. In addition to its presence in the lecithin molecule, choline is found widely distributed elsewhere in nature, either free or combined, and in the light of recent research appears to play an important part in a variety of physiological processes. In combination with acetic acid the compound acetylcholine is of significance in nerve activity, as discussed later. In the diet choline has been shown by du Vigneaud and collaborators to be a suitable source of the labile methyl group (methyl attached to nitrogen or sulfur), which apparently cannot be synthesized by the animal body but must be obtained from the diet. Choline is thus a dietary component, functioning like a vitamin, and in fact is found wherever the water-soluble B vitamins are found. Further aspects of the biochemistry of choline will be found in Chapters 33 and 35.

Cephalins. Cephalins differ from lecithins in that they contain the weaker base aminoethyl alcohol CH₂OH·CH₂NH₂ instead of choline. Cephalins have also been isolated from brain by Folch which apparently contain the amino acid serine, CH₂OH·CHNH₂·COOH instead of aminoethyl alcohol; an inositol phosphatide has also been obtained. Lysolecithin and lysocephalin are prepared by treating lecithin or cephalin with cobra venom. An enzyme present in the venom splits off the unsaturated fatty acid radical leaving the structure otherwise unchanged. Compounds of this type have a strong hemolytic action on red cells and the hemolytic action of venom is probably brought about in this way. These lysophosphatides combine readily with cholesterol, molecule for molecule, the resulting compound having no hemolytic power.

Sphingomyelin. Sphingomyelin represents a third type of phospholipid found in nervous tissue. It is a diaminomonophosphatide made up of a molecule each of fatty acid, phosphoric acid, and of the bases choline and sphingosine. Sphingosine is:

Among the fatty acids found have been the saturated acids—lignoceric, C₂₄H₄₈O₂, and another acid, probably hydroxystearic. The fatty acid is apparently in an amide linkage with the amino group of sphingosine. The complete structure would be as follows, R indicating the fatty acid radical.

The content of sphingomyelin (and of lecithin as well) is considerably increased in the liver and spleen in the condition known as Niemann-Pick's disease.

GLYCOLIPIDS (CEREBROSIDES). Glycolipids or cerebrosides are lipids containing a carbohydrate group and nitrogen but no phosphorus. They include phrenosin and kerasin. They are found in many tissues besides the brain. In Gaucher's disease (splenomegaly) excessive amounts of kerasin are found in the spleen, which is normally practically free from this compound. Cerebrosides appear to be an important constituent of the myelin sheath of medullated nerve fibers, which contain about three times as much cerebroside as is found in nonmedullated nerves. On hydrolysis they yield one molecule each of fatty acid, sphingosine, and galactose; glycolipids containing glucose have, however, been isolated from a few sources. The fatty acid in phrenosin is the hydroxy acid phrenosinic acid C24H48(OH)COOH, and in kerasin it is lignoceric acid. The glycolipids are relatively less soluble in ether and more soluble in hot alcohol than the phosphatides.

Gangliosides Gangliosides represent a class of cerebrosides first described by Klenk, which are found in brain gray matter, spinal cord, and other tissues. On hydrolysis they yield one molecule each of a base, presumably sphingosine, stearic acid, and neuraminic acid, and three molecules of galactose.

SULFOLIPIDS (SULFATIDES). The sulfolipids containing the sulfuric acid group and the aminolipids are not yet well characterized.

Cholesterol. Cholesterol, one of the primary cell constituents, is present in fairly large amount in nervous tissue. It is a monatomic alcohol containing one double bond and possesses the formula C₂₇H₄₅OH. Its structure is as follows:

The carbon atoms are numbered as shown for purposes of reference. The four rings A, B, C, and D form the cyclopentano-perhydrophenanthrene nucleus, which is characteristic not only of cholesterol and other plant and animal sterols but also of a wide variety of naturally occurring compounds of surprisingly diverse physiological significance. These compounds

include (a) the bile salts, (b) the steroid hormones, (c) the sterol vitamins, (d) the aglycone portion of the cardiac glycosides (digitalis, etc.), (e) the sapogenins, derived from plant saponins; and one might also include here the carcinogenic hydrocarbons of the phenanthrene type. The possible interrelationship of these varied compounds whose chemical structures are fundamentally similar has attracted considerable attention; it has been shown for example that the cholesterol of the bile may be a precursor of the chemically similar cholic acid derivatives also present.

Cholesterol is soluble in ether, chloroform, benzene, and hot alcohol. It crystallizes in the form of thin, colorless, transparent plates (see Fig. 112). Cholesterol is present in bile, and occurs abundantly in one form of biliary calculus. It is also present in blood and its quantitative determination is of clinical importance (see Chapter 23). It has been found in feces, wool fat, egg yolk, and milk, frequently in the form of its esters of higher fatty acids. It is found in the tissues of all animals. The cholesterol present in the animal body has its origin from animal foods or through synthesis in the body; work with isotopes has indicated that acetic acid may be a major intermediate in this synthesis. It does not appear to arise from plant sterols. That cholesterol may be synthesized in the animal body is proved by experimental work using isotopes as well as by such facts as that hens continue to lay eggs containing cholesterol when fed a cholesterol-free diet and that the tissues of the rat contain the usual cholesterol content when fed a diet containing no sterols.

Various isomers and derivatives of cholesterol are found in plant and animal tissues; only a few may be considered here. A further discussion of steroid isomerism will be found in Chapter 26. Allocholesterol or coprostenol is an isomer of cholesterol differing only in that the double bond is in the 4-5 instead of the 5-6 position. Coprosterol or coprostanol is formed by the addition of two hydrogen atoms at the double bond in allocholesterol. It is found in the feces being formed by bacterial reduction. Ergosterol (a provitamin D) differs from cholesterol in having two more double bonds, one in the 7-8 position and one in the side chain. with an additional methyl group in the side chain which thus becomes --CH(CH₂)·CH:CH·CH(CH₂)·CH(CH₂)·CH₃. On suitable irradiation ergosterol finally yields calciferol with a rupture of the Bring. 7-Dehydrocholesterol, found in the skin, is also activated by irradiation to produce a compound with vitamin-D activity. Stigmasterol obtained from plant sources differs from ergosterol in having only one double bond in the nucleus (like cholesterol) and in having the second methyl group in the side chain replaced by an ethyl group. The phytosterols or plant sterols comprise several different sterols. According to Schoenheimer, the bulk of plant sterols do not appear to be absorbed by the body.

Inorganic Salts. Nervous tissue yields about 1 per cent of ash which is made up in great part of alkaline phosphates and chlorides.

CHEMICAL CHANGES IN NERVOUS ACTIVITY

The carbohydrate metabolism of nervous tissue appears to follow much the same course as that of muscle tissue, going by way of pyruvic and lactic acids. Since glycogen is low in amount in the brain and glucose appears to be the major carbohydrate substrate, this organ is more immediately dependent upon the blood sugar supply. Nerves consume oxygen and liberate heat to a greater extent following stimulation.

The transmission of impulses along a nerve or from nerve fibers to muscle fibers or secretory cells, or from one nerve fiber to another across synapses in ganglia, is thought to involve chemical changes, either directly or as the source of potential differences. According to one view, the nerve action current results from a redistribution of diffusible ions between the center of the nerve and the periphery, taking place successively along the nerve fiber. This redistribution of ions may be under the control of chemical agencies.

At the motor nerve endings in voluntary muscle, stimulation appears to liberate the compound acetylcholine (see below). Involuntary muscles and secretory cells are controlled by two sets of nerves, sympathetic and parasympathetic. The parasympathetic fibers liberate acetylcholine at the nerve endings in such cells. Stimulation of such nerves causes smooth muscle fibers, as in blood vessels, to relax with dilation of the vessels. Stimulation of the sympathetic nerves brings about the liberation of a substance called sympathin, and causes contraction of the vessels, thus having an effect opposite to that of the parasympathetic nerves but identical with that produced by treating the fiber with adrenaline. Nerves may therefore be classified as (1) cholinergic or (2) adrenergic. The cholinergic nerve fibers include motor nerves, all preganglionic fibers, and the postganglionic parasympathetic fibers. The adrenergic are the sympathetic fibers. Sympathin is similar to adrenaline in some respects, but may be apparently differentiated into two components, one excitory (sympathin E) and one inhibitory (sympathin I), which is not true of adrenaline.

Acetylcholine is sometimes called parasympathin. It is an unstable compound and is rapidly hydrolyzed to choline and acetic acid by an acetylcholine esterase found at nerve endings and in some instances along the nerve fiber itself.

$$\begin{array}{ccccccccc} \mathrm{CH_4 \cdot CO \cdot O \cdot CH_2 \cdot N} \equiv (\mathrm{CH_3})_3 & \rightleftharpoons & \mathrm{CH_2OH \cdot CH_2 \cdot N} \equiv (\mathrm{CH_3})_3 + \mathrm{CH_3 \cdot COOH} \\ & & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & \\ & & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & \\ & & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & \\ & & & \\ & & & \\ & & \\ & & & \\ & & \\ & & & \\ & & \\ & & \\ & & & \\ & \\ & & \\ & & \\ & \\ & & \\ & & \\ & \\ & & \\ & & \\ & \\ & & \\ & \\ & & \\ & & \\ & \\ & &$$

This reaction is reversible as shown; the synthesis of acetylcholine from choline and acetic acid has been demonstrated in brain tissue, the reaction requiring the "high energy phosphate" of ATP (Nachmansohn). The acetylation of choline is discussed further in Chapter 33 in connection with biological acetylation in general. Thus acetylcholine formation and breakdown appear to be under the control of acetylcholine esterase; the exact significance of this control in connection with the transmission of the nerve impulse from nerve to nerve and from nerve to receptor cell is still a matter of dispute.

Acetylcholine esterase is reversibly inhibited by the drug eserine (also called physostigmine). This affords a useful tool in studying acetyl-

choline formation, and also serves to explain in part the pharmacological action of this drug. The compound diisopropylfluorophosphate ("DFP")

likewise specifically inhibits acetylcholine esterase, in an irreversible manner. Further studies using DFP and eserine should aid in obtaining an understanding of the role of acetylcholine and its esterase in nerve action.

EXPERIMENTS ON THE LIPIDS OF NERVOUS TISSUE

1. Preparation of Pure Lecithin: 1 Free 4 pounds of brain tissue from adhering foreign tissue and mince in a chopping machine. Dry in a vacuum drying oven. (If such an oven is not available dry the tissue by treating several times with cold acetone.) Extract twice with acetone, using about 1.6 liters. Extract the residue with 2.4 liters of hot alcohol. Concentrate to one-third the original volume. Put in the refrigerator at 0° C. over night. Filter. To the filtrate add a cold saturated solution of cadmium chloride sufficient to completely precipitate the lecithin.

To avoid decomposition in purification do not use high temperatures when effecting solution or concentration, and reduce the use of water to a minimum. The principal impurity in the cadmium precipitate is cephalin. To remove this shake the salts well with ether and centrifuge. Repeat 8 to 10 times. Suspend 10 g. of the salts in 40 ml. of chloroform and shake at room temperature until a slightly opalescent solution is formed. Add a cold 25 per cent solution of ammonia gas in 95 per cent methyl alcohol as long as a precipitate is formed, avoiding a large excess. Centrifuge. Concentrate at about 10 to 15 mm. pressure on a water bath at 35° to 40° C. Dissolve in dry ether and concentrate as before to get rid of moisture. Repeat. Dissolve in a minimum amount of ether and pour into acetone (about 50 ml.). Decant. Dry the residue in a vacuum desiccator over H₂SO₄ and keep in a sealed glass tube to prevent oxidation.

- 2. Preparation of Crude Lecithin: Treat the finely divided brain of a sheep or a rabbit with enough ether to cover well, and allow it to stand in the cold for 48 to 72 hours. The cold ether will extract lecithin and cholesterol. Filter and add two volumes of acetone to the filtrate to precipitate the lecithin. Filter off the lecithin, saving the filtrate for the preparation of cholesterol (see below) if desired. Test the lecithin as follows:
 - a. Microscopical Examination: Suspend a small portion in a drop of water on a slide and examine under the microscope. Do you see any "myelin forms"?
 - b. Osmic Acid Test: Treat a small portion with osmic acid. What happens?
 Why?
 - c. Acrolein Test: Make the acrolein test according to the directions on p. 93.
 - d. Test for Phosphorus: See p. 193.

¹ The preparation from egg yolk is somewhat simpler. Stir the fresh egg yolks to a homogeneous emulsion with an eggbeater. Strain through cheesecloth. Pour into a double volume of hot 95 per cent alcohol. Allow to cool. Precipitate with cadmium chloride and purify as indicated above.

² The lecithin prepared in this way is satisfactory for the qualitative tests.

³ Osmic acid serves to detect fats which contain unsaturated fatty acid radicals; e.g., oleic acid, in their molecula.

- 3. Preparation of Cephalin: Free 4 pounds of brain tissue from membranes, mince in a hashing machine, and dry in a vacuum drier. Pulverize and dry further. Extract exhaustively with acetone, using about 2 liters. Free from acetone in the vacuum drier and extract with about 3 liters of 95 per cent alcohol. Extract the residue with 2 liters of ether. Concentrate to a small volume. Let stand at 0° C. over night. Centrifuge and pour supernatant liquid into 98.5 per cent alcohol warmed to 60° C. Dissolve the precipitate in ether. Allow it to stand at 0° C. over night. Repeat the precipitation with alcohol and redissolving in ether until on standing the ethereal extract no longer deposits a sediment of white matter. The final precipitate is dried and preserved as for lecithin.
- 4. Preparation of Cholesterol. Place a small amount of finely divided brain tissue under ether and stir occasionally for one hour. Filter, evaporate the filtrate to dryness on a water bath, and test the cholesterol according to the directions given below. (If it is desired, the ether-acetone filtrate from the lecithin may be used for the isolation of cholesterol. In these cases it is simply necessary to evaporate the solution to dryness on a water bath.) Upon the cholesterol prepared by either of the above methods make the following tests:
 - a. Microscopical Examination: Examine the crystals under the microscope and compare them with those in Fig. 112.
 - b. H₂SO₄ Test (Salkowski): Dissolve a few crystals of cholesterol in a little chloroform and add an equal volume of concentrated sulfuric acid. A play of colors from bluish-red to cherry-red and purple is noted in the chloroform, while the acid assumes a marked green fluorescence.
 - c. Acetic Anhydride-H.SO. Test (Liebermann-Burchard): Dissolve a few crystals of cholesterol in 2 ml. of chloroform in a dry test tube. Now add 10 drops of acetic anhydride and 1 to 3 drops of concentrated sulfuric acid. The solution becomes red, then blue, and finally bluish-green in color.
 - d. Formaldehyde-H₂SO₄ Test: To 2 ml. of a chloroform solution in a dry test tube add 2 ml. of formaldehyde-H₂SO₄ solution (1 part of 40 per cent formaldehyde to 50 of the acid). Note the cherry color in the chloroform. Pour off the chloroform into another tube and add 2 to 3 drops of acetic anhydride. Note the blue color. This test is said to be more delicate than Salkowski's test.
- 5. Preparation of Glycolipid: Mince 100 g. of sheep brains. Transfer to a 500-ml. flask and add slowly with shaking 200 ml. of alcohol. Heat on a water bath for one hour with occasional shaking. Filter hot. Treat the residue on the water bath with another 100 ml. of alcohol for 15 minutes. Filter and combine the filtrates. Let stand over night. Filter off the precipitate on a small paper. Transfer the paper to a beaker containing 50 ml. of hot alcohol. Stir to dissolve the lipid and filter hot. Let cool. Filter or centrifuge and wash the precipitate with ether to remove cholesterol. The residue consists mainly of the glycolipids phrenosin and kerasin.
 - a. Microscopical Examination: Suspend a small portion in a drop of water on a slide and examine under the microscope.
 - b. Solubility: Try the solubility of the glycolipid in water, and in dilute acid and alkali, and in hot and cold alcohol and hot and cold ether.
 - c. Phosphorus: Test for phosphorus according to the directions in Chapter 7, p. 193. How does the result compare with that obtained with lecithin?
 - d. Place a little glycolipid on platinum foil and warm. Note the odor.
 - e. Hydrolysis of Glycolipid: Place the remaining glycolipid in a small evaporating dish, add equal volumes of water and dilute hydrochloric acid, and boil for one hour. Cool, neutralize with solid sodium carbonate, filter, and test with Benedict's solution. Is there any reduction, and if so how do you explain it?

⁴ Pure cholesterol may be prepared from gallstones. Extract with benzens. Evaporate. Recrystallize from alcohol.

6. Tests for Choline:

- a. Rosenheim's Periodide Test: Prepare an alcoholic extract of the fluid under examination, and after evaporation apply Rosenheim's iodo-potassium iodide solution to a little of the residue. In a short time dark brown plates and prisms of choline periodide begin to form and may be detected by means of the microscope. Occasionally they are large enough to be visible to the naked eye. They somewhat resemble crystals of hemin (see Chapter 22). If the slide be permitted to stand, thus allowing the fluid to evaporate, the crystals will disappear and leave brown oily drops. They will reappear, however, upon the addition of fresh iodine solution. v. Stanek claims that this choline compound has the formula C.H. NOI I.
- b. Rosenheim's Bismuth Test: Extract the fluid under examination with absolute alcohol, evaporate, and re-extract the residue. Repeat the extraction several times. Dissolve the final residue in 2 to 3 ml. of water and add a drop of Kraut's reagent. Choline is indicated by the appearance of a bright brick-red precipitate.

Enzymes and Their Action: Cell Respiration

The myriad chemical transformations going on continually in living matter would not be possible without enzymes, which are the most important tools of the living cell. For the hydrolysis or the oxidation of such substances as fats and proteins, in the laboratory we commonly employ strong acids or alkalies or oxidizing agents and high temperatures. Such reagents and temperatures are incompatible with the existence of living matter. The cells are, however, able to carry out such reactions at approximate neutrality, at body temperatures, and at high speed with the aid of enzymes. As an example it has been shown that it takes 10,000,000 times as great a concentration of hydrogen ion as of the enzyme sucrase to decompose a given amount of cane sugar in a given time at body temperature.

Enzymes are organic catalysts produced by living organisms. They are generally soluble and colloidal substances, characterized by great activity, specificity, and susceptibility to the influence of pH, of temperature, and of other environmental changes.

Catalysis. As indicated, enzymes act catalytically. Catalysts are substances that alter the speed of chemical reactions without themselves undergoing any permanent change. This definition indicates that catalysts do not initiate chemical reactions but only speed up reactions already proceeding at a slow rate. Thus hydrogen peroxide undergoes a very slow spontaneous decomposition at room temperature with the formation of water and oxygen. The addition of a little finely divided platinum or of an enzyme called catalase enormously increases the rate of this decomposition. Catalysts function in many reactions, however, which cannot definitely be shown to be proceeding in their absence. It may be assumed in these cases that the reaction is actually proceeding but at an immeasurably slow rate. From the practical standpoint, however, the catalyst or enzyme in these cases does initiate a reaction.

Inorganic catalysts are of great importance in industry. Thus sulfur dioxide reacts slowly with oxygen to form sulfur trioxide. If, however, oxides of nitrogen are present, they catalyze the reaction so that it proceeds much more rapidly, e.g.,

$$NO + \frac{1}{2}O_2 = NO_2$$

 $SO_2 + NO_2 = SO_3 + NO$

Further analogies between enzymes and inorganic catalysts will be mentioned later.

Classification. All of the enzymes which have been isolated in pure condition to date are proteins. The properties which are used to classify proteins are much too general to be of use in classifying enzymes. Hence it is customary to classify them according to their action. Some enzymes contain characteristic prosthetic groups conjugated with the protein and these groups are also used for further classification. For example, oxidizing enzymes are commonly subdivided according to whether they contain heme, riboflavin, etc., as prosthetic groups.

Hydrolases. A great many enzymes catalyze hydrolysis reactions. This large group is commonly designated as hydrolases. The hydrolases, like other enzymes, are further classified according to their substrates, i.e., the substances on which they act. The nomenclature is harmonized as far as possible by using the termination ase in the names of enzymes. Thus we have esterases hydrolyzing esters, carbohydrases hydrolyzing carbohydrates, proteinases hydrolyzing proteins, amidases hydrolyzing amides, etc. Under each of these groups are individual enzymes which act on specific substrates, such as maltase which splits maltose, lactase which hydrolyzes lactose, etc. The source of the enzyme may also be indicated in its name, such as salivary amylase, pancreatic lipase, etc. Some of the old names for enzymes are still used as a matter of convenience—such names, for example, as pepsin and trypsin.

Oxidizing Enzymes. Another large group of enzymes catalyzes oxidations. These may be called oxidizing enzymes. Oxidizing enzymes are frequently divided into two groups—oxidases and dehydrogenases—which are distinguished by their mode of action. This is not an entirely satisfactory division since some enzymes can be placed in either group. A more suitable classification makes no attempt to distinguish between oxidases and dehydrogenases—other criteria are used instead. For example, the following groups may be recognized: (1) Enzymes containing iron, (2) enzymes containing copper, (3) enzymes containing coenzymes 1 or 2, (4) enzymes which catalyze the reduction of cytochrome, (5) enzymes which contain riboflavin (yellow enzymes), and (6) various other oxidizing enzymes.

There are still other enzymes that do not fit into either of these groups. For example, phosphorylases act similarly to hydrolases, except that a phosphoric acid residue, and not water, is used in splitting the substrate. There are other enzymes, the hydrases, which remove or add water to the substrate without hydrolyzing it, and there are still other enzymes, the true desmolases, which catalyze the splitting of a carbon chain. Thus, zymohexase catalyzes the reversible splitting of fructose-1,6-diphosphate into the triosephosphates, dihydroxyacetone phosphate and phosphoglyceric aldehyde. The mutases catalyze the oxidation of one molecule of the substrate and the simultaneous reduction of another molecule of the substrate.

In a number of cases two or more names are commonly applied to the same enzyme. For example, amylase is also known as diastase; sucrase is commonly called invertase or saccharase; cytochrome oxidase was formerly called indophenol oxidase, etc. Sometimes such synonyms arose be-

cause enzymes from different sources at first were not recognized to be identical. For example, tyrosinase or monophenol oxidase was at one time thought to be distinct from polyphenol oxidase. In other cases the original name given to an enzyme has proved to be inadequate. For example, the name zymase was at one time used for the yeast enzyme which ferments sugars to alcohol. Subsequently it was found that the original zymase was really several enzymes and the original name had to be discarded.

A list of some of the more important enzymes is given in this connection, without attempting to adhere to a rigid classification (see table, pp. 266-267).

Chemical Nature. The problem of the purification of enzymes has been essentially one of their separation from other associated proteins. Because of the difficulties of such separation and purification the chemical nature of enzymes has been much in doubt. The first preparation of a crystalline enzyme was that of urease by Sumner in 1926 (see Fig. 80). Since that time crystalline pepsin was obtained by Northrop (see Fig. 81), crystalline trypsin and chymotrypsin by Northrop and Kunitz (see Figs. 82 and 83), and pepsinogen by Herriott and Northrop. Crystals of yellow respiratory ferment were obtained by Warburg, and those of carboxypeptidase by Anson. Subsequently about 20 different enzymes have been obtained in crystalline form. All of these crystalline preparations have proved to be proteins, and the specific action of these enzymes has never been observed in the absence of the specific proteins. There is additional evidence which shows rather clearly that the enzymes and crystalline proteins are identical. If the protein is destroyed or denatured the enzyme action is lost. Also, various crystalline enzyme preparations have been tested for homogeneity using such criteria as diffusion, movement in an ultracentrifuge, migration in an electrical field, solubility, etc., and with the exception of pepsin each has been found to consist of a single component. Pepsin appears to be a mixture of similar proteins. Some of these crystalline enzymes have been recrystallized as many as ten times without change in composition and properties.

Further evidence that the enzyme itself is a protein has been presented, as in the case of pepsin, by showing that if the protein of the material is denatured through the action of alkali the activity of the enzyme is decreased in a parallel manner. For example, pepsin becomes completely denatured and inactive at pH 10.5. If the solution is adjusted to pH 5.4 and is allowed to stand at this pH, a small part of the protein is renatured and there is a corresponding appearance of activity of the enzyme. The solution should be adjusted to about pH 1 before testing for the enzyme activity.

Crystalline trypsin denatured by heat also shows on standing a parallel reappearance of activity and of native protein in the solution. The trypsin may also be hydrolyzed by pepsin in acid solution and the loss in activity is just proportional to the hydrolysis of the trypsin protein.

In the case of those crystalline enzymes which have been most studied it seems clear that the enzyme activity is bound up with the integrity of

CLASSIFICATION OF ENZYMES

Name and Class	Distribution	Substrate	End-products
Hydrolases Carbohydrases 1. Amylase	Pancreas, saliva, malt.	Carbohydrates Starch, dextrin, etc.	Maltose and dextrins
2. Lactase	etc. Intestinal juice and	Lactose	Glucose and galactose
3. Maltase	mucosa Intestinal juice, yeast,	Maltose	Glucose
4. Sucrase	etc. Intestinal juice, yeast,	Sucrose	Glucose and fructose
5. Emulsin	etc. Plants	8-Glucosides	Glucose, etc.
	1 Idii US	Nucleic acid and de-	1
Nucleases		rivatives	No. 1
1. Polynucleotidase	Pancreatic juice, intes- tinal juice, etc.	Nucleic acid	Nucleotides
2. Nucleotidase	Intestinal juice, and other tissues	Nucleotides	Nucleosides and phos- phoric acid Carbohydrate and
3. Nucleosidase	Animal tissues	Nucleosides	Carbohydrate and bases
Amidases		Amino compounds and	
1. Arginase	Liver	Arginine	Ornithine and urea
2. Urease	Bacteria, soybean, jack bean, etc.	Urea	Carbon dioxide and ammonia
3. Glutaminase	Liver, etc	Glutamine	Glutamic acid and am-
4. Transaminase	Animal tissues	Glutamic acid and oxal- acetic acid, etc.	a-Ketoglutaric acid, as- partic acid, etc.
Purine Deaminases		Purine bases and deriv-	
1. Adenase	Animal tissues	atives Adenine	Hypoxanthine and am-
2. Guanase	Animal tissues	Guanine	monia Xanthine and ammonia
		Peptides	
Peptidases	Yeast, intestines, etc.	Polypeptides	Simpler peptides and amino acids
2. Carboxypeptidase	Pancreas	Polypeptides	Simpler peptides and amino acids
3. Dipeptidase	Plant and animal tis- sues and bacteria	Dipeptides	Amino acids
4. Prolinase	Animal tissues and yeast	Proline peptides	Proline and simpler peptides
Proteinases	Gastric juice	Proteins Proteins	Proteoses, peptones,
2. Trypsin	Pancreatic juice	Proteins, proteoses, and	etc. Polypeptides and amino
3. Cathepein	Animal tissues	peptones Proteins	acida Proteoses and peptones
4. Rennin	Calf stomach	Casein	Paracasein
5. Chymotrypsin		peptones	Polypeptides and amino
6. Papain	Papaya, other plants	Proteins, proteoses, and peptones	acids
7. Ficin	Fig sap	Proteins	Proteoses, etc.
Esterases	Pancreas, castor bean, etc.	Esters	Alcohols and acids Glycerol and fatty acids
2. Esterases	Liver, etc. Plant and animal tis-	Ethyl butyrate, etc. Esters of phosphoric	Alcohols and acids Phosphate and alcohol
4. Sulfatases	Animal and plant tis-	acid Esters of sulfuric acid	Sulfuric acid and al-
5. Choline esterase	Blood	Acetylcholine	cohol Choline and acetic acid
Iron Ensymes 1. Catalase	All living organisms ex- cept a few species of	Hydrogen peroxide	Water and oxygen
2. Cytochrome oxidase	microorganisms All living organisms ex-	Reduced cytochrome c in the presence of oxy-	Oxidized cytochrome c
3. Peroxidase	microorganisms Nearly all plant cells	A large number of phenols, aromatic amines, etc., in the presence of H ₂ O ₂	Oxidation product of substrate and water

CLASSIFICATION OF ENZYMES.—(Continued)

Name and Class	Distribution	Substrate	End-products
Copper Enzymes 1. Tyrosinase (polyphenoloxidase, monophenoloxidase) 2. Ascorbic acid oxidase.	Plant and lower animal tissues Plant tissues	Various phenolic com- pounds Ascorbic acid in the	Oxidation product of substrate Dehydroascorbic acid

Enzymes Containing Co- enzymes 1 and/or 2 1. Alcohol dehydrogenase	Animal and plant tis-	Ethyl alcohol and other alcohols $l(-)$ Malic acid	Acetaldehyde and other aldehydes Oxalacetic acid
2. Malic dehydrogenase	Animal and plant tis-	l-Isocitric acid	Oxalacetic acid
3. Isocitric dehydrogenase	sucs		
4. Lactic dehydrogenase.	Animal tissues and yeast		Pyruvic acid
 5. β-Hydroxybutyric dehydrogenase 6. Glucose dehydrogenase 7. Robison ester dehy- 	Liver, kidneys, and heart Animal tissues Erythrocytes and yeast	l-\$-Hydroxybutyric acid d-Glucose Robison ester (hexose-	Acetoacetic acid d-Gluconic acid Phosphohexonic acid
drogenase 8. Glycerophosphate de- hydrogenase	Animal tissues	6-phosphate) Glycerophosphate	Phosphoglyceric acid
Enzymes Which Reduce			
Cytochrome 1. Succinic dehydrogenase (as ordinarily prepared)		Succinic acid	Fumaric acid
Yellow Enzymes 1. Warburg's old yellow enzyme	Yeast	Reduced coenzyme 2	Oxidized coenzyme 2 and reduced yellow
2. Diaphorase	Bacteria, yeasts, higher plants, and animals	Reduced coenzyme 1	Oxidized coenzyme 1 and reduced diapho-
3. Hass enzyme	Yeast	Reduced coenzyme 2	rase Oxidized coenzyme 2 and reduced yellow
4. Xanthine oxidase	Animal tissues	Hypoxanthine, xanthine, aldehydes, reduced coenzyme 1, etc.	enzyme Xanthine, uric acid, acids, oxidized coen- zyme 1, etc. In pres- ence of air, HrO:
5. d-Amino acid oxidase	Animal tissues	d-Amino acids +O ₂	α-Keto-acids + NH ₁ + H ₂ O ₂
6. Cytochrome e reductase	Yeast	Reduced coenzyme 2 and cytochrome c	Oxidized coenzyme 2 and reduced cyto- chrome c
Hydrases 1. Fumarase	Living organisms in general		l-Malic acid
2. Aconitase	Animals and plants	Citric acid	cis-Aconitic acid and
3. Enclase	Animal tissues and yeast	2-Phosphoglyceric acid	
Mutases 1. Aldehyde mutase	Liver and yeast	2 Acetaldehyde + H ₂ O	Acetic acid and ethylalcohol
2. Glyoxalase	Laving organisms in general	Methyl glyoxal and other substituted glyoxals	d(-)Lactic acid
Desmolases 1. Zymohexase (aldolase)	All cells	Fructose-1,6-diphos- phate	Dihydroxyacetone phosphoric acid and phosphoglyceric acid
2. Carboxylase 3. Carbonic anhydrase	Plant tissues Erythrocytes	Pyruvic acid Carbonic acid	Acetaldehyde and CO ₂ CO ₂ + H ₂ O
Other enzymes 1. Phosphorylase	Animal and plant tis-	Starch or glycogen and phosphate	Glucose-1-phosphate
2. Phosphohexoisomerase			Fructose-6-phosphate
3. Hexokinase	Yeast	Adenosine triphosphate + glucose	Adenosine diphosphate + glucose-6-phos-
4. Phosphoglucomutase.	Plants and animals	Glucose-1-phosphate	Glucose-6-phosphate

the protein of the preparation and that these enzymes are thus properly characterized as proteins. Experiments by Northrop on the acetylation of pepsin suggest that the activity is bound up, not with the primary amino groups, but with the presence of free hydroxyl groups of tyrosine. That certain enzymes may owe their activity to groups of a nonprotein

Fig. 83. Chymotrypsin crystals. (Courtesy, Dr. John H. Northrop.)

character combined with protein is clear from our knowledge of the oxidases, some of which appear to be heme-protein derivatives, the activity of which is bound up with the iron-pyrrole group. Peroxidase is a specific example of such an oxidase. Heme has, however, much less peroxidase activity than its natural protein combinations so that both elements are evidently essential for proper function. Preparations of certain other enzymes—as amylase, sucrase, and lipase—have been variously

reported as protein-free or very low in protein. Protein tests made on enzyme solutions are, however, inconclusive since the protein tests are far less sensitive than the tests for enzyme activity. As to the nature of the groups in the enzyme molecules which are responsible for the specificity of their action, almost nothing is known except in the cases of some of the oxidases.

Specificity and Mechanism of Enzyme Actions. Not only do proteinases not act upon carbohydrates, nor carbohydrases upon proteins, but much greater degrees of specificity exist. Thus maltose, lactose, and sucrose require different enzymes for their hydrolysis. Further, the maltase of yeast splits maltose (an α -glucoside) and certain other α -glucosides but not β -glucosides, while β -glucosidase or emulsin hydrolyzes only β -glucosides. The maltase will not hydrolyze any glucosides in which the α -glucose residue has been altered. The specificity appears to depend primarily on the glucose residue and secondarily on the group attached to it. The dependence of enzyme action on the configuration of the substrate is further brought out by the fact that dipeptidase will attack glycyl-l-leucine but not glycyl-d-leucine. It was findings of this sort that led Emil Fischer to suggest that the relation of enzyme to substrate was much like that of a key to a lock.

It has been pointed out that enzymes are catalysts. Our knowledge of the mechanisms involved in enzymic catalyses is, however, very slight. There is much evidence that enzymes form intermediate compounds with the substrates on which they act. This intermediate compound is believed to be much less stable than the original substrate so that the latter now breaks down spontaneously, the enzyme being again liberated. According to the views of some workers there may be two groups (or perhaps more) in the enzyme which are involved, one group acting chiefly to bind the enzyme with the substrate while the second combines with another part of the substrate so as to reduce the stability of the substrate. This view has been developed especially in connection with the peptidases.

Intestinal dipeptidase will split all peptides made up of naturally occurring amino acids. It will not split peptides containing the optical isomers of these amino acids. Thus glycyl-l-leucine will be split but not glycyl-d-leucine. If the free carboxyl group of the dipeptide is esterified (as by making the ethyl ester), hydrolysis still occurs, indicating that the enzyme does not combine with the carboxyl group. If the free amino group is acetylated, the compound is not split. This indicates that the enzyme combines with the amino group of the peptide. If the H of the NH group of the peptide is substituted, it is not acted upon. Replacement of the H of the adjacent C atoms also prevents splitting.

These observations indicate that the enzyme must have at least four groups showing a similar space relationship to these four groups in the dipeptide. It has been suggested further that the enzyme combines with the dipeptide first through the amino group and then a second group in the enzyme attaches to the NH group, this latter linkage leading to a lowered stability of the peptide linkage so that splitting occurs. It has been shown that acetylation of the NH group in peptides does lead to

instability. The findings may be summarized diagrammatically as follows. It must be understood, however, that no explanation of the mechanism of such enzyme actions is yet established.

Action of Physical and Chemical Agents on Enzymes. Variations of temperature and of hydrogen-ion concentration of the medium have a marked effect on enzyme action. The speed of action must naturally also vary with the concentration of the enzyme and the concentration of the substrate. The effects of activators, of coenzymes, and of a proper concentration of electrolyte are in many cases of importance as well as the negative effects of inhibitors or "poisons." As digestion proceeds the products of the reaction may have an inhibiting effect.

Influence of Temperature. Most enzymes are inactivated by heating their solutions to temperatures in the neighborhood of 60° C. This inactivation is associated with a denaturation of the protein of the preparation. In some cases there is, on standing, an appreciable reversal of the denaturation process with the re-appearance of some enzyme activity. Heat resistance may be influenced by the presence of protective substances, such as the enzyme substrate, or by pH. Trypsin is more resistant in acid than in alkaline solutions and is in fact very resistant. In acid solution it may endure temperatures near the boiling point. Under these conditions it is denatured but the process is rapidly reversed on cooling. Temperatures as low as freezing do not commonly destroy enzymes.

Within their active range most enzymes have a temperature coefficient (Q_{10}) of about 2; i.e., they approximately double their activity for each 10 degrees (Centigrade) rise in temperature. As the temperature rises, however, inactivation influences the result, since inactivation also increases with rise in temperature. The optimum temperature for the action of an enzyme is thus determined by the balance between increase of activity with temperature and decrease in amount of enzyme present due to inactivation. In prolonged experiments enzyme destruction becomes more important than in short experiments and the optimum temperature for such experiments is therefore lower. The majority of enzymes act most rapidly at 40° to 50° C. For certain plant proteinases the optimum is higher.

Influence of Hydrogen-ion Concentration. Enzymes are inactivated by certain degrees of acidity or alkalinity. Thus yeast sucrase is inactivated rapidly below pH 3 and pepsin above pH 8. By the optimum pH of an enzyme is meant the pH at which it shows greatest activity. For most enzymes this point lies between pH 4 and 8 and for many be-

tween pH 5 and 7. For practically all enzymes the pH range is rather narrow and activity falls off rapidly on both sides of the optimum. The best pH depends to some extent on temperature and enzyme and substrate concentrations. The nature of the buffer may change the optimum pH of an enzyme considerably. The same is true for the nature of the substrate. When the substrates are ionizable, as in the case of proteins, the optimum pH may vary with the substrate. This is true for pepsin. One of the lowest pH optima is that for pepsin (pH 2) and one of the highest that of blood phosphatase (pH 9). Alterations in pH may effect the dispersion of the enzyme, the rapidity of combination of enzyme and substrate, and the decomposition of the enzyme-substrate complex with the formation of reaction products.

Influence of Other Physical Agents. Enzymes may be destroyed by shaking, by ultraviolet irradiation, and by x-rays. These agents probably act by denaturing the protein of the enzyme preparations.

Influence of Chemical Agents. Most enzymes when acting at optimum temperatures will show, on the addition of chemical agents, either an inhibiting effect or no effect at all. In some cases, however, an acceleration is noted and certain enzyme preparations are inactive unless additions are made.

If salivary amylase is dialyzed free from NaCl it becomes inactive on starch, but activity is restored on the addition of sodium, potassium, or certain other chlorides. The chloride here may be called a coenzyme; i.e., it belongs to a class of substances specific for particular enzymes and which are necessary for the activity of those enzymes. In this sense phosphate which is essential for the action of zymase is also a coenzyme, as well as the organic crystalloidal substance cozymase which is also necessary for zymase action. More recent usage limits the term coenzyme to organic compounds which act in this manner; e.g., diphosphopyridine nucleotide.

Activators and kinases are believed to bring about chemical changes in the inactive forms of enzymes, so as to render them active. Thus HCl changes inactive pepsinogen to active pepsin. The pepsinogen here is called a zymogen or proenzyme and the HCl (or more strictly the H ion) is spoken of as an activator. Activators of an organic character are sometimes called kinases. Thus trypsinogen is changed to active trypsin by enterokinase. The distinction between activators, kinases, and coenzymes is by no means always clear.

Enzymes are poisoned by a variety of substances which form compounds with them. A number of heavy metals stop enzyme action, apparently by combining with the enzyme acting as an acid, though combination with sulfhydryl groups in enzymes may also be involved. Urease is sensitive to traces of heavy metals. H₂S may combat this toxicity of the heavy metals probably by combining with them.

HCN and H₂S have little effect on most hydrolytic enzymes. The proteinase called papain is, however, activated by them and the action of keratinase is much facilitated by the presence of H₂S. Certain oxidases are inactivated by these substances in small amounts apparently because they combine with the active iron of these enzymes.

Certain acids such as phosphotungstic or picric acids combine with the enzyme, acting as a base, to form inactive compounds.

Antienzymes include various naturally occuring inhibitors with some degree of specifity. The blood serum contains antitrypsin and the mucosa of the intestinal tract appears to contain some antipepsin and antitrypsin. In addition there are various antienzymes which are true immune bodies produced by the usual methods for producing antibodies. For example, antiluciferase, antiurease, and anticatalase have been produced by injecting the appropriate enzymes into animals.

Kinetics of Enzyme Action. With an excess of substrate and a given amount of enzyme the degree of hydrolysis is in most cases proportional directly to the time of digestion. As digestion proceeds, however, decrease in amount of substrate slows up the reaction. Accumulation of digestion products may have an inhibiting effect on the enzyme, due in part to a combination of the products with the enzyme and in some cases, where the action is appreciably reversible, to the reverse action. There may also be some inactivation of enzyme otherwise than through combination with end-products. If a buffer is not used, in certain cases a change in pH may occur as digestion proceeds. For these and other reasons it is difficult to give an equation for any enzyme reaction except for a limited segment of its reaction curve. Hence it is usually best in studying a given enzyme preparation to plot a curve from experimental data for the special conditions under consideration.

Synthetic Action of Enzymes. The intestinal mucosa contains an enzyme called phosphatase which catalyzes the following reversible reaction:

$$Na_2HPO_4 + C_3H_5(OH)_3 \rightleftharpoons C_3H_5(OH)_2PO_4Na_2 + H_2O$$

Sodium Glycerol Sodium phosphate glycerophosphate

In other words, phosphatase catalyzes the decomposition of sodium glycerophosphate into sodium phosphate and glycerol and also catalyzes the reverse reaction. The point of equilibrium depends upon the concentrations of the reacting substances and is the same whether we start with sodium phosphate and glycerol or with sodium glycerophosphate and water. A high concentration of glycerol is necessary if the reaction is to be forced toward the right. The reversible action of lipase has also been demonstrated.

One of the most striking demonstrations of the reversibility of enzyme action can be obtained with phosphorylase. This enzyme, which is found in animal tissues as well as tissues of plants, catalyzes the breakdown of glycogen or starch to glucose-1-phosphate:

The glucose-1-phosphate (Cori ester) can be isolated readily from the system. If glucose-1-phosphate is added to a potato phosphorylase preparation, starch is rapidly formed and can be detected by the color it gives

with iodine solution. Muscle phosphorylase likewise produces starch from glucose-1-phosphate. Phosphorylase prepared from liver, brain, heart, or yeast forms glycogen from glucose-1-phosphate.

The possibility of reversible or synthetic action of enzymes has thus been demonstrated and it is of the greatest interest to know the part that such reversible enzyme action may play in the synthesis of proteins, fats, carbohydrates, and other substances in the animal body. Evidence on this point is as yet slight.

OXIDATION AND REDUCTION SYSTEMS

Most if not all of the energy of living matter is derived from oxidative processes. Oxidation involves the loss of negative electrons from the substance oxidized, these electrons passing to the oxidizing agent which is simultaneously reduced. Thus the reaction of ferric chloride with potassium iodide involves a transfer of electrons from the iodide ions to the ferric ions so that the iodide is said to be oxidized and the iron reduced. Biological oxidations involve the same transfer of electrons.

$$Fe^{+++} + 3Cl^{-} + K^{+} + I^{-} \rightleftharpoons Fe^{++} + 3Cl^{-} + K^{+} + I$$

In many oxidations the products of the reaction possess less energy than the reacting substances and in these cases energy is liberated as heat or in some other form.

Many oxidations are coupled with the formation of esters of phosphoric acid such as adenosine triphosphate. Inorganic phosphate is used to form these esters. The esters which are formed primarily are very labile and there is a considerable free-energy decrease (about 10,000 calories) when they are hydrolyzed. Such an ester is adenosine triphosphate which contains two such labile phosphoric acid groups. These labile phosphoric acid residues are connected in a manner similar to that found in pyrophosphoric acid and the bond is sometimes called a high energy phosphate bond. The formation of such compounds is a matter of considerable significance. It suggests how a cell might make use of the energy of oxidation. For example, in the presence of hexokinase from yeast, the following reaction occurs:

adenosine triphosphate + glucose → adenosine diphosphate + glucose-6-phosphate

Thus glucose is changed into a form in which it can readily enter into the intermediate reactions of carbohydrate metabolism. One might ask why phosphatase could not do the same thing with glucose. Phosphatase catalyzes the following reaction:

It is commonly considered that all enzyme reactions are reversible. However, thermodynamic considerations suggest that, although this reaction

may be reversible, the equilibrium would be so far to the right that the reverse reaction would be physiologically insignificant. Thus there would be very little glucose-6-phosphate formed. On the other hand, in the reaction cited with adenosine triphosphate, the equilibrium position is far to the side of glucose-6-phosphate and adenosine diphosphate. In this way it is thought that the cell can use at least part of the energy produced by oxidation reactions to form materials which are useful to the cell.

The substances principally utilized for energy in the body are carbohydrates, fats, and proteins. Neither these nor their hydrolysis products, however, readily react in neutral solution with molecular oxygen. In the living cell, however, such oxidations readily take place through the aid of enzymes which are present. The exact manner in which this is accomplished is not clear in most cases. At one time it was thought that there were two means of accomplishing these oxidations. Some substrates were thought to be oxidized by activation of hydrogen in the substrate. The substrate, as a result, was dehydrogenated. Other substrates were thought to be oxidized by "active oxygen." Subsequent work has clarified the picture somewhat and it is now realized that both types of oxidation may occur in the complete oxidation of a substrate. The substrate itself may be oxidized by removal of hydrogen. The hydrogen is then passed from one compound to another until it finally combines with oxygen to form water.

Oxidation by Activation of Hydrogen. Wieland proposed the idea that oxidations are accomplished by removing hydrogen from the substrate. The enzymes capable of catalyzing such oxidations are called dehydrogenases or dehydrases. The former term is preferred. These enzymes are inhibited by narcotics such as urethane. The action of such an enzyme may be represented as follows:

$$AH_2 + B \rightarrow A + BH_2$$

Here AH₂ is the substrate, B is the hydrogen acceptor, A is the oxidized substrate, and BH₂ is the reduced hydrogen acceptor. Thus hydrogen is simply "activated" and transferred from one compound to another. A specific example is the oxidation of lactic acid to pyruvic acid by the action of lactic dehydrogenase in the presence of coenzyme 1:

It should be pointed out that while such an oxidation can be represented as a transfer of 2H from one compound to another, it can also be represented as the transfer of 2H⁺ and 2 electrons. Probably the latter representation is more nearly correct. Also it must be remembered that unless the appropriate enzyme and a suitable hydrogen acceptor are both present, no oxidation will occur.

In the presence of methylene blue, under anaerobic conditions, the above reaction may proceed farther, provided a trace of a suitable yellow

enzyme is present. The following reactions occur:

- (1) Reduced coenzyme 1 + Ye → Coenzyme 1 + YeH₂
- (2) $YeH_2 + Mb \rightarrow Ye + MbH_2$

Here Ye, YeII₂, Mb, and MbH₂ represent yellow enzyme, reduced yellow enzyme, methylene blue, and reduced (colorless) methylene blue, respectively. This type of reaction is the basis of the Thunberg method described on p. 282. If methylene blue is used only very small amounts of coenzyme 1 are needed since the coenzyme can be used over and over again. As fast as it is reduced by the lactic acid it will be re-oxidized by the yellow enzyme, which in turn will be re-oxidized by the methylene blue. A dehydrogenase that reacts in this way is called an anaerobic dehydrogenase. This means simply that such an enzyme cannot react directly with gaseous oxygen.

If oxygen is admitted into the system the following reaction will occur:

$$MbH_2 + O_2 \rightarrow Mb + H_2O_2$$

In this case the oxygen can be said to act as the hydrogen acceptor. The oxidation of the reduced methylene blue is analogous to the action of aerobic dehydrogenases which use gaseous oxygen directly to oxidize the substrate. An example is the oxidation of xanthine to uric acid in the presence of xanthine oxidase:

The hydrogen peroxide which is formed will eventually inhibit the enzyme action, but the hydrogen peroxide may be removed by the action of catalase:

$$2H_2()_2 \rightarrow 2H_2() + ()_2$$

Catalase is a heme-protein found in all living cells, with the exception of certain bacteria. Its function appears to be the removal of the hydrogen peroxide which is toxic.

The hydrogen peroxide may also be removed by peroxidase. This enzyme, in the presence of H_2O_2 , oxidizes various phenolic compounds and amines, such as pyrogallol, guaiacol, hydroquinone, tyrosine, adrenaline, etc. Peroxidase is a heme-protein—in fact, even hemin itself has a very slight peroxidase action. Peroxidase, like other heme-containing enzymes, is inhibited by HCN, H_2S , and sodium azide. If an alcoholic solution of gum guaiac is added to the solution of peroxidase and hydrogen peroxide, a blue color is formed.

Oxidation by activation and transfer of hydrogen also occurs in the oxidation of aldehydes. First of all the aldehyde is hydrated:

$$R-CHO + H_2O \rightarrow R-CH-OH$$

$$OH$$
Aldehyde Hydrated aldehyde

The hydrated aldehyde is then oxidized:

This type of oxidation occurs in the oxidation of acetaldehyde to acetic acid. An analogous reaction occurs in the oxidation of glucose-6-phosphate to phosphogluconic acid.

At present it is thought that most of the oxidations in living organisms, with the exception of a few bacteria, are similar to the above scheme, except for the fact that the initial hydrogen acceptor—e.g., coenzyme 1—is re-oxidized by a system or systems of enzymes which finally react with one or more of the cytochromes. As a result the cytochrome is reduced and the whole of the oxidation finally passes through this compound to oxygen.

Cytochromes. By use of the spectroscope Keilin was able to demonstrate in living cells the presence of three closely related substances which he called cytochromes a, b, and c. Cytochromes appear to be present in all living cells, except a few bacteria. The cytochromes are heme-protein compounds. The absorption bands of the reduced cytochromes may be easily observed by looking at a yeast suspension with a spectroscope. If a stream of air is bubbled through the suspension the cytochromes are oxidized and the bands disappear. In animal tissues the cytochromes commonly exist predominantly in the oxidized form.

In the presence of succinic dehydrogenase, as ordinarily prepared, the following reactions occur:

Succinic acid
$$+$$
 2 Cytochrome $c \rightarrow$ Fumaric acid $+$ 2 Reduced cytochrome $c + 2\Pi^+$

The reduced cytochrome c is not oxidized directly by oxygen; instead, it is oxidized by cytochrome oxidase in the presence of oxygen. When first observed this phenomenon led to the concept of oxidation by activation of oxygen.

Oxidation by Activation by Oxygen. Warburg found in living cells a heme-containing compound which has the property of activating oxygen and which he called the respiratory enzyme. The activity of the enzyme is dependent upon the iron present, since HCN, in small amounts, and carbon monoxide inhibit the action, apparently through combination with the metal. The inhibition by carbon monoxide can be obtained only in the dark. Warburg's respiratory enzyme is apparently identical with the enzyme which was formerly called indophenol oxidase. This enzyme is now known as cytochrome oxidase.

Cytochrome oxidase, in the presence of molecular oxygen and cytochrome c, oxidizes dimethyl-p-phenylenediamine (p-aminodimethylaniline) and in the presence of α -naphthol, a blue substance, indophenol blue, is formed:

$$H_3C$$
 CH_3
 H_3C CH_3
 OH
 NII_2
 OH
 O

The mixture of α -naphthol and dimethyl-p-phenylenediamine is called the "Nadi reagent" from the first two letters of each chemical name. In the above reaction the Nadi reagent is oxidized by the cytochrome c which is added along with the enzyme. The resulting reduced cytochrome c is oxidized by the enzyme in the presence of oxygen. Thus the enzyme is cytochrome oxidase and this name is to be preferred to indophenol oxidase. It should be noted that water and not hydrogen peroxide is formed as one of the products of the oxidation.

This utilization of oxygen led to the concept that oxygen was being activated. In a great many tissues (probably in all animal tissues, and possibly in all tissues of all living organisms, except a few bacteria), the oxidation of reduced cytochrome by oxygen in the presence of cytochrome oxidase is a reaction of considerable significance. It is thought that this oxidation represents the final step in a long series of oxidations which start with the primary substrates such as hexose-o-phosphate, lactic acid, etc. There is some evidence that acids such as succinic, malic, fumaric, oxalacetic, isocitric, and α -ketoglutaric play a part in these oxidations. Coenzymes 1 and 2 and the yellow enzymes are also involved. The primary function of the coenzymes 1 and 2 and the yellow enzymes is apparently one of hydrogen transport. These are the substances which effect the transfer of hydrogen from one compound to another.

A series of reactions may be presented to show such course of events. Hexose-6-phosphate (Robison ester) is oxidized in the presence of Robison ester dehydrogenase (Zwischenferment), coenzyme 2, the yellow enzyme cytochrome c reductase, and cytochrome oxidase as follows:

- (1) Hexose-6-phosphate + coenzyme 2 → phosphohexonic acid + reduced coenzyme 2.
- (2) Reduced coenzyme 2 + cytochrome c reductase → coenzyme 2 + reduced cytochrome c reductase

(3) Reduced cytochrome c reductase + 2 cytochrome c

→ cytochrome c reductase + 2 reduced cytochrome c + 2H+

(4) 2 Reduced cytochrome $c + 2H^+ + \frac{1}{2}O_2 \rightarrow 2$ cytochrome $c + H_2O$

Robison ester dehydrogenase and cytochrome oxidase catalyze reactions (1) and (4), respectively. Thus the picture is one of transfer of hydrogen (H⁺ + electron) from one compound to another until cytochrome c is reached. The reduction of cytochrome c can be represented best by a simple electron transfer. The resulting reduced cytochrome c is oxidized by an electron transfer to oxygen in the presence of cytochrome oxidase. Probably the cytochrome oxidase is first reduced by electron transfer from the reduced cytochrome c. Then the reduced cytochrome oxidase is oxidized by electron transfer to oxygen, which then forms water by combination with 2H⁺.

Yellow Enzymes. Cytochrome c reductase is one of the yellow enzymes. These enzymes all contain riboflavin (vitamin B₂ or G) in their prosthetic groups. The prosthetic group of cytochrome c reductase consists of riboflavin phosphate (isoalloxazine-d-ribose-phosphate) which is sometimes called a mononucleotide. There are other yellow enzymes which contain such mononucleotides as prosthetic groups. An example is the old yellow enzyme of Warburg. Other yellow enzymes contain prosthetic groups composed of riboflavin-phosphate-phosphate-d-ribose-adenine. Such a compound is called a dinucleotide. Examples of yellow enzymes which contain isoalloxazine-adenine dinucleotide prosthetic groups are diaphorase, the Haas yellow enzyme, xanthine oxidase, and d-amino acid oxidase. These yellow enzymes function in hydrogen transport as outlined above. It is the prosthetic group of these enzymes which is oxidized and reduced.

Copper Enzymes. There are various enzymes which contain copper. These are all inhibited by HCN in much the same way as the iron-containing enzymes cytochrome oxidase, catalase, and peroxidase. One of these copper enzymes is tyrosinase. This enzyme is apparently identical with monophenol oxidase and polyphenol oxidase. This enzyme oxidizes various phenolic compounds such as phenol, catechol, cresols, tyrosine, pyrogallol, and dopa (3,4-dihydroxy-phenyl-alanine). For example:

Water, not hydrogen peroxide, is always formed as a result of oxidation by this enzyme and gaseous oxygen is used as the hydrogen acceptor. Tyrosinase is also inhibited by H₂S and by CO. The inhibition by carbon monoxide is not influenced by light. Tyrosinase is commonly found in plant tissues, bacteria, and fungi; it also occurs in various lower animals. Tyrosinase is very similar to lacease, which is also a copper-containing

enzyme. Laccase is found in various plant tissues and differs from tyrosinase in that it does not oxidize tyrosine or p-cresol.

Ascorbic acid oxidase is another plant copper-containing enzyme. It catalyzes the oxidation of *l*-ascorbic acid (vitamin C) in the presence of oxygen:

The dehydroascorbic acid may be reduced by hydrogen sulfide.

It has been proposed by various workers that one or more of these copper-containing enzymes function in plant tissues in much the same way as does cytochrome oxidase in animal tissues. The matter is as yet unsettled.

Sulfhydryl Group in Oxidations. Practically all tissues give a purple color with sodium nitroprusside and ammonia. This indicates the presence of the sulfhydryl group R—SH. Such a group is found in the amino acid cysteine HOOC·CH(NH₂)·CH₂SH. Cysteine is not, however, found to any extent in the tissues as such but is found in appreciable amounts in the form of glutathione, a tripeptide of glycine, cysteine, and glutamic acid, which has the following structure:

On oxidation cysteine may be converted into the disulfide form or cystine: $R-SH+HS-R+O\to R-S-S-R+H_2O$ and the cystine may be reduced to cysteine: $R-S-S-R+2H\to 2R-SH$. Glutathione may also be oxidized to the disulfide form $2G-SH\to G-S-G$, this reaction also being reversible. The widespread occurrence of glutathione and the amounts found in cells indicate its importance but its mode of action is not yet clear. Glutathione has been synthesized.

EXPERIMENTS ON ENZYMES¹

ROLE OF IRON IN OXIDATIONS

1. Catalysis of Decomposition of Hydrogen Peroxide by Metals: Transfer 5-ml. portions of hydrogen peroxide to each of 4 test tubes. To one add a very

'If it is deemed advisable by the instructor to give all the practical work upon ensymes at this point in the course, additional experiments will be found in the chapters on digestion.

small amount of finely divided metallic platinum,² to the second a small amount of powdered magnetite (Fe₂O₄), to the third a similar amount of ordinary ferric oxide or hematite (Fe₂O₃), and to the fourth a small amount of magnetite and a few drops of 1 per cent NaCN (*Poison!*). Note any evolution of gas. After a few minutes add a few drops of an alcoholic solution of guaiac. This is oxidized to a blue color by active oxygen. Which tubes show this reaction? Cyanide paralyzes cell respiration apparently by inactivating the iron which is an essential part of the system.

EXPERIMENTS ON PLANT OXIDASES

- 1. Demonstration of Potato Oxidases: It is convenient to combine the study of potato oxidases with a study of the composition of the potato. This throws light on the value of the potato as a food. It also gives information as to the composition of a typical vegetable cell.³
 - a. Preparation of Potato Extracts: Wash and peel a medium-sized potato. Grate rapidly and transfer the gratings at once to a piece of cheesecloth which is suspended in a beaker containing about 200 ml. of distilled water. Work gently with the hand to get out as much of the starch as possible. Keep this extract (water extract No. 1). Make a second extraction using 200 ml. of distilled water (water extract No. 2). Make a third extraction and if this does not contain an appreciable amount of starch discard it. Work the pulp until it is practically starch-free.
 - b. Tests on Pulp: Work a portion of the pulp very thoroughly with water until it is practically free from starch as indicated by the iodine test. Test for protein, using Millon's test, and for carbohydrate by the Molisch test.
 - c. Tests on Water Extract No. 1: Pour off the supernatant liquid from the extract when the starch has settled out. Filter. Test for reducing sugars by Benedict's test. Test for protein. Boil 20 ml. of the extract and filter. Test the filtrate for inorganic chlorides, sulfates, and phosphates. Indicate in your notebook what information you have obtained as to the food value of the potato.
 - d. Separation of Starch: Combine the starch obtained from extracts No. 1 and No. 2. Wash by decantation with distilled water. Drain off the water and turn the beaker upside down so that the starch will drain, otherwise molds may develop.
 - e. Experiments on Potato Oxidase: Into each of a series of 5 clean test tubes introduce 5 ml. of potato extract (extract No. 2 filtered). (If the extract is kept over it must be preserved with toluene.) Introduce other reagents according to the following series: (1) Potato extract + 10 drops of 1 per cent phenol, (2) potato extract + 10 drops of 1 per cent catechol, (3) potato extract + 10 drops of guaica solution, (4) potato extract + 10 drops of pyrogallol solution, and (5) potato extract + 5 drops of α-naphthol solution + 5 drops of p-phenylenediamine hydrochloride solution. This combination of α-naphthol and p-phenylenediamine is known as the Nadi reagent.

Mix the contents of the tubes by shaking. Watch for any color changes. If necessary let stand until the next laboratory period (add toluene), and examine again. In this experiment the phenol C_0H_0OH , catechol $C_0H_4(OH)_2$, and pyrogallol $C_0H_3(OH)_2$ are oxidized with the production of brown-col-

² Use a solution of colloidal platinum (see p. 8) or a powder prepared by dipping filter paper in platinic chloride solution and igniting in a crucible. Welo and Baudisch have shown that magnetite produces active oxygen even when heated to 330° C. although it then has the same composition (FerO₃) as it has when heated still further to 550° C., but the latter product sets free molecular, not active, oxygen. Ferrous hydroxide also catalyzes a rapid decomposition of peroxide.

³ This experiment is based upon the laboratory directions of Dr. William H. Welker.

⁴ The phenol, catechol (pyrocatechol), p-phenylenediamine hydrochloride, and pyrogallol are 1 per cent aqueous solutions. The a-naphthol is a 1 per cent solution in 95 per cent alcohol. For the guaisc solution dissolve 0.5 g. of gum guaisc in 30 ml. of 95 per cent alcohol.

ored compounds. The guaiaconic acid in the guaiac is oxidized to guaiac blue. In the last tube we have the production of indophenol from the α -naphthol and phenylenediamine under the influence of oxidase.

Two oxidases appear to be active in these tests. Monophenoloxidase (also called polyphenol oxidase and tyrosinase) is responsible for the oxidation of the phenol to catechol, then to o-quinone, and finally with condensation reactions to brown compounds of uncertain composition.

Polyphenoloxidase also acts upon cathechol to form o-quinone and then the brown compounds just mentioned. It also acts upon pyrogallol forming purpurogallin.

$$OH \rightarrow HO \longrightarrow O$$

$$OH \rightarrow HO$$

$$OH$$

Cytochrome oxidase in the presence of cytochrome c oxidizes the p-phenylenediamine and in the presence of α -naphthol there is formed indophenol.

$$H_2N$$
 $NH_2 + OH \rightarrow H_2N$ $NH_2 - N = O$

Peroxidase in the presence of hydrogen peroxide also gives this reaction. At least part of the color obtained in the above test is due to the action of peroxidase since the color develops more slowly if catalase is added to the potato oxidase preparation.

The oxidation of the guaiaconic acid of the guaiac to guaiac blue is apparently due to the action of the o-quinones formed as indicated above, on the guaiac, rather than any direct action of the enzymes on the guaiac itself except in the case of the slight peroxidase action due to the presence of some peroxide. Peroxidase appears to oxidize the guaiac directly.

2. Experiments on Potato Peroxidase: Prepare a series of 5 tubes containing 5-ml. portions of potato extract and 10 drops of oxidase reagents as in the preceding experiment. Prepare still another series but use potato extract previously boiled for 5 minutes. Then to each tube add 10 drops of 3 per cent hydrogen peroxide solution. Note whether oxidation takes place more rapidly than in Exp. 3 where no hydrogen peroxide is used. Is the peroxidase destroyed by boiling?

The potato has a greater peroxidase than phenoloxidase activity, which accounts for the more rapid action in the presence of H₂O₂.

3. Resistance of Oxidase and Peroxidase to Heat: Into each of 3 test tubes introduce 5 ml. of potato extract. Put in a water bath at 70° for 10 minutes. To the first tube add 2 drops of 1 per cent catechol solution and then to each 10 drops of guaiac solution, and to the third tube only, 10 drops of hydrogen peroxide solution. The appearance of a blue color in the presence but not in the absence of hydrogen peroxide indicates that peroxidase is

not destroyed at 70° but that the phenol oxidase is not stable at this temperature. How would you prepare a solution containing peroxidase but not oxidase? The fact that the addition of catechol does not suffice to bring back the direct oxidase action indicates that it is not the catechol compounds but the oxidase that is destroyed at this temperature.

4. Role of Catechol Compounds in Oxidase System: Into each of 2 clean test tubes introduce 5 ml. of potato extract. To one add 1 drop of 1 per cent catechol solution. Let stand for 5 minutes. Then to each tube add 10 drops of guaiac solution. Let stand and note any color change.

Most potatoes contain relatively little of the catechol compounds. The addition of catechol therefore hastens the oxidation of the guaiac since the oxidation of the guaiac is secondary to the formation of o-quinones from catechol compounds, the o-quinones being capable of directly oxidizing guaiac.

- 5. Preparation of Peroxidase: Scrapings of horseradish may be extracted with alcohol and dried. On extraction with water these dried scrapings give a peroxidase solution free from oxidase. By a more complicated process a preparation showing about 1,000 times the activity of the original material has been obtained.
- 6. Determination of Peroxidase: Into a 250-ml. flask introduce 100 ml. of a saturated solution of leucomalachite green, 2 ml. of 0.166 N sodium acetate saturated with toluene, 1 ml. of hydrogen peroxide, and from 0.0025 to 0.05 unit of peroxidase in not more than 5 ml. of solution. All should be brought to 20° before mixing and kept at that temperature. Measure 10 ml. of N H₂SO₄ into a small flask and add all at once at the end of 5 minutes to the digestion mixture to stop the action. Rinse the small flask with 5 ml. of water. After 15 to 30 seconds neutralize with a little more than an equivalent amount of NaOH solution. Shake vigorously to eliminate bubbles of CO₂. Compare with a standard malachite green solution containing 10 mg. per liter and set at 5 or 10 mm. The standard is made up in 0.05 N acetic acid and preserved with toluene. Yellow artificial light is better than daylight for the comparison. Under the given conditions one unit of peroxidase forms 53 mg. of malachite green.

EXPERIMENTS ON ANIMAL OXIDASES

1. Schardinger Reaction: Place 5 ml. of milk in each of 3 test tubes. Heat one to boiling and cool. To each tube add 1 ml. of 0.02 per cent methylene blue solution. To tubes 1 and 2 add 1 ml. of 0.4 per cent formaldehyde solution. Mix by gentle rotation, add 1 to 2 ml. of paraffin oil, and put in a water bath at about 40° C. The milk in tube 2 should gradually decolorize. The reaction is an example of anaerobic oxidation in the presence of a hydrogen acceptor (methylene blue) and may be written thus:

$$CH_2O + H_2O \rightarrow CH_2(OH)_2 + M \rightarrow HCOOH + M \cdot H_2$$

This reaction is given more slowly by milk which has been heated and more rapidly by milk which has a high bacterial count.

 Study of Tissue Oxidations by the Methylene Blue Method of Thunberg and Ahlgren:

Principle: Finely divided tissue is suspended in a solution containing methylene blue, phosphate solution to regulate the acidity, and the substance whose action

⁵ The dye should be recrystallized twice from alcohol, once from petroleum other, and again from alcohol. Saturate titrated 0.05 N acetic acid with the dye at 20°. The solution freed from air under a vacuum will keep for months. If precipitation occurs warm to redissolve.

 6 Dilute 30 per cent hydrogen peroxide (reagent grade) 100 times. Titrate with KMnO₄ and dilute further so that each ml. contains 0.25 mg. $\rm H_2O_2$.

it is desired to determine. The tube is evacuated, placed in a water bath, and the time required for the methylene blue to be decolorized is determined. This is a measure of the rate of oxidation in the mixture. The nature of the substances capable of being oxidized by the tissue can be determined and the influences governing the oxidation process studied.

Procedure: The tube⁷ most convenient for use in this experiment is illustrated in Fig. 84. Into each of 3 tubes introduce 0.9 ml. of a mixture of

8 ml. of methylene blue 1:2000 and 6 ml. of a phosphate buffer of pH 7. Then add 0.1 ml. of water to the first tube, of 0.1 M potassium succinate to the second, and of 0.1 M potassium glycerophosphate to the third. Then add 0.2 g. of finely divided washed rabbit muscle to each. Evacuate each tube for 2 or 3 minutes with a strong water-jet filter pump. Place the tubes in a constant-temperature water bath at 35°. Observe from time to time and note when each tube just loses its last trace of blue color. Record the number of minutes required in each case. Do the succinate and glycerophosphate solutions decolorize first? What does this indicate as to the oxidation of these substances by muscle tissue?

Fig. 84. Vacu u m t u b e . (Thunberg.)

- 3. Nitroprusside Reaction for Glutathione: Rub up in a (Thunberg.) mortar a small piece of fresh liver or kidney tissue, a little sand, and a few ml. of saturated ammonium sulfate solution. Add 5 or 6 drops of 2 per cent sodium nitroprusside and 2 ml. of concentrated ammonium hydroxide solution. The mixture turns purple.
- 4. Estimation of Glutathione in Tissue: See Chapter 23.
- 5. Preparation of Glutathione: 10 Procedure: Add 20 ml. of concentrated H₂SO₄ slowly to 100 ml. of 89 per cent alcohol, keeping the mixture cool. When cold add 80 ml. of ether. Pour on to 2,000 g. of compressed bakers' yeast, coarsely crumbled in a large jar. Stir for a few minutes until homogeneous. Pour on to 2 large Buchner funnels, the papers being covered with thin layers of kieselguhr. After 4 hours filtration may nearly stop. If so, pour off the fluid upper layer on to another filter and suck dry for a few hours more. Do not use too high a vacuum at first or the mixture will froth as the ether boils off.

⁷ The tube is made of hard, colorless glass and is of about 10 ml. capacity. The stopper is greased with a mixture of: rubber 1 part, petroleum jelly 2 parts, and heavy liquid petrolatum 1 part. Tubes may be obtained from the Scientific Glass Apparatus Co., Eimer and Amend, and others.

Solutions required are: Stock solution of methylene blue, 1 g. in 500 ml. f water. Phosphate buffer solution of pH 7.

* The muscles of frogs and other animals may also be used. The animals should be killed by a blow and not by anesthesia. One or more g. of muscle tissue freed as much as possible from ligaments, fat, and blood are cut up on a watch glass with a scissors of the Cooper type for 3 to 5 minutes. A drop or two of water may be added to assist cutting. The tissue may then be washed if desired by shaking with an excess of water, rubbing in a mortar, atraining through silk, and drying with filter paper. Keep in a covered beaker placed in a dish containing pieces of ice. The divided tissue is best used as soon as possible but may generally be kept for an hour at 20°. Uncut tissue may be kept somewhat longer. In weighing the tissue a microbalance weighing up to 500 mg. is convenient, a small celluloid shell being attached to hold the material. A glass rod with a spoon-shaped tip is used to introduce the tissue into the tube.

There may be some foaming during the evacuation which should be continued until the solution boils when warmed with the hand. Foaming may be reduced by rotating the tube in a horizontal position so as to distribute the material on the sides of the tube or by first putting the tubes in cold water. After evacuation, to get all material into the bottom of the tubes they may be rotated for a few seconds in a hand centrifuge. It is also well after evacuation and closing the stopper to remove the tube from the side tube while holding both under water. The side tube is filled with water so that leakage of air is less probable.

¹⁰ For a procedure involving the use of a supercentrifuge see Kendall, Mason, and Mc-Kensie: J. Biol. Chem., 87, 55 (1930); 88, 409 (1930).

The combined filtrates (about 1100 ml.) are titrated with NaOH, using Congo red as an indicator (the filtrate is generally just acid to Congo red), and the amount of 20 per cent H₂SO₄ necessary to bring the filtrate to 0.5 N added.

Prepare about 1 g. of cuprous oxide by boiling ordinary Fehling's solution with an excess of glucose cautiously added. It should be bright red. Wash by decantation on a filter. It may be kept in a dry state. Rub up and suspend in about 30 ml. of water. With thorough stirring add 2-ml. portions of suspension at a time to the yeast extract previously carefully warmed on a water bath with stirring to 50°. When about half of the oxide has been added, allow the salt to settle and pour the mother liquor off for further additions of oxide. At a later stage the addition of cuprous oxide will cause the re-solution of some of the cuprous-glutathione compound already formed. When this occurs reprecipitate by blowing air through the solution for about an hour. The precipitate redis-

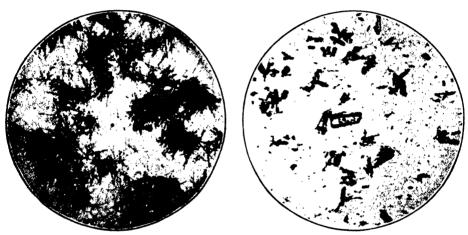

Fig. 85. Crystals of glutathione. (Left) First crystallization. (Right) Recrystallized. (Courtesy, Kendall, McKenzie, and Mason: J. Biol. Chem., 84, 657 (1929).

solves on very prolonged aeration. Although flocculent and amorphous, this compound has the normal copper content (17 per cent) and gives crystalline glutathione on decomposition.

Wash the cuprous salt with 0.5 N H₂SO₄ on the centrifuge and then with water until the washings are free from sulfate. If a centrifuge is used about 10 washings are required. Or use a device prepared with two Jena sintered glass filters (grade 4) of suitable size. Put the cuprous salt in one and place the other upside down on top, a water-tight joint being made with a piece of wide rubber tubing. Connect the lower funnel to a reservoir of distilled water about a meter above it, and attach the upper one to a flask and filter pump. Wash until the filtrate remains free from sulfate after shaking the filtration apparatus.

Suspend the precipitate in four to five times its bulk of distilled water and decompose with well-washed H_2S . Filter. Free from H_2S by a stream of hydrogen. Evaporate to a small bulk in a vacuum desiccator at room temperature. If the volume of filtrate is too large for this and distillation in vacuum is necessary, use a good pump and distillat 25°. If the mixture does not crystallize spontaneously before reaching a sirupy consistency, rub with a glass rod to start crystallization. Yield, about 1.5 g. For the crystalline form of glutathlone, see Fig. 85.

EXPERIMENTS ON CATALASE

The various animal tissues as liver, kidney, blood, lung, muscle, and brain contain enzymes called catalases which possess the property of decomposing hydrogen peroxide with the production of molecular oxygen and water. Catalase is also found in many plant tissues.

- 1. Demonstration of Catalase: Shake up about 0.5 g. of pulped liver tissue with 10 ml. of water in a test tube. Add rapidly, enough 3 per cent $\rm H_2O_2$ to fill the tube and invert at once into a beaker containing water. When the tube is full of gas test with a glowing match for oxygen.
- 2. A Permanent Catalase Preparation: 11 Run 100 g. of kidney cortex through a meat-chopper and grind with sand in a mortar. Add 10 ml. of water saturated with chloroform and let stand for several days with occasional shaking. Filter through muslin and paper. Add one-fifth volume of chloroform. Filter. Keep in a dark place with a little chloroform as a preservative.
- 3. Determination of Catalase: Titration Method: Introduce into three 250-ml. flasks 90 ml. of M/150 H₂O₂ and 10 ml. of a mixture of equal parts of M/15 Na₂HPO₄ and M/15 KH₂PO₄ and put in an ice bath at 2°. To the first flask add 10 ml. of enzyme solution, to the second 5 ml. of enzyme solution and 5 ml. of the phosphate buffer, and to the third 10 ml. of buffer only Cool all solutions to 2° before mixing. The reaction of the solutions will be pH 7.0. Keep at 2° for 10 minutes. Add 20 ml. of 20 per cent sulfuric acid to each flask and titrate with 0.05 N KMnO₄ to a permanent rose color. Subtract the titration value of control. One ml. of 0.05 NKMnO₄ represents 0.0004 g. or 0.28 ml. of available oxygen.

PREPARATION AND PURIFICATION OF ENZYMES

Purified enzyme preparations may be made from digestive secretions containing the enzyme. More often, however, the source is an animal or plant tissue. To obtain the enzyme in concentrated form it must be freed as far as possible from the mixture of substances making up the cell.

In the case of animal tissues the material should be immediately refrigerated and used as soon as possible. It may be cut up with a scissors or run through a meat-chopper and then rubbed in a mortar with quartz sand or ground glass. Freezing with liquid air or carbon dioxide will often aid comminution and check fermentative processes. The material may also in some cases be dehydrated by drying in a current of warm air or by dehydrating with acetone or alcohol followed by treatment with ether to remove fat and then grinding very fine in a ball mill.

The comminuted tissue may then be extracted by use of a suitable solvent (e.g., water, salt solutions, glycerol, or solutions of definite pH) which will extract the enzyme with as little other material as possible. The mixture may then be filtered or centrifuged. Since enzymes are proteins, the greatest difficulties in enzyme purification are connected with the removal of protein contaminations. Methods used in the purification of proteins are therefore useful (see Chapter 6).

Just as with proteins the exact procedure will vary in each case. The procedures generally required include dialysis, precipitation by means of salts or by liquids such as alcohol or acetone, and selective adsorption and elution.

¹¹ Morgulis, Beber, and Rabkin: J. Biol. Chem., 68, 521 (1926). This preparation will keep for several years. For a preparation from liver see Dixon: Biochem. J., 19, 507 (1925).

Dialysis, employing most commonly the collodion bag, removes soluble diffusible substances including the salts that may be used in precipitation. Electrodialysis may also be employed. By means of fractional precipitation with salts such as ammonium sulfate separation from many protein materials may be accomplished. In some cases alcohol may inactivate the enzyme. Among the most useful adsorbents are different types of aluminum hydroxide. For example, by choosing a suitable form of this adsorbent and the proper acidity of solution, separation of the enzymes of the pancreas has been accomplished. Associated with adsorption methods is of course the elution of the adsorbed material from the aluminum hydroxide-enzyme complex by suitable solvents, among which are solutions of alkali phosphates of different reactions or dilute ammonia. For the preparation of the different forms of aluminum hydroxide see footnote 12. Since preparations of pure crystalline enzymes are of the greatest interest there follows

12 Preparation of Adsorbents: Alumina A. Warm 250 g. of Al₂(SO₄)₃·18H₂O in 750 ml. of water to 55° and pour the solution all at once with the most vigorous mechanical stirring into 2.5 liters of 15 per cent ammonia warmed to 55°. The temperature rises to 58° and is kept between 55° and 60° with continued stirring for half an hour. Transfer to a 5-liter flask with a reflux condenser and boil gently for 48 hours. Dilute in a jar with water to 12 liters. Wash 3 times by decantation. Stir the precipitate with 500 ml. of 15 per cent ammonia to decompose the traces of basic sulfate. Wash until for three successive times the wash water no longer comes away clear and the precipitate becomes a plastic gel from which the wash water can be completely poured.

Alumina B. Precipitate as for Alumina A. After the precipitation stir for not more than half an hour. Then dilute at once to 12 liters and wash by decantation as above.

Alumina Cα. Ammonia alum is used. Ammonia used should be standardized by titration and should be measured accurately. Dissolve 22 g. ammonium sulfate in 600 ml. of water. Warm to 63° and add 100 ml. of 10 per cent ammonia. Warm quickly to 58°. Add with vigorous mechanical stirring all at once a solution of 76.7 g. of ammonia alum in 150 ml. of water, this solution being previously warmed to 58°. The temperature rises to 61°. Do not let the temperature go below 58°. Ten minutes after beginning precipitation, separate as rapidly as possible from the mother liquor by centrifuging. Transfer with 1500 ml. of water containing 1.25 g. of NH₁ to a 1500-ml. flask and shake. Centrifuge. Repeat using 2.5 g. of NH₃. Each treatment with ammonia requires about 17 minutes. Then wash three times more, using water only. The last supernatant fluid should remain turbid. The whole procedure from the first precipitation should require about 2½ hours, and must be expedited as the preparation is unstable.

Alumina $C\beta$. The α compound changes into the β form on standing a few hours. The flocculent suspension becomes a plastic gel less soluble in acid. The β form changes gradually (10 days to several months) into the γ form.

Alumina $C\gamma$. Precipitate as for the α form. Stir for 15 minutes at 60°. Transfer with 5 liters or more of water to a tall jar and wash by decantation. To the fourth wash water add 80 ml. of 20 per cent NH₃ to decompose the basic sulfate. Wash 12 to 20 times more with water or twice after the supernatant fluid no longer becomes clear. Some months' standing under water is required for complete conversion to the γ form to take place. The precipitate becomes more flocculent and is insoluble in cold dilute or fairly strong HCl.

Alumina D. Dissolve 130 g. of pure commercial aluminum hydroxide with 140 g. of KOH (80 per cent) in 900 ml. of hot water. Dilute to one liter and filter. Dilute to 10 liters. Precipitate by running a gentle stream of carbon dioxide through the solution for two days. Decant and wash 12 times with water containing carbon dioxide and then with distilled water. The final washings remain turbid.

Aluminum Metahydroxide. If one of the above forms of aluminum hydroxide be heated suddenly with ammonia in a sealed tube to 250° and kept at that temperature for 8 to 9 hours, there is a complete conversion to the metahydroxide form.

Kaolin. Kaolin is best treated with acid before use. To 500 g. of kaolin add 1500 ml. of pure HCl (sp. gr. 1.18) and warm very slowly so that the mixture begins to boil at the end of the first day and then boil for another day. Wash with water by decantation. Repeat the treatment with acid and washing three times more. Wash with cold water until the washings show practically no acidity but the kaolin itself reacts strongly acid on litmus paper.

Other Adsorbents. Ferric hydroxide, magnesium oxide, and stannic and silicic acids are used. Substrates may also be used as specific adsorbents as tristearin for lipase, casein for trypsin, and coagulated egg albumin for pepain.

Elution. Solutions of ammonia or of disodium phosphate are most generally useful in

- a description of methods used in the preparation of certain of these. Methods for the preparation of active preparations of vegetable lipase and sucrase are also included since these are more readily obtained from vegetable sources. Other enzyme preparations are discussed in the chapters dealing with digestion.
- 1. Preparation of Crystalline Urease: 12 Dilute 158 ml. of redistilled acetone 14 to 500 ml. at 22° C. (= 31.6 per cent acetone). Pour over 100 g. of Arlco jack bean meal in a beaker. Stir 3 to 4 minutes and filter through a Schleicher and Schüll, No. 595, or Whatman, No. 1, filter. Allow about 150 ml. to filter at room temperature. Complete the filtration in the ice chest at 2° to 2.5° C., over night. Centrifuge off the crystals that form, using cold centrifuge tubes. Examine microscopically (see Fig. 80). Drain and stir up with 5 to 10 ml. of cold 31.6 per cent acetone. Centrifuge again. Dissolve the crystals in 15 to 40 ml. of distilled water at room temperature and free the solution from insoluble matter by centrifuging. The activity of the concentrated solution is not lost very rapidly provided the material is kept in the ice chest.
- 2. Preparation of Crystalline Pepsin: Dissolve 500 g. of Parke Davis pepsin (U.S.P. 1:10,000) in 500 ml. of water and add 500 ml. of N H₂SO₄. Add with stirring 1000 ml. of saturated MgSO₄ solution. Filter through fluted paper (S. and S. No. 1450½) and then with suction. Discard the filtrate. The precipitate must not stand at room temperature more than 24 hours.
 - Precipitate 1: Wash twice with an equal volume of $\frac{2}{3}$ saturated MgSO₄. Filter with suction. Discard the filtrate.
 - Precipitate 2: Stir with water to a thick paste and run in M/2 NaOH until complete solution. Great care must be taken to avoid local excess of NaOH. The pH must never rise above 5.0. Add M/2 H₂SO₄ with stirring until a heavy precipitate forms (pH about 3.0). Let stand 3 to 6 hours at 8° C. Filter with suction.
 - Precipitate 3: Stir with water to a thick paste at 45° C. Add M/2 NaOH carefully until the precipitate dissolves (filter if cloudy and discard the precipitate). Place the beaker containing the precipitate in a vessel containing about 4 liters of water at 45° C., inoculate with pepsin crystals, and allow to cool slowly. Cooling should require 3 to 4 hours and a heavy crystalline precipitate should form at about 30° to 35° C. (see Fig. 81). Keep the solution at 20° for 24 hours. Filter off the thick crystalline paste with suction.
 - Precipitate 4: Wash with a small amount of cold water and then with ½ saturated MgSO4 and keep under saturated MgSO4 at 5° C. The filtrate may be treated with M/2 H₂SO4 to attain a pH of 3.0, the amorphous precipitate filtered off and treated like Precipitate 3.
- 3. Preparation of Crystalline Trypsin and Chymotrypsin: Remove the pancreas from cattle within one hour after slaughter, and immerse in cold N/4 H₂SO₄. Drain off the acid, mince, and suspend for 24 hours in 2 volumes of N/4 H₂SO₄ at 5° C. Strain through gauze. Add solid (NH₄)₂SO₄ to 0.4 saturation. Filter. Saturate to 0.7 saturation. Let stand 2 days at 5° C. Dissolve in water and re-fractionate between 0.4 and 0.7 saturation. Dis-

freeing adsorbed engymes from combinations with alumina.

acid.

Different ensymes are differently adsorbed. The properties of an ensyme as far as adsorption is concerned may change during purification. In a general way the more finely dispersed gels such as alumina A, B, and C have more adsorptive power than those with less surface such as the microcrystalline D and metahydroxide. For numerous applications see Willstütter, et al.: "Untersuchungen über Ensyme," Berlin, Julius Springer, 1928.  Commercial acetone distilled over fused CaCl: and soda-lime, to remove the water and

solve the precipitate from 0.7 saturation in 0.25 saturated (NH₄)₂SO₄. Adjust to pH 5.0. Let stand 2 days at 25° C. Filter. Crystals are chymotrypsinogen. (Retain filtrate for trypsin.) Recrystallize chymotrypsinogen in 0.25 saturated (NH₄)₂SO₄ at pH 5 about 8 times. Dissolve in N/50 H₂SO₄. Adjust to pH 7.6. Add a trace of trypsin. Let stand 2 days at 5° C. Adjust to pH 4. Salt out in 0.7 saturated (NH₄)₂SO₄. Filter. Dissolve in N/100 H₂SO₄. Let stand 24 hours at 25° C. Filter off chymotrypsin crystals. (See Fig. 83.)

Take the filtrate from the chymotrypsinogen crystallization for the preparation of trypsin. Adjust to pH 4.0, precipitate in 0.7 saturated $(NH_4)_2SO_4$, and refractionate between 0.4 and 0.7 saturated $(NH_4)_2SO_4$. Filter. Wash the precipitate from 0.7 saturation with sat. MgSO₄. Dissolve in 0.4 M borate of pH 9.0. Cool to 5° C. Bring to 0.5 saturation with MgSO₄. Let stand 3 days at 5° C. Filter off the crystals of trypsinogen. Wash with 0.5 sat. MgSO₄. Dissolve in N/50 H₂SO₄. Bring to 0.5 sat. with MgSO₄. Add 0.4 M borate to give a pH of 9.0. Let stand 1 day at 5° C. and filter off the crystals of trypsin (see Fig. 82). Yield, about 6 g. from 7 liters of acid extract of the pancreas.

4. Preparation of Vegetable Lipase: Procedure of Willstätter and Waldschmidt-Leitz: Rub in a mortar to a paste 20 g. of hulled castor beans. 15 Then with continued rubbing add 140 ml. of water in portions of 5 to 10 ml. Centrifuge for 15 minutes at 3,000 revolutions per minute. Three layers are formed. Pour off the upper creamy layer and retain. Pour off the clear water layer and discard. Rub up the residue with 140 ml. of water as before and centrifuge. Pour off the creamy top layer and combine with the first portion. Use this suspension for lipase experiments.

5. Preparation of Sucrase from Yeast: Introduce 100 g, of compressed yeast into a 400-ml, beaker. Warm the yeast to 30° C, by placing the beaker for some time in a water bath at a slightly higher temperature. Add 10 ml, of toluol. Stir thoroughly with a heavy glass rod. The yeast should become liquefied in 30 to 45 minutes. Add 200 ml, of water. Mix thoroughly and centrifuge. To the residue in the centrifuge tubes add a small amount of water and mix well, then add more water at 30° C, to make a total of 200 ml. Stir and centrifuge. To the yeast residue after pouring off the water add 100 ml, of water saturated with toluol and 10 ml, of toluol and incubate at 30° over night. Dilute with 4 volumes of water. With vigorous stirring carefully add acetic acid (not over 1 N) until a test with methyl red indicates a pH of about 3.5 to 4.0. Centrifuge. To the supernatant fluid add some infusorial earth and filter. Neutralize with ammonia to complete change of color with bromcresol purple. Keep in a refrigerator.

QUANTITATIVE ESTIMATION OF ENZYME ACTION

The amount of enzyme present in any mixture is expressed in terms of its activity as compared with an arbitrary standard. Either the time required for a given amount of enzyme preparation to bring about a definite degree of conversion of the substrate or the amount of preparation needed to bring about a definite degree of conversion in a specified time may be made the basis of comparison. Inasmuch as enzyme action is greatly influenced by the pH of the solution, by the presence of inorganic salts and activators, and by temperature, it is important that the conditions in the digestion mixtures should be made as nearly identical as possible and that the enzyme if in inactive form should be properly activated.

¹⁶ The greatest care must be taken to avoid poisoning by the ricin which is present in the meats.

Chemical reactions follow the law of mass action—that is, their speed is proportional to the product of the concentrations of the reacting substances. In most enzyme reactions the speed of decomposition of the substrate tends at first to be directly proportional to the amount of enzyme present, particularly if the substrate is present in large excess. Later the reaction may slow up due to decrease in the amount of substrate or combination of the enzyme with substrate or products of the reaction. In quantitative studies of enzyme action it is best to have a large excess of substrate and to keep the time of the experiments within the period when decomposition is proportional to time. To establish these limits an experiment must be conducted and a curve plotted showing the extent of decomposition at different time intervals. In certain cases direct proportionality does not exist even in the early stages. In such cases a curve prepared as above will suggest the rule to be applied in the calculation of results.

DEMONSTRATION OF THE REVERSIBLE ACTION OF AN ENZYME

The enzyme phosphorylase is found in plant and animal tissues. This enzyme catalyzes the following reaction:

The reaction is reversible and either glycogen or starch can be used to form glucose-1-phosphate (Cori ester). Whether glycogen or starch is formed from glucose-1-phosphate depends upon the source of the enzyme. Muscle phosphorylase (in vitro) and the phosphorylase from higher plants form a polysaccharide which is probably identical with the amylose fraction of starch. Yeast phosphorylase and the phosphorylase from liver, brain, and heart form glycogen from glucose-1-phosphate.

The position of the equilibrium is influenced by pH. At pH 7 an equilibrium is obtained when the total phosphate is 23 per cent as Cori ester and 77 per cent as inorganic phosphate.

1. Formation of Glucose-1-phosphate: (Hanes method as modified by Sumner and Somers). Boil 8 g. of soluble starch with about 100 ml. of water. Cool and add 12 g. of Na₁HPO₄ and 5 g. of KH₂PO₄ dissolved in about 300 ml. of water. Add 100 ml. of potato-cyanide extract. Dilute to one liter, add toluene, and mix. Keep at 20° to 25° C. for about 24 hours.

Inactivate the phosphorylase by adding 0.1 N iodine until the solution gives a permanent reddish-brown color. Remove the iodine by adding 0.1 N thiosulfate until all brown color has disappeared. Add 10 to 20 mi. of 2 per cent pancreatin and allow to digest until no more dextrin remains, as shown by the iodine test. (This will take three or four hours.) Add 40 g. of barium acetate and about 8 ml. of 28 per cent ammonia, or enough to make the suspension definitely alkaline to phenol red. Mix well, centrifuge, and pour the supernatant through cotton. To each volume of supernatant add 2 volumes of 95 per cent alcohol and centrifuge down the barium sait of glucose-1-phosphate. Discard the supernatant. Stir the precipitate with 30 to 60 ml. of water and enough 2 N sulfuric acid to give a pink color with thymol blue paper. Now add saturated potassium hydroxide cautiously until the suspension just falls to give a blue or brown

color with Congo red paper. Add 6 g. of trichloroacetic acid and mix. To every volume of the suspension add 2 volumes of 95 per cent alcohol and stir. Centrifuge down the suspended matter. Decant the clear supernatant solution. Add saturated potassium hydroxide to it until it is decidedly alkaline to phenol red. The di-potassium salt of glucose-1-phosphate usually separates as an oil. Chill overnight at 0° to 5° C. Next day filter off the crystals, wash several times with 95 per cent alcohol and then with acetone, and dry at 50° C. The yield will be about 3.5 g. and the product will be about 85 per cent pure.

The potato-cyanide is prepared by disintegrating about 325 g. of recently sliced potato in 100 ml. of 0.01 N neutralized potassium cyanide in a blender. The disintegrated mass is squeezed in cheesecloth and the

juice is centrifuged to eliminate the starch.

The hexose-1-phosphate, or Cori ester, is C₆H₁₁O₅PK₂·2H₂O. Does a trace of it reduce Benedict's solution? Heat a trace of it in boiling water for 5 minutes with 1 ml. of N sulfuric acid. Neutralize with 0.1 N NaOH. Now

test for glucose. Test also for inorganic phosphate.

2. Formation of Starch from Glucose-1-Phosphate: Prepare 5 to 10 ml. of 0.1 per cent glucose-1-phosphate in water. Add a drop of phenol red and enough 0.1 N hydrochloric acid to bring the alkaline solution to approximate neutrality. Place 1 ml. of the solution in a test tube and add about 1 ml. of potato-cyanide extract. Add a drop of 0.01 per cent boiled starch solution and mix. This primes the reaction. From time to time remove a drop or two of the digest and test on a porcelain spot plate by adding a few drops of 0.01 N iodine solution. Is starch formed? What is the chemical reaction?

CELL RESPIRATION

The ultimate objective in the study of those enzymes which are found within cells is to apply this knowledge to an understanding of the metabolic processes upon which the cell depends for its maintenance and function. The contributions of enzyme chemistry to this subject have been numerous and important, but it is clear that the isolation of an enzyme or enzyme activity from cells does not necessarily give information as to the significance of the enzyme in the intricate processes of metabolism within the cell. An alternate method of approach, therefore, is to study the metabolic behavior of the isolated intact cell or tissue, under as nearly physiological conditions as possible, and to integrate knowledge gained in this way with that acquired by the study of individual enzyme systems.

It was Warburg who first showed that animal tissues and organs (liver, kidney, brain, etc.) could be prepared in the form of thin sections or minces which would continue to carry on metabolic processes (respiration, substrate utilization) for many hours after removal from the animal body if placed under suitable conditions, and that such metabolism could be followed quantitatively. While it is obvious that cells under these circumstances are no longer under the control of nervous or hormonal mechanisms, metabolic data obtained by this method of approach do not disagree with results obtained on the intact animal where the two methods can be compared, and have furnished valuable information concerning the localization of specific metabolic processes in individual organs of the animal body, as well as the effect of different substrates, coenzymes, activators, inhibitors, etc., on cell metabolism

In the study of isolated cells and tissues, chief attention has been directed to the respiration, and specifically to the oxygen consumption. In fact, some have defined the respiration of cells in terms of oxygen consumption alone, but carbon dioxide production is an equally important phase of respiration, and any complete characterization of cell respiration must include both oxygen consumption and carbon dioxide production. In addition to respiratory data, much valuable information has been obtained by the use of the Warburg tissue-slice technic concerning other metabolic characteristics of cells, such as substrate utilization,

fermentative (glycolytie) ability, glucose and glycogen synthesis, urea formation, conjugation of foreign organic compounds, etc. The discussion in these pages will be confined to respiration and glycolysis, two characteristics of cell metabolism which are readily measured manometrically, but it cannot be too strongly emphasized that knowledge of this type is essentially incomplete until it is supplemented with precise information concerning substrate utilization and end-product formation; this fact should be more generally recognized.

Measurement of Oxygen Consumption. The basis of the Warburg method for the measurement of the oxygen consumption of living cells is the apparatus shown in Fig. 86. This is sometimes referred to as the Warburg apparatus, but more properly is called the Barcroft-Warburg apparatus since it was adapted by Warburg from that developed by Barcroft for the study of blood gases. It consists of a suitable vessel, containing the material to be studied in the proper fluid medium, and attached in a closed system to a manometer for measuring changes in gas pressure. Various types of vessels in common use are shown in Fig. 87; many other types have been described for special purposes. In general, an ordinary Barcroft-Warburg vessel has a capacity of 15 to 20 ml., with a center

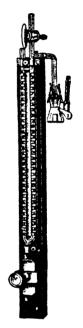

Fig. 86. Bareroft-Warburg manometer with attached vessel.

well and one or more side-bulbs; larger and smaller vessels have also been used. The type of bored side-bulb plug illustrated is much to be preferred over the more common solid plug.

To provide for accurate temperature control, manometers and vessels are so constructed that the manometer may be mounted on the side of a constant-temperature water bath (thermostat), with the vessel completely immersed in the water. To ensure equilibration between fluid medium and gas phases in a vessel during an experiment, the manometer mounting is attached to a shaking device which shakes vessel and manometer horizontally at speeds which ordinarily amount to 110-115

¹⁶ Complete equipment of the type described here (manometers, glassware, and thermostat) may be obtained from E. Machlett and Son, New York City; the Arthur H. Thomas Co., Philadelphia; or the American Instrument Co., Silver Springs, Md.

oscillations per minute, with an excursion of 3-4 cm. A complete assembly of this type is illustrated in Fig. 88.

The detailed application of the Warburg procedure for the measurement of oxygen consumption is given in the experiments which follow this discussion. The principle is as follows: The tissue, usually in the form of thin slices, is incubated at body temperature in a suitable buffered medium, in a vessel with attached manometer, the vessel containing

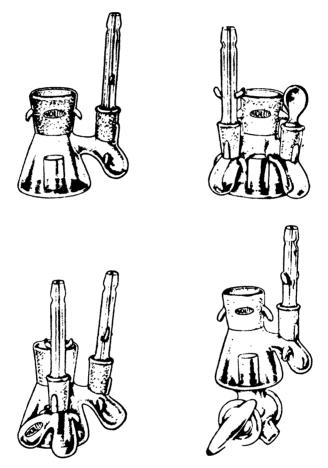

Fig. 87. Types of vessels used for manometric studies on cell respiration.

oxygen rather than air. The center well of the vessel contains a little strong alkali solution which absorbs any CO₂ produced, so that any pressure changes are due to oxygen consumption alone. The side-bulbs provide for the addition of substrate, activators, inhibitors, etc., during an experiment if desired. The gas phase in vessel and manometer capillaries is kept at constant volume; oxygen consumption is measured therefore by a fall in pressure, which is read on the manometer. The pressure readings when multiplied by a constant ("vessel constant") give

the oxygen consumption, usually expressed in microliters (cubic millimeters). Readings are made at suitable intervals; they may be plotted graphically against time, or may be averaged to give the oxygen consumption over a given time interval. The standard method for expressing oxygen consumption is in terms of the number of microliters consumed in one hour by 1 mg. (dry weight) of tissue; this is symbolized by Q_{01} . By convention, the consumption of a gas is given a negative value. Thus a Q_{01} , of Q_{01} represents the consumption of 6 microliters of oxygen per hour by 1 mg. dry weight of tissue.

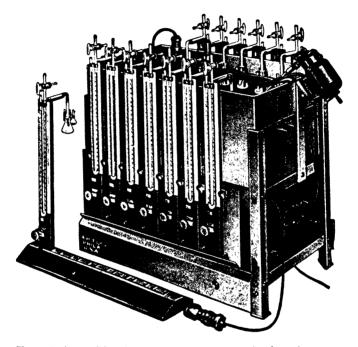

Fig. 88. Assembly of constant-temperature bath and manometers as used for studies on cell respiration.

Representative Q₀, values for various animal tissues are given in the table on p. 297. These values must be considered as approximations only, since it is known that the oxygen consumption of many tissues is affected by: the presence or absence of various substrates, the previous nutritional history of the animal, the inorganic ion composition of the medium and the type of buffer used, the length of elapsed time between the death of the animal and the start of an experiment, and even the duration of the experiment itself since oxygen consumption may not be linear with respect to time. Despite these limitations, many valuable data have been obtained by this procedure, particularly where comparative and not absolute values are desired, as in studies on the relative effects of various substrates, coenzymes, and inhibitors, comparison between normal and abnormal tissues, etc.

A more serious limitation in the Warburg method, and one which is

receiving increasing recognition, is that the tension of CO₂ must be maintained at or near zero during the experiment, otherwise manometer readings will not reflect changes in oxygen content alone. This requirement means that metabolism is proceeding in the virtual absence of CO₂, and it is known that certain metabolic processes (e.g., the formation of urea by liver cells) require the presence of CO₂; even the oxygen consumption of some tissues is significantly affected by the presence or absence of a physiological tension of CO₂. Furthermore, measurements by the Warburg method are not possible in such media as normal blood serum or other bicarbonate-containing media, since such media require the maintenance of a finite tension of CO₂ to establish the pH.¹⁷ For the measurement of oxygen consumption and other respiratory characteristics of tissues in the presence of physiological tensions of CO₂, the differential manometer described in the next section in connection with the measurement of CO₂ production must be used.

Measurement of Carbon Dioxide Production. Measurement of carbon dioxide production by respiring cells or tissues is technically more difficult than is measurement of oxygen consumption. There is no satisfactory direct method for the continuous measurement of the carbon dioxide produced by cell respiration, as there is for the measurement of oxygen consumption. For this reason, relatively little work has been done on this phase of respiration, and this is unfortunate, for, as we now know, carbon dioxide is produced not by the direct oxidation of carbon compounds by oxygen but rather by decarboxylation of organic acids, and in a manner essentially independent of oxygen consumption but presumably of equal importance to the cell. Carbon dioxide production usually is expressed by giving the value of the respiratory quotient (R.Q.), which is the ratio of the volume of carbon dioxide evolved to the volume of oxygen consumed in the same time; hence if the Qo, and R.Q. are given, the carbon dioxide production is defined.

One method for the determination of R.Q. in phosphate buffer using the ordinary Barcroft-Warburg manometers is to set up duplicate tissue preparations but to omit the alkali from the center well of one vessel. Pressure changes in the vessel containing alkali are due to oxygen consumption alone; pressure changes in the second vessel, without alkali, represent the net (and opposing) effects of oxygen consumption and carbon dioxide production. At the end of the experiment, by subtracting the pressure change due to oxygen consumption alone, as established on the first manometer, from the reading of the second manometer, the pressure change due to carbon dioxide production may be obtained. Conditions in the two vessels, including vessel constants, must be as nearly alike as possible. This, of course, cannot be true with respect to the CO₂ tension, which is zero in the first vessel and continuously increasing in the second vessel. Results will therefore be in error if the CO₂ tension influences

¹⁷ For a method of measuring oxygen consumption by the Warburg method in "neutralized" serum—i.e., serum which has been freed of bicarbonate by treatment with acid and evacuation—see Macleod and Rhoads: Proc. Soc. Exptl. Biol. Med., 41, 268 (1939); Warren: Am. J. Physiol., 128, 455 (1940).

metabolic processes within the cell, and this is known to be the case with a number of different types of cells. This method is therefore not widely used.

It is also possible to so arrange matters that only one vessel containing alkali is used, and the CO₂ absorbed by the alkali is measured by liberating with acid at the end of the experiment. This method is technically

quite difficult, is not too accurate, and likewise suffers from the disadvantage that measurements are made

in the presence of a zero CO₂ tension.

To permit measurement of carbon dioxide production (and oxygen consumption as well) in the presence of a physiological tension of carbon dioxide, and therefore in media such as blood serum or Ringer-bicarbonate solution which are more nearly physiological than phosphate or similar buffers, various types of socalled differential manometers have been developed. One such type¹⁸ is illustrated in Fig. 89. It consists of two independent vessels and manometers, with the manometers so arranged that pressure changes in the two vessels may be opposed to one another on the manometer, to permit precise measurement of the pressure differences between the vessels rather than the total pressure in each. In use, the two vessels are charged with identical amounts of medium and tissue. the medium being either blood serum or Ringer-bicarbonate, and the gas phase being oxygen containing a physiological concentration (usually 5 per cent) of carbon dioxide. At the beginning of the experimental period, the tissue in one vessel is killed by tipping in acid from a side-bulb, and the tissue in the other vessel is then allowed to respire for the desired length of time, after which it too is killed by the addition of acid. Although the total pressure in both vessels is now quite high, due to the liberation of CO₂ from the decomposed bicarbonate in the medium, by opposing one vessel pressure against the other on the manometer only the difference in pressure caused by the respiration of

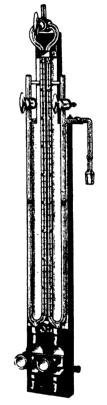

Fig. 89. Constant-volume differential manometer.

the tissue in the second vessel during the experimental period will register on the manometer. This pressure difference is due to both oxygen consumption and carbon dioxide production. After it is noted, alkali is admitted into both vessels through a bottom stockcock (see Fig. 87 for the type of vessel used) and all the carbon dioxide is absorbed. Again the differential reading is noted; this is now due solely to oxygen consumption by the respiring tissue. The carbon dioxide production is obtained by subtracting this reading from the first differential reading. Thus the oxygen consumption and R.Q. are accurately measurable under a continuous physiological tension of carbon dioxide. The only disadvantage of this

¹⁸ Summerson: J. Biol. Chem., 131, 579 (1939).

method over the simple Warburg method as far as oxygen consumption measurements are concerned is that the Warburg method gives continuous readings, while the differential method gives but one reading, representing the entire experimental period. Conditions, therefore, must be selected so that respiration is linear with respect to time, or nearly so.

The use of the differential manometer is technically somewhat more difficult than is that of the simple Barcroft-Warburg manometer, but it is the only accurate basis for the measurement of cell respiration under conditions which closely simulate those prevailing normally, and the increased significance of the results obtained more than justifies the technical difficulties.

A further advantage of the differential manometer is that it permits the measurement of aerobic acid production ("aerobic glycolysis," see below) by respiring tissues. If the tissue produces acid—e.g., lactic acid—aerobically in a medium containing bicarbonate, neutralization of the acid results in the decomposition of an equivalent amount of bicarbonate to produce gaseous CO₂. This CO₂ is indistinguishable manometrically from the CO₂ of respiration unless the differential manometer is used, where it is readily done by a simple method which need not be described here (for details see Summerson [loc. cit.] and also books by Dixon and by Umbreit, et al., cited in the Bibliography). Since the production of acid aerobically is a characteristic which differentiates tumor tissues from many (but not all) normal tissues (see table on p. 297), the differential manometer is useful in metabolic studies on such tissues.

Anaerobic and Aerobic Glycolysis. Practically all tissues show the ability to produce lactic acid from either glucose or glycogen under anaerobic conditions. Such production of lactic acid is known as glycolysis, although strictly speaking this term implies merely a disappearance of carbohydrate rather than the specific production of lactic or other acids. With certain tissues—e.g., liver, kidney—the anaerobic formation of lactic acid is at the expense of tissue glycogen and is independent of the presence of glucose; it has been proposed that the term glycolysis be restricted to such origin of lactic acid from glycogen, and that the term glucolysis be used where glucose is the source of the lactic acid.

Anaerobic glycolysis by tissues is readily measured with the simple Barcroft-Warburg manometers by suspending the tissue in a bicarbonate-containing medium in equilibrium with the proper tension of CO_2 in the gas phase to maintain a suitable pH, but with nitrogen rather than oxygen present. Since in the absence of oxygen there is no respiration, pressure changes on the manometer will ordinarily be due solely to decomposition of bicarbonate by the acid produced anaerobically. Anaerobic glycolysis usually is represented by the symbol $Q_0^{N_2}$, and is expressed in terms of microliters of CO_2 produced by the action of acid on the bicarbonate present, per milligram dry tissue per hour. The anaerobic glycolytic power of various animal tissues is given in the table on p. 297. No distinction is made in this table between glucolysis and glycolysis, and the values for certain tissues such as liver and kidney are subject to considerable variation because the rate of glycolysis usually falls off continuously

throughout the average experimental period. It will be noted that various tissues differ considerably in their $Q_G^{N_2}$ values, and that tumor tissues in general (but not exclusively) are quite high in this respect.

The production of acid aerobically is also measurable in terms of the decomposition of bicarbonate, is symbolized by $Q_G^{O_2}$, and expressed in the same units as for anaerobic glycolysis. Aerobic glycolysis is more difficult to measure than anaerobic glycolysis, since there must be a way to differentiate the CO_2 of acid production from the respiratory CO_2 . The only successful way to do this is with the differential manometer, as discussed previously. In contrast to acid production anaerobically, which in the majority of cases is quantitatively due to lactic acid, only a fraction of the acid produced aerobically is usually accountable for as lactic acid. Little specific information is available concerning the nature of other acids produced under these circumstances. As can be seen from the data below, most normal adult tissues have a relatively low aerobic glycolysis; certain specialized normal adult tissues, and all tumor tissues are characterized by a significant aerobic glycolysis.

It is felt by some that the inhibition of anaerobic glycolysis ("fermentation") by aerobic metabolism, which is called the "Pasteur effect," may be associated with the presence of a specific enzyme ("Pasteur enzyme") whose function is to orient cell metabolism into either fermentative or oxidative pathways. Evidence for the existence of such an enzyme is limited at the present time.

EXPERIMENTS ON CELL RESPIRATION

1. Calibration of Vessel and Manometer: Principle. For the calculation of changes in gas content in a vessel from the manometer

piece of rubber tubing carrying a screwcock and connected to a leveling-bulb containing mercury. The manometer stopcock should be lightly greased and may be held secure by rubber bands. Turn the manometer stopcock so that mercury may enter from the rubber tubing and rise into the manometer capillaries. By carefully releasing the screwcock on the rubber tubing, allow mercury to enter the manometer capillaries and rise in the side-arm and main limb until the mercury level reaches both the calibration mark on the side arm and the 150-mm. graduation on the main limb. Slight further tilting of the manometer may be necessary at this point. If there are any trapped air bubbles, lower the leveling-bulb to retract the mercury and repeat the adjustment.

When both capillaries of the manometer are filled with mercury to the desired points, turn the manometer stopcock very slightly to cut off the flow of mercury, place a tared beaker under the straight capillary orifice of the manometer stopcock, and then turn the stopcock so that the mercury drains from the manometer capillaries into the beaker. Any droplets of mercury remaining behind may be forced out and into the beaker by blowing down the capillaries. Weigh the mercury, determine its temperature, and calculate the volume of the side-arm and main limb capillaries. Call this volume $V_{\rm M}$.

Calculation. The total volume of empty vessel and manometer gas space, V_T , is equal to $V_V + V_M$. From the value of V_T , the vessel constant k under a particular set of experimental conditions is calculated as follows:

$$k = \frac{V_T}{P_0} \cdot \frac{273}{T} - \frac{V_F}{P_0} \left(\frac{273}{T} - \alpha \right)$$

where V_T is the total volume of vessel and manometer, as described above, and V_F is the volume of fluid medium in the vessel during an experiment; both of these volumes are expressed in microliters (cubic millimeters) rather than in milliliters (1 ml. = 1000 microliters). P_{σ} is the equivalent of 1 atmosphere pressure in mm. of manometer fluid (760 for mercury, 10,000 for Brodie fluid, see below). T is the temperature in degrees Absolute at which measurements are made, and α is the absorption coefficient (solubility) of the gas undergoing absorption or evolution.²⁰ For the derivation of this equation, see the book by Dixon; the form of the equation is that described by Macleod and Summerson.²¹

It can be seen that the constant for a particular vessel and manometer depends upon the size of the vessel, the volume of medium used, the temperature, and the nature of the gas concerned. The following example illustrates the calculation of the vessel constant for oxygen, $k_{\rm On}$ for a particular vessel and manometer where $V_{\rm T}=15.75$ ml. and 2.0 ml. of medium are employed, at 38° C.

$$V_T = 15.75 \text{ ml.} = 15,750 \text{ }\mu\text{l.}$$

 $V_F = 2.00 \text{ ml.} = 2,000 \text{ }\mu\text{l.}$
 $T = 38^{\circ} \text{ C.} = 311^{\circ} \text{ A.}$
 $P_o = 10,000$
 $\alpha_{01} = 0.024 \text{ at } 38^{\circ} \text{ C.}$

¹⁰ At 38° C., α for O₂ is 0.024; for N₂, 0.012; and for CO₂ in water 0.55; in Ringer solution, 0.537, and in Ringer solution containing 0.3 N HCl, 0.517. For values of other gases and at other temperatures, see handbooks giving physical constants of gases.

³¹ Macleod and Summerson: Science, 91, 201 (1940).

$$k_{0i} = \frac{15,750}{10,000} \times \frac{273}{311} - \frac{2,000}{10,000} \left(\frac{273}{311} - 0.024\right)$$

$$= 1.38 - 0.17$$

$$= 1.21$$

The vessel constant will be different with other amounts of medium, at other temperatures, and for other gases. For routine work on oxygen consumption at 38° C., the only variable is likely to be the volume of medium employed. Vessel constants should therefore be calculated for the various volumes of medium apt to be used, or the simple graphical method described by Macleod and Summerson (loc. cit.) for this purpose may be employed.

The calibration is described for a manometer fluid setting at the 150-mm. mark on the graduated limb. This is the most satisfactory position, but calibration obviously can be made to some other setting. If a thread of mercury is placed in the graduated capillary, the length in mm. noted, and the mercury then weighed and its volume computed, the volume of the graduated capillary per mm. may be obtained, and from this it is possible to calibrate the manometer at any setting on the scale provided the calibration at one setting is also known. This is of value under certain circumstances.

Manometer Fluid. The most commonly used manometer fluid is the aqueous salt solution described by Brodie, 22 with a specific gravity of 1.033, so that 10,000 mm, are equal to 1 atmosphere (760 mm, of mercury); this makes for obvious convenience in calculation, with a much greater sensitivity than mercury. For special purposes, however, any other fluid whose P_o value is known (water, mercury, paraffin oil, etc.) may be used.

The manometer fluid usually is contained in a stoppered rubber tube attached to the manometer which acts as a reservoir, controlled by the pressure of a screwcock. The fluid may gradually leak out or be otherwise lost; it may be replenished at any time, even during an experiment, by inserting a hypodermic needle attached to a syringe containing extra fluid through the rubber tube wall, at a slight angle to form a "Bunsen valve" after withdrawal of the needle. It may also be added through the open top of the manometer, with precautions to avoid trapping air bubbles. Should such bubbles be present, they may be forced to the top of the fluid column and dissipated by alternate pinching and release of the rubber tube reservoir with the fingers, to force the manometer fluid up and down.

 Measurement of Oxygen Consumption of Rat Liver Slices by Warburg Method: (a) Preparation of Tissue: Kill a young adult rat by a blow on the head, followed by severing the neck vessels and spinal cord at the neck with scissors. Open the abdominal cavity and remove the liver as quickly

²² Brodie fluid is made as follows: Dissolve 23 g. of sodium chloride and 5 g. of bile salts (sodium tauroglycocholate, or sodium glycocholate, Merck) in 500 ml. of water. A few drops of an alcoholic thymol solution may be added as a preservative, and it is convenient to color the fluid by adding a few hundred mg. of a suitable dye (Crystal violet, Gentian violet, or Evans blue). The specific gravity of the final solution should be 1.033; i.e., 10 ml. should weigh 1.033 times as much as 10 ml. of water at the same tenperature.

as possible. Rinse the liver in a beaker containing Ringer's solution, ²³ then cut off the largest lobe of the liver and place flat on a pad of filter paper to drain momentarily. With a sharp thin razor blade moistened with Ringer's solution, cut off a small portion of the liver in such a way that the cut surface makes an angle of about 45° with the table top, and discard this portion. Continue cutting free-hand along the plane of the first cut surface to obtain a number of thin slices of liver, making each slice as uniformly thin as possible (the leading edge of the razor blade should be visible through the slice as it is being cut). With practice, uniform slices about 0.5 mm. thick are readily obtained. As each slice is obtained, transfer it to a flat dish containing Ringer's solution, and keep the blade of the razor and the cut surface of the liver moistened with Ringer's solution. Continue cutting until sufficient slices for the experiment are obtained; usually two to four slices are required per vessel.

(b) Preparation of Vessels: Measure duplicate (or triplicate) 2-ml. portions of medium²⁴ into clean dry Barcroft-Warburg vessels, avoiding the center well. In another vessel place a few ml. of water; this will be the thermobarometer control. With a forceps or platinum wire, transfer a liver slice from the dish to a pad of filter paper and drain momentarily, then quickly transfer to a tared watch-glass on a balance. Add more slices treated in the same way until the desired weight of liver tissue is obtained; 100 to 200 mg. wet weight is usually satisfactory. Immediately transfer the weighed clump of slices to one of the vessels, immersing them in the medium. The vessel may be shaken briefly to separate the slices. In like manner, charge the remaining vessels containing medium with weighed amounts of tissue. The weights of tissue in each vessel need not be identical, but they should be known to the nearest milligram.

When all the vessels are ready, obtain one more known weight of tissue by exactly the same procedure, but transfer this to a small tared watchglass or weighing dish. This is to be dried in an oven overnight at 100° C., and weighed again, to determine the dry weight of the tissue.

When the tissue is in place in the vessels, complete the preparation of the vessels by placing in the center well of each (except the thermobarometer vessel) 0.2 ml. of 10 per cent KOH solution, using a pipet with a fine tip. No alkali must get into the medium surrounding the center well. It is advantageous, but not absolutely necessary, at this point to insert a small roll of starch-free filter paper (Whatman No. 40 is satisfactory) in the center well so that the top of the roll projects a millimeter or two above the rim of the center well; the alkali, being absorbed on the paper roll, thus projects into the gas space of the vessel and is better able to absorb CO₂.

(c) Preparation of Manometers: When all the vessels are ready, mount each one on its manometer, using a small amount of suitable stopcock grease, 25 and attaching the vessels firmly to the manometer shanks by small springs or wound rubber bands. Fill each vessel containing tissue with oxygen by passing a slow stream of the washed gas from a tank, 26 through

 22 Ringer's solution may be prepared as follows: to 960 ml, of 0.154 M NaCl solution add 20 ml, of 0.154 M KCl solution and 20 ml, of 0.11 M CaCl $_2$ solution.

 24 The usual medium is Ringer-phosphate. To 10 volumes of Ringer's solution add 1 volume of M/15 phosphate buffer, pH 7.4. For preparation of phosphate buffer, see Chapter 1. If glucose is desired in the medium, a level of 200 mg, per 100 ml, may be established by adding 2 ml, of 10 per cent glucose solution to $100\,$ ml, of medium. The presence of glucose in the medium does not affect the oxygen consumption of liver slices, but is necessary with many other tissues.

¹⁶ Fisher "Cello-Seal," obtainable from the Fisher Scientific Co., Pittsburgh, and Eimer and Amend, New York City, is quite satisfactory. Ordinary petroleum jelly or anhydrous lanolin may also be used, but since these become somewhat soft at 38° C., it usually is necessary to tighten the vessels on the manometers at least once during the preliminary incubation period when they are used.

¹⁶ Tanks containing oxygen and other gas mixtures mentioned here may be obtained from the Ohio Chemical Co., New York City.

the vessel, attaching the rubber tube delivering the gas to the top of the manometer so that the gas passes through the manometer stopcock and capillaries into the vessel and out the opened side-bulb of the vessel. A few minutes' passage is sufficient for each vessel; all the vessels can be gassed at once if a multiple manifold attached to the tops of all the manometers is used. It is not necessary to gas the thermobarometer vessel.

When the vessel is filled with oxygen, turn the stopcock at the top of the manometer so as to close off the manometer and divert the flow of gas to the outside air; at the same time, have the greased plug for the side-bulb ready, and as soon as the gas flow has been diverted, insert this plug and fasten it securely. Continue in this way with each of the other vessels being gassed.

Place the manometers one by one on the constant-temperature bath, which should be at 38° C. As each vessel enters the thermostat, the temperature rise will cause expansion of the enclosed gas and the manometer fluid will rise. Release the excess pressure by momentarily opening the manometer stopcock to the air and then closing it. This operation may have to be repeated. The thermobarometer is placed on the bath with the manometer stopcock open.

Start the shaking device and shake vessels and manometers for 10 minutes; this is usually sufficient to bring about temperature and pressure equilibrium. During this time, adjust the manometer fluid so that the level in the closed limb is approximately at the calibration setting (usually the 150-mm. point on the scale). Since the pressure change to be expected during the experiment will be negative, the level of manometer fluid in the open limb should be as high as possible, to permit maximum range of readings. It may be necessary here also to release the pressure within a vessel momentarily to permit the indicated adjustment of manometer fluid level in each limb. During the preliminary equilibrium period, close the thermobarometer also; the level of manometer fluid should be about the same in each limb here.

When measurements are to be begun, stop the shaking device, note the time, and immediately set the manometer fluid level in the inner (closed) limb of the first manometer at exactly 150 mm. Record the fluid level in the open limb, to the nearest mm. Now read the thermobarometer in the same way. For each vessel reading there must be a thermobarometer reading unless temperature and atmospheric pressure remain sufficiently constant so that one thermobarometer reading suffices for all the vessels; this is rarely true.

Continue with the reading of the second manometer in the same way, until all of the manometers containing tissue have been read. When this has been done, start the shaking device. Repeat the readings as above, at suitable time intervals, usually 10 or 15 minutes, for the duration of the experimental period.

Calculation. Subtract each reading for a vessel from the previous reading, and from this subtract algebraically the change in thermobarometer reading during the same time, to obtain the net change in pressure for the time interval covered by the readings. Multiply the pressure change, h, by the vessel constant for oxygen under the particular experimental conditions, k_0 , to obtain the oxygen consumption in microliters. Multiply this by $\frac{60}{t}$, where t is the time in minutes, and

divide the result by the dry weight of the tissue, in mg., to obtain the Qo, value for the tissue.

$$(1) h \times k_{0i} = X_{0i}$$

(2)
$$X_{o_i} \times \frac{60}{t} \times \frac{1}{\text{dry weight}} = Q_{o_i}$$

Example. The protocols of a typical experiment are illustrated as follows:

Time (Minutes)	Manometer No. 1	Thermo- barometer	Net Change
0	282	151	
15	260	153 2	
30	$\begin{array}{c c} -22 \\ 238 \end{array}$	150	-24
	-22	-3	-19
45	211 -27	$\frac{146}{-4}$	-23
60	190	146	
	-21	0	-21
		l	87 for 1 h

$$h = -87$$

 $k_{01} = 1.43$ at 2 ml. V_F
 $N_{02} = 1.43 \times -87 = -124 \mu l$.
Wet weight of tissue = 98 mg.
 C_F solids in tissue = 24.3
Dry weight of tissue = 98 × 0.243 = 24 mg.
 $Q_{01} = -124 \times {}^{60}{}_{60} \times {}^{1}{}_{24} = -5.2$

The per cent of solids in the slices is obtained from the weight before and after drying overnight in an oven at 100° C. The water content of tissue slices stored in Ringer's solution is not necessarily the same as that of the original fresh tissue. Many of the data in the literature are based upon dry weights obtained by removing the slices from a vessel at the end of the experiment, draining, drying, and weighing. Results by this method usually are considerably higher than those obtained on the basis of the "initial" dry weight as described here, and may be seriously in error, particularly if (as usually happens), the slices disintegrate to some extent during an experiment. Results are occasionally reported on some basis other than the dry weight, such as in terms of milligrams of protein nitrogen, etc. The dry weight procedure is most commonly followed.

With vessel constants of approximately 1.5, and a manometer scale length of 300 mm., it usually is possible to measure the absorption of about 400 microliters of oxygen without resetting the manometer. If it is wished to continue measurements beyond this point, the manometer may be reset by opening the manometer stopcock momentarily to admit

a little air, closing it, and then adjusting the fluid level in the closed limb to the 150-mm. mark again, and reading the new level of fluid in the open limb against the thermobarometer as usual, continuing with the readings as described in the procedure above. If at the end of an experimental period the fluid level in the open limb is below the graduated range when the manometer is set at 150 mm., and it is desired to obtain a reading without resetting the manometer, set the manometer level at two successive points above the 150 mark—e.g., at 170 and at 160—make each reading quickly, and extrapolate to the reading at 150, since the change in reading between 160 and 150 will be the same as that between 170 and 160.

3. Measurement of Anaerobic Glycolysis by Tissues: Prepare the tissue as described under Exp. 2, but use Ringer-bicarbonate solution containing added glucose as the medium, 27 and do not put any alkali into the center wells. After attaching the vessels to the manometers, pass a stream of washed nitrogen gas containing 5 per cent carbon dioxide 28 through the vessels for 20 to 30 minutes at room temperature to completely displace any oxygen present. During the gassing period run the manometer fluid up and down once or twice to replace the air in the manometer capillary by the gas mixture, and shake the vessels occasionally to aid in displacing any air bubbles trapped in the medium. In turning the gas off and closing the vessels, take suitable precautions against the possible diffusion of room air into the system in the process. Vessels with bored plugs in the side-bulbs, which can be left in place but clear for the passage of gas during the gassing period, and then closed by a quarter-turn, are much to be preferred over the type having solid side-bulb plugs.

The rise in pressure caused by immersing the vessels in the thermostat at 38° is released as described under Exp. 2, again with precautions against allowing air to reënter the system. Since the readings will always be positive in this type of experiment (i.e., the pressure will increase due to decomposition of bicarbonate by the acid produced), set the manometer fluid level in the open limb at the bottom of the scale rather than at the top. This is easily done by forcing up the manometer fluid in the closed limb to about 200 mm., opening the stopcock cautiously to release most (but not all) of the excess pressure, then closing the stopcock and lowering the manometer fluid level to the 150 mark on the closed limb. If this is done properly, the fluid level in the open limb will be low down on the scale at this point.

Equilibrate by shaking for 10 minutes, then start readings, making them against a thermobarometer (which need not be gassed) just as described for the measurement of oxygen consumption in Exp. 2. Read at suitable intervals for the desired length of time.

Calculation. Subtract each reading from the next one, and subtract algebraically from this the change in thermobarometer reading during the same period, as for Exp. 2, to obtain the net increase in pressure due

²⁷ To 5 volumes of Ringer's solution add 1 volume of 0.15 M NaHCO₂ solution. Bubble the nitrogen (95 per cent)-CO₂ (5 per cent) gas mixture through this solution for about 15 minutes before using, to bring to pH 7.4. A glucose concentration of approximately 200 mg. per 100 ml. may be established by adding 2 ml. of 10 per cent glucose solution to each 100 ml. of medium.

²⁸ Tanks containing 95 per cent nitrogen-5 per cent carbon dioxide gas mixture may be obtained from the Ohio Chemical Co., New York City. The gas mixture may be freed from the traces of oxygen usually present by passing through a heated tube filled with metallic copper turnings. Pass the dried gas through a wash bottle containing water to saturate with water vapor before entering the vessels.

to acid production. Multiply by the vessel constant for CO₂ at the fluid volume used, k_{CO} , to obtain the number of microliters of CO₂ evolved as the result of acid production. Express results in terms of $Q_{\text{O}}^{N_2}$, which is defined as the number of microliters of CO₂ equivalent to the acid produced by 1 mg. dry weight of tissue in one hour, under anaerobic conditions.

With certain tissues anaerobic glycolysis proceeds linearly for hours provided sufficient glucose is present; with other tissues the rate of glycolysis is independent of the presence of glucose (and hence is presumably at the expense of glycogen) and may show a continual decrease with time. In this latter instance, the Q values represent the average for an hour, or may be computed on the basis of shorter experimental periods.

Salivary Digestion

Digestion in General. The greater part of the food elements in the diet require special treatment to render them capable of absorption and utilization by the body. Water, glucose, and certain inorganic salts and vitamins are exceptions, but the proteins, fats, and carbohydrates, as well as other substances, must be split up into simple components as monosaccharides, glycerol, fatty acids, amino acids, etc. The necessary changes are chiefly hydrolytic in character and involve especially the action of enzymes found in the different parts of the gastro-intestinal tract. Because of the variations in the quantity and character of food ingested and the variety of changes that must be brought about, the different parts of the gastro-intestinal tract must show a considerable power of adaptation and coördination. In this, both hormone and nervous mechanisms are concerned.

Certain changes similar to those occurring in digestion may take place in foods prior to ingestion. In the ripening of certain fruits, such as the banana, starch is changed to dextrin and maltose through the action of amylase. Meats on storage undergo some self-digestion or autolysis. This process may be hastened for commercial purposes ("tenderizing") by the application of proteolytic enzyme preparations to meat cuts. In the cooking of foods connective-tissue fibers are gelatinized and starch granules are broken up and some dextrinization of starchy foods occurs. Cooking also increases the palatability of foods and in this way promotes the secretion of digestive juices.

Secretion of Saliva. The saliva is secreted by three pairs of glands—the parotid, submaxillary, and sublingual—reinforced by numerous small glands called buccal glands. These secretions vary in character. Thus in man the parotid saliva is watery and has a high digestive power. The secretions of the other glands are higher in mucin and more viscid. Ordinary saliva is a mixture of the secretions of these glands and shows considerable variations in composition in different individuals, and in the same individual at different times.

The secretion of saliva is governed by a set of nerve fibers cerebral in origin, together with fibers from the sympathetic nervous system. No hormone mechanism in salivary secretion is known. Ordinarily the secretion of saliva is the result of a reflex stimulation of the secretory nerves through a center in the medulla oblongata. Psychic stimuli, brought about by such influences as the thought of food, pass from the higher nerve centers to the secretory center and also give rise to secretion. The results of Pavlov on dogs show it to be rather difficult in certain cases to differentiate between the two types of stimuli. Pavlov found that dropping several pebbles into a dog's mouth caused the flow of but one or

two drops of saliva, while sand in the mouth induced a copious flow of a thin watery saliva. Ice water caused no secretion, but acid or bitter solutions which the animal wished to reject caused a free flow of saliva. Dry food caused the secretion of a watery saliva, while meat led to the flow of a more slimy secretion, such as would aid in the lubrication of this food for swallowing. Drawing the attention of the animal to these foods, without actually giving them to him, gave rise to similar secretions. Thus, also, the pretense of throwing sand into the mouth of the dog gave rise to a profuse watery secretion.

The amount of saliva secreted by an adult in 24 hours has been variously placed, as the result of experiment and observation, between 1000 and 1500 ml., the exact amount depending, among other conditions, upon the character of the food. In the absence of obvious external stimuli, the rate of salivary secretion in the adult appears to be between 0.1 ml. and 0.9 ml. per minute.¹

Composition of Saliva. Salivary composition depends on many factors: stimulation, diet, age, time of day, disease, etc. To insure reproducible, representative samples for analysis, the conditions for collection should include (a) a definite physiological, postabsorptive state (before breakfast), (b) no brushing of the teeth, rinsing of the mouth, or smoking prior to collection, (c) about a two-hour interval between arising and collection, including a 15-minute rest period immediately preceding collection. Stimulation yields a relatively more dilute saliva but the difference diminishes as collection is prolonged.

Ordinarily saliva varies from weakly alkaline to weakly acid, the pH ranging approximately from 6.0 to 7.9. There is evidence that normal individuals under 20 and without dental defects secrete a saliva with a pH between 7.0 and 7.2. No absolute correlation has been shown between salivary acidity and caries or other dental disorders. However, lower pH values occur more frequently among caries-susceptible individuals. There is evidence that increased acidity of saliva is a late rather than early manifestation of the caries syndrome as compared with changes in the level of other salivary constituents. Dental erosion is usually accompanied by greatly increased total salivary acidity. The acid secretion from the gingival crevice and the marginal gingiva tends to dissolve enamel in the regions already predisposed as a result of unfavorable metabolic conditions.

Saliva is a dilute secretion having an average specific gravity of 1.007 with about 0.7 per cent of solid matter, about 0.5 per cent being organic and 0.2 per cent inorganic. Of the organic matter about 0.4 per cent is protein, chiefly mucin, with small amounts of albumin and globulin. Other organic constituents are salivary amylase, urea, uric acid, cholesterol, and phospholipid. Average values have been reported of total nonprotein nitrogen 13 mg., urea plus ammonia nitrogen 11 mg., and uric acid 1.5 mg. per 100 ml. These amounts averaged 37 per cent, 76 per cent, and 40 per cent, respectively, of the corresponding constituents in blood. Analyses of the saliva for these constituents possess a certain clinical

¹ Spealman: Am. J. Physiol., 139, 225 (1943).

value in the study of nephritis but are little used for this purpose. Normal saliva contains no glucose. Increases in cholesterol and in lipid phosphorus have been noted in certain dental disorders.

The normal composition of saliva is shown in the accompanying table.

COMPOSITION OF NORMAL SALIVA*

Constituent			Norma	l Ran ge	
Acidity (pH)	6.0		7.9		
Titratable alkalinity (as 0.02 N HCl)			190.0	ml. per	100 ml.
Ammonia N			10.0	mg. per	100 ml.
Calcium, total, as Ca		_	8.0	mg. per	100 ml.
Inorganic phosphate, as P			25.0	mg. per	100 ml.
Chloride, as Cl	30.0		60.0	mg, per	100 ml.
Carbonate, as CO2			45 0	ml. per	100 ml.
Protein	200.0		400.0	mg. per	100 ml.
Cholesterol.				mg. per	
Lipid P	0 05	-	0.20	mg. per	100 ml.
A The nation have given are broad on gality	collecte	d in	o recetal	morntive at	ate and

*The values here given are based on saliva collected in a postabsorptive state, and (with the exception of those for cholesterol and lipid P) by stimulation. Possible relationship to caries may be found in the following constituents ammonis, calcium and phosphate (especially the adsorbable fractions), carbonate, cholesterol, and hind P. Acknowledgment is made to Dr. Frances Krasnow for the data from which this table was compiled.

Potassium thiocyanate, KSCN, is also generally present in the saliva to the extent of several milligrams per milliliter. The significance of thiocyanate in the saliva is not known; it probably comes from the ingested cyanides present in certain fruits and in tobacco smoke and from the breaking down of protein material.

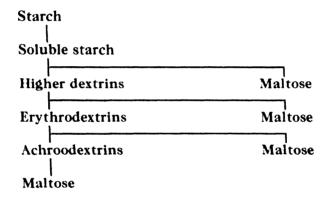

The so-called tartar formation on the teeth is composed almost entirely of calcium phosphate with some calcium carbonate, mucin, epithelial cells, and organic debris derived from the food. The calcium salts are beld in solution as acid salts, and are probably precipitated by alkalinity caused by ammonia formation through bacterial action or through loss of CO₂ from the saliva. The various organic substances just mentioned are carried down in the precipitation of the calcium salts. There is evidence of increased salivary calcium in individuals suffering from excessive tartar deposition.

Salivary Amylase. The principal enzyme of the saliva is known as salivary amylase. The name ptyalin, formerly used for this enzyme, is now obsolete. Salivary amylase is an amylolytic enzyme, or, more properly, a mixture of enzymes, none of which has as yet been obtained in the pure state. The enzyme catalyzes the hydrolytic splitting of starch, glycogen, and the dextrins into simpler molecules, the process being a progressive one with the disaccharide maltose as the ultimate end-product.

The first product of the action of the amylase on starch is soluble starch, whose formation is indicated by the disappearance of the opalescence of the starch solution. Soluble starch gives a blue color with iodine; its formation from starch is not associated with the production of free reducing sugar (maltose). Further action of amylase on starch apparently consists largely in the hydrolytic splitting of the second glycoside linkage from a free end of the long chain (straight or branched) of glucose residues which make up the starch molecule. This action produces the disaccharide

maltose and a series of smaller polysaccharide molecules which are relatively ill-defined and which are known as the dextrins.

The various dextrins differ in molecular size and complexity, depending upon the extent of amylase action. The higher members of the series resemble starch in giving a blue or purple color with iodine; as the molecule becomes smaller by the splitting off of maltose, a red color is given with iodine (erythrodextrins), and the lower members of the series give no color at all with iodine (achroodextrins). Thus during the action of salivary amylase on starch, free maltose is produced almost immediately and progressively increases in amount; at the same time the color reaction with iodine changes from blue through red to colorless. Both the increase in reducing sugar and the change in the iodine color reaction are used in following the course of action of amylase on starch. The changes described above may be represented graphically as follows:

It must be borne in mind, however, that our knowledge of the course of starch hydrolysis by amylase is incomplete. This is due to the complicated nature of both starch (see Chapter 2) and amylase. Most amylases appear to be mixtures of two enzymes, α - and β -amylase, which are said to produce respectively α - and β -maltoses on starch hydrolysis. According to one study on malt amylase, starch is completely hydrolyzed to maltose by α - $+\beta$ -amylase + a complement present with these in malt. Without complement 80 per cent of the starch may be split, leaving 20 per cent of residual dextrin with slight reducing power. α -Amylase atone leaves about 60 per cent of dextrins giving no color with iodine while β -amylase alone leaves about 40 per cent of dextrins giving a blue color with iodine. The amylase of saliva is chiefly α -amylase. Both amylases are found in malt extract. Malt extract kept for several days at 0° and a pH of 3.6 contains only β -amylase. α -Amylase is obtained by extraction of ungerminated barley with water.

Salivary amylase acts in alkaline, neutral, or faintly acid solutions. The optimum acidity is pH 6.6. Amylase is destroyed at acidities greater than pH 4 or at concentrations of free HCl greater than 0.0005 per cent. By sufficiently increasing the alkalinity of the saliva, the action of the salivary amylase is inhibited.

Electrolytes have an important influence upon the action of amylases. For example, Rockwood has shown that Cl, Br, and NO₂ ions have a pronounced stimulating action upon salivary amylase. Removal of chlorides from saliva by dialysis renders the amylase inactive. Amino acids, particularly asparagine, have an accelerating action. Salts of the heavy metals such as silver and mercury inhibit because they combine with the enzyme which is apparently of a protein nature.

Because of its sensitivity to acid, salivary amylase ceases to act in the stomach as soon as the gastric contents show throughout the presence of free hydrochloric acid. Since, however, the amylolytic activity of human saliva is very great, an appreciable digestion of starch may occur during the period of mastication and swallowing. Furthermore, the food which is swallowed is not immediately mixed in its entirety with gastric juice and the protein of the food has a certain binding power for free acid, so that a certain interval may intervene between the entrance of the food into the stomach and the destruction of the amylase. This period varies much in different animals and depends also on the size and character of the meal. In certain experiments on normal men Bergeim found that salivary digestion might continue for 15 to 30 minutes, and that with meals with bread and mashed potatoes there was a conversion of the starch to maltose of about 60 and 75 per cent, respectively.

The digestion of the starch of foods decreases their bulk, and for this reason, and because starch has some inhibitory action on pepsin, salivary digestion may have some favorable effect on protein digestion in the stomach. The action of salivary amylase is not, however, essential, since the pancreatic juice contains a powerful amylase.

The saliva of rodents is amylolytic. Hog saliva contains amylase, but much less than human saliva. The saliva of carnivorous animals is free from amylase, as is also that of herbivorous animals.

Maltase is found in traces in saliva. Maltase splits maltose into glucose but the amount of such digestion in the mouth is very slight. It is claimed that dipeptide- and tripeptide-splitting enzymes are present in saliva. This action in at least some cases is due to bacteria and in any case is not of digestive importance.

Mucin. Mucin gives saliva its viscosity. It is a glycoprotein, insoluble in water or dilute acid but soluble in dilute alkali. When precipitated, as upon the teeth, mucin forms with alkali a slippery mass which dissolves but slowly. It is therefore removed from the teeth with difficulty and may furnish a nucleus for the deposit of other substances. Mucin may be precipitated from saliva by dilute acid or by alcohol. It is an acid substance existing in saliva as the potassium salt. It gives the usual protein color reactions, but is not coagulated by heat in neutral solutions. It is precipitated by saturating with ammonium sulfate. On hydrolysis it yields besides protein a mucoitin sulfuric acid which on further decomposition gives sulfuric acid, acetic acid, glucuronic acid, and glucosamine.

Microscopical examination of saliva reveals epithelial cells, salivary corpuscles (white blood cells?), mucus, food debris, and numerous microorganisms from the true bacteria, higher bacteria, fungi, and protozoa

groups. Pus cells and red blood cells may be evident in pathological conditions of the mouth.

EXPERIMENTS ON SALIVA

A satisfactory method of obtaining the saliva necessary for the experiments which follow is to chew a small piece of pure paraffin wax, thus stimulating the flow of the secretion, which may be collected in a small beaker. It must be remembered in this connection that paraffin-stimulated saliva is quite different in some respects (e.g., pH) from ordinary saliva. Filtered saliva should be used in every experiment except the microscopical examination and the quantitative determination of amylase activity.

 Microscopical Examination: Examine a drop of unfiltered saliva microscopically, after staining with methylene blue, and compare with Fig. 90.

Reaction: Test the reaction to litmus or other suitable indicator paper. Estimate the approximate pH of the saliva. Measure 2 ml. of fresh saliva

into a small test tube. Add 10 drops of an indicator solution suitable for measuring pH at the estimated pH of the saliva.2 Compare with 2-ml. portions of pH standard solutions2 treated with the same amount of indicator in similar tubes. The standards should differ by 0.2 pH unit.3 Determine the pH of the saliva. The comparison is best made in a comparator block, with a tube containing saliva only placed behind the standard, and a tube of plain water behind the saliva-indicator tube.

Fig. 90. Microscopic constituents of saliva. (a) Epithelial cells, (b) salivary corpuscles, (c) fat drops, (d) leukocytes, (c, f, g) bacteria, (h, i, k) fissionfungi.

3. Specific Gravity: Partially fill a urinometer cylinder with saliva, introduce the urinometer, and observe the reading.

4. Test for Mucin: To a small amount of saliva in a test tube add 1 to 2 drops

of dilute acetic acid. Mucin is precipitated.

5. Biuret Test: Render a little saliva alkaline with an equal volume of NaOH and add a few drops of a very dilute (2 to 5 drops in a test tube of water) copper sulfate solution. The formation of a purplish-violet color is due to mucin. This reaction is given by protein material and simply indicates that mucin is a protein.

6. Millon's Reaction: Add a few drops of diluted (1:5) Millon's reagent to a little saliva. A light yellow precipitate formed by the mucin gradually turns red upon being gently heated. This reaction indicates the presence

of protein (mucin).

7. Preparation of Mucin: Pour 25 ml. of saliva into 100 ml. of 95 per cent alcohol, stirring constantly. Cover the vessel and allow the precipitate to stand at least 12 hours. Pour off the supernatant liquid, collect the pre-

² See Chapter 1 for the preparation and use of indicators, standards, and the comparator block.

⁸ To obtain a closer approximation of the reaction of saliva in the mouth, draw the sample into a pipet directly from the mouth (without previous chewing of paraffin), and dilute with the indicator in the test tube, under a thick layer of mineral oil. (Krasnow, Oblatt, and Kaplan: J. Dental Research, 15, 367 (1936).

cipitate on a filter, and wash it, in turn, with alcohol and ether. Finally dry the precipitate, remove it from the paper, and make the following tests on the mucin: (a) Test its solubility in water, dilute acid, and dilute alkali; (b) Millon's reaction; (c) dissolve a small amount in NaOII, and try the biuret test on the solution; (d) boil the remainder, with 10 to 25 ml. of water to which 5 ml. of dilute HCl has been added, until the solution becomes brownish. Cool, render alkaline with solid sodium carbonate, and test by Benedict's solution. Reduction should take place. Why? Does the unhydrolyzed mucin reduce Benedict's solution?

Mucin may also be prepared from salivary glands.

- 18. Inorganic Matter: Acidify about 20 ml. of saliva with a drop or two of dilute acetic acid, heat to boiling, and filter to remove protein. Test the filtrate for chlorides, phosphates, sulfates, and calcium. For chlorides, acidify with HNO3 and add AgNO3. For phosphates, acidify with HNO3, heat, and add molybdate solution. For sulfates, acidify with HCl and add BaCl2 and warm. For calcium, acidify with acetic acid and add ammonium oxalate, (NH4)2C2O4.
- 9. Viscosity Test: Place filter papers in two funnels, and to each add an equal quantity of starch paste (5 ml.). Add a few drops of saliva to one lot of paste and an equivalent amount of water to the other. Note the progress of filtration in each case. Why does one solution filter more rapidly than the other?
- 10. Test for Nitrites: Add 1 to 2 drops of dilute II₂SO₄ to a little saliva and stir thoroughly. Now add a few drops of a freshly prepared potassium iodide solution and some starch paste. Nitrous acid is formed which liberates iodine, causing the formation of a blue color with the starch.
- 11. Thiocyanate Tests:
 - a. Ferric Chloride Test: To a little saliva in a small porcelain crucible, or dish, add a few drops of dilute ferric chloride and acidify slightly with dilute HCl. Red ferric thiocyanate Fe(SCN)₃ forms. To show that the red coloration is not due to iron phosphate, add a drop of HgCl₂ to form colorless mercuric thiocyanate. For best results in this test, compare the reaction of saliva with a control run on distilled water.
 - b. Solera's Reaction: This test depends upon the liberation of iodine through the action of thiocyanate upon iodic acid. Moisten a strip of starch paste-iodic acid test paper' with a little saliva. If thiocyanate is present the test paper will assume a blue color, due to the liberation of iodine and the subsequent formation of the so-called iodide of starch.
- 12. Digestion of Starch Paste: To 25 ml. of starch paste in a small beaker. add 5 drops of saliva and stir thoroughly. At intervals of a minute remove a drop of the solution to one of the depressions in a test tablet and test by the iodine test. At the same time add 3 drops of the mixture to one of a series of test tubes set up with 5-ml. portions of Benedict's reagent. The opalescence of the starch solution should soon disappear, indicating the formation of soluble starch which gives a blue color with iodine. The soluble starch should soon be transformed into erythrodextrin which gives a red color with iodine, and this in turn should pass into achroodextrin which gives no color with iodine. This is called the achromic point. When this point is reached complete the Benedict tests by placing all the tubes in a boiling water bath for 3 minutes, and note the degree of reduction in each tube. Tabulate your results with the iodine and Benedict tests in parallel columns. Also perform a phenylhydrazine test for maltose (the osazone crystals may not have the typical appearance of maltosazone). A positive Benedict test may be obtained while the solution still reacts red with iodine inasmuch as some maltose is formed from the soluble starch coincidently with the formation of the erythrodextrin. How long did it take for a complete transformation of the starch?

⁴ See Appendix.

Saliva from different individuals may vary markedly in amylolytic power. For a graphic representation of the above changes see p. 309.

- 13. Separation of the Products of Salivary Digestion: To 25 ml. of 1 per cent starch paste in a small beaker add 1 ml. of saliva and stir thoroughly. At intervals of one minute test a drop of the mixture by the iodine test. If the blue color persists after five minutes add another 1 ml. of saliva. When the mixture reacts red with iodine, indicating that erythrodextrin has been formed, add 100 ml. of 95 per cent alcohol. Allow to stand until the white precipitate has settled. Filter, evaporate the filtrate to dryness on a water bath, dissolve the residue in 5 to 10 ml. of water, and try Benedict's test and the phenylhydrazine reaction. On the dextrin precipitate try the iodine test.
- 14. Digestion of Raw Starch: Shake up a small amount of raw starch with a little water in a test tube. Add a few drops of saliva, mix well, and allow to stand. After 10 to 20 minutes filter and test the filtrate by Benedict's test. What is the result? Add toluene, let stand for two days, and test again.
- 15. Influence of Temperature: Into each of four tubes place about 5 ml. of 0.2 per cent starch paste. Immerse one tube in a beaker containing crushed ice, keep a second at room temperature, and place a third in the incubator or the water bath at 40° C. (If the temperature of the bath or incubator is allowed to rise to 70° C. or over the enzyme is destroyed and no digestion takes place.) Now add to the contents of each of these three tubes 5 drops of saliva and shake well; to the contents of the fourth tube add 5 drops of boiled saliva. Test frequently by the iodine test, using the test tablet, and note in which tube the most rapid digestion occurs. Explain the results.
- Explain the results.

 16. Estimation of Amylase in Saliva: Pipet exactly 1 ml. of unfiltered saliva into a 100-ml. cylinder. Dilute to the 100-ml. mark, and mix well. Pipet 5 ml of 1 per cent soluble starch into a test tube. Add 2 ml. of 1 per cent NaCl solution and 2 ml. of a buffer solution of pH 6.65 and put in a water bath maintained at 38°. Prepare a series of 10 test tubes each containing 2 ml. of a light yellow iodine solution. Now add 1 ml. of diluted saliva to the starch mixture and return to the bath at once. Record the time of this addition. At the end of each minute of digestion, with a pipet remove 2 drops of the mixture and add to one of the tubes of iodine solution. Record the time when no change in color appears in the iodine solution (achromic point). If this time is less than 5 or more than 20 minutes, repeat, using a different dilution of saliva such as will give a digestion time of about 10 minutes. Thus if 3 minutes are required, dilute 30 ml. of the original diluted saliva to 100 ml., and use 1 ml. of this for the test.

One unit of amylase may be considered as the amount required to digest 5 ml. of 1 per cent soluble starch to the achromic point in 10 minutes under the conditions of the test. The number of units of amylase in 1 ml. of the saliva tested will equal 10 over the number of minutes to the achromic point times 100 (or whatever the dilution of the original saliva might be). From 100 to 150 units are frequently found.

17. Influence of NaCl on Salivary Amylase: Repeat the preceding experiment but replace the NaCl solution by water. A longer time should be required, showing that NaCl accelerates the action of salivary amylase. If saliva be dialyzed free from chlorides it becomes inactive.

18. Influence of pH on Salivary Amylase: In Exp. 16 the solution had a pH of 6.6. Replace the phosphate buffer of this experiment by another buffer of pH 5.8 and in a second experiment use a buffer of pH 8.0. Which gives digestion in the shortest time and is hence nearest the optimum pH?

Bee Chapter 1.

19. Influence of Acids and Alkalies:

- a. Influence of Free Acid: Prepare a series of six tubes in each of which is placed 4 ml. of one of the following strengths of free HCl: 0.2 per cent, 0.1 per cent, 0.05 per cent, 0.025 per cent, 0.0125 per cent, and 0.006 per cent. Now add 1 ml. of starch paste to each tube and shake them thoroughly. Complete the solutions by adding one drop of saliva to each and repeat the shaking. The total acidity of this series would be as follows: 0.16 per cent, 0.08 per cent, 0.04 per cent, 0.02 per cent, 0.01 per cent, and 0.0048 per cent. Place these tubes on the water bath at 40° C. for 10 to 20 minutes. Add a few drops of iodine solution to each tube. What do you find?
- b. Influence of Combined Acid (Protein Salt): Repeat the first three experiments of the above series using combined hydrochloric acid instead of the free acid. How does the action of the combined acid differ from that of the free acid? (For a discussion of combined acid, see p. 318.)
- c. Influence of Alkali: Repeat the first four experiments under (a) replacing the HCl by 2 per cent, 1 per cent, 0.5 per cent, and 0.05 per cent Na₂CO₃. Make weakly acid with acetic acid before trying the iodine test (see Starch, p. 76).
- d. Nature of the Action of Acid and Alkali: Place 2 ml. of saliva and 2 ml. of 0.2 per cent HCl in a test tube and leave for 15 minutes. Neutralize the solution, add 4 ml. of starch paste, and place the tube in the incubator or water bath at 40° C. In 10 minutes test by the iodine and Benedict tests and explain the result. Repeat the experiment, replacing the 0.2 per cent HCl by 2 per cent Na₂CO₃. What do you deduce from these two experiments?
- 20. Excretion of Potassium Iodide: Ingest a small dose of potassium iodide (0.2 g.) contained in a gelatin capsule with the aid of a glass of water, quickly rinse out the mouth with water, and then test the saliva at once for iodine. This test should be negative. Make additional tests for iodine at two-minute intervals. The test for iodine is made as follows: Take 1 ml. of dilute NaNO₂ solution and 1 ml. of dilute H₂SO₄⁷ in a test tube, add a little saliva directly from the mouth, and a small mount of starch paste. The formation of a blue color signifies that the potassium iodide is being excreted through the salivary glands. Note the length of time elapsing between the ingestion of the potassium iodide and the appearance of the first traces of the substance in the saliva. If convenient, the urine may also be tested at 15- or 30-minute intervals after ingestion of the iodide. The chemical reactions taking place in this experiment are indicated in the following equations:
 - (a) $2\text{NaNO}_2 + \text{H}_2\text{SO}_4 \rightarrow 2\text{HNO}_2 + \text{Na}_2\text{SO}_4$
 - (b) $2KI + H_2SO_4 \rightarrow 2HI + K_2SO_4$
 - (c) $2HNO_2 + 2HI \rightarrow I_2 + 2H_2O + 2NO$

Inasmuch as iodide is absorbed from the stomach very slowly, if at all, but is very rapidly absorbed when it enters the intestine, the rapidity of appearance of the iodide in the saliva is an index of the rapidity with which the drug leaves the stomach, which depends on the motor activity of the stomach, the amount of food therein, etc. By drinking a glass of water with the iodide a more rapid result is obtained.

⁶ HCl of the proper strength in solution containing an excess of protein (e.g., Witte's peptone), boiled until no longer blue to Congo red paper.

Instead of this mixture a few drops of HNOs possessing a yellowish or brownish color (containing HNOs) may be employed.

14

Gastric Digestion

Following mastication the food is carried by peristaltic movements of the esophagus to the stemach. Here it undergoes further mechanical disintegration and chemical changes primarily in the protein constituents. The food thus treated is in a better condition to be handled by the intestines, to which it is passed on in small portions at a time, and in which digestion is completed.

Spallanzani (1783) found that gastric juice dissolved meat, and so demonstrated the chemical nature of gastric digestion. He noted also that the juice was acid, but the nature of this acid and of the active agent pepsin was not demonstrated until later.

A great advance in our knowledge of gastric digestion, particularly in man, was made through the observations of Beaumont on his patient Alexis St. Martin, who in 1822 following a gunshot wound was left with an opening from the stomach through the abdominal wall to the exterior. Through this opening Beaumont found it possible to follow the course of gastric digestion with different foods and under varying conditions of health, and to obtain pure gastric juice for digestion experiments outside the body.

Pavlov extended our knowledge, particularly through the development of an operation by means of which he created in dogs a small stomach pouch separate from the main stomach, and opening to the exterior, so that the secretion in the small pouch could be studied without interfering with processes in the stomach proper. In this way the influence of different foods and of other factors on gastric secretion could be studied. The development of the small stomach tube which could be retained in place throughout the period of gastric digestion, with aspiration of the stomach contents at any time, has given additional information of physiological and clinical value.

Secretion of Gastric Juice. There is a slight continuous secretion of gastric juice into the empty stomach. As a result there is almost always present in the stomach before meals about 50 ml. of secretion which is called the residuum.

PSYCHIC PHASE. Following the presentation of food, before any food reaches the stomach there is a psychic secretion of gastric juice. This is induced by the sight, taste, or thought of food.

GASTRIC Phase. Following this, with the passage of food into the stomach, there occurs the gastric phase of gastric secretion due to the local chemical action of such substances as protein digestion products, or meat extractives, and some mechanical action due to distention of the stomach by food. A substance, gastrin, has been isolated from gastric mucosa. When injected into the blood, this markedly stimulates gastric

secretion. It is believed to be a hormone of gastric secretion, i.e., a substance liberated from the gastric mucosa in the presence of food, which passes by way of the blood to the acid-secreting cells, stimulating them to action. The question of whether or not gastrin is identical with the compound histamine is as yet unanswered. Histamine is the decarboxylation product of the amino acid histidine, and is a powerful stimulant of gastric secretion in addition to its well-known effect on blood pressure. Considerable clinical use is made of the stimulating effect of histamine in studies on gastric acidity. The relation between gastrin and histamine has been reviewed by Ivy. A preparation of gastrin free of histamine has been reported,² the active principle apparently being a protein.

INTESTINAL PHASE, A third intestinal phase of gastric secretion is brought about through the action of protein digestion products and other food substances in the intestines. Whether these substances act by liberating a hormone from the mucosa, or are absorbed and themselves act upon the gastric cells (a so-called secretagogue effect) is not yet clear. Undigested fat in the intestine inhibits gastric secretion apparently by liberating from the mucosa a hormone called enterogastrone which depresses the action of the gastric cells. This chalone also inhibits gastric movements and when sufficiently purified should prove useful in the treatment of gastric ulcer. It has already been shown to prevent gastrojejunal ulcer in the dog.³ Urogastrone, a substance similar in action to enterogastrone and found in the urine, is apparently a metabolic derivative of enterogastrone.

Water has a stimulating action on gastric secretion and the drinking of considerable water has been shown to improve the utilization of various foods. Nor has the drinking of water with meals by normal individuals been shown to be undesirable. The influence of different foods on gastric secretion is discussed later.

The study of gastric secretion and the gastric mucosa in nutritional deficiencies has received some attention. Thus in canine blacktongue (the closest animal counterpart to human pellagra), a mild pallor of the gastric mucosa was observed consistently upon gastroscopic examination.⁵ This was accompanied by anemia, loss of weight, and decreased muscular tone of the stomach wall. The tonus of the stomach returned to normal as early as six to seven days after the institution of therapy. There was no change in acid gastric secretion during the disease or following niacin therapy. The therapeutic effect of thiamine was also negative. Shapiro and co-workers found atrophic gastritis to be somewhat more common in nutritional deficiencies, than in a control group of 10 other patients. However, no significant changes in the gastric mucosa were observed after treatment with large doses of thiamine, niacin, riboflavin, panto-

thenic acid, p-aminobenzoic acid, and vitamin A. In two cases the atrophic changes disappeared after choline chloride therapy.

Composition of Gastric Juice. Normal gastric juice is a thin, light-colored fluid which is acid in reaction and has a specific gravity averaging about 1.007. It contains about 0.5 per cent of solid matter which is made up principally of sodium chloride, potassium chloride, earthy phosphates, mucin, and the enzymes pepsin, gastric rennin, and gastric lipase. The acidity of the gastric juice is due to free hydrochloric acid. The gastric juice is a composite secretion from at least three different types of cells in the gastric mucosa; these are (1) the parietal cells, (2) the chief cells, and (3) the mucous cells. There is good evidence that the parietal cells furnish the hydrochloric acid of gastric juice, the chief cells supply pepsin and possibly other enzymes, and the mucous cells secrete mucin. Babkin⁷ claims that the secretory activity of the various types of gland cells should not be considered en masse but rather that "various nerves . . . or chemical agents stimulate or inhibit each set of secretory elements separately." This view is also accepted by others.

It is believed that the parietal-cell secretion is essentially an isotonic solution consisting largely of hydrochloric acid (about 160 milliequivalents per liter) and potassium chloride (about 7 milliequivalents per liter). The acidity of the parietal-cell secretion corresponds therefore to a solution 0.16 N in hydrochloric acid, or containing 0.5 to 0.6 per cent hydrochloric acid. This maximal acidity, which is apparently constant and independent of the rate of secretion, is lowered somewhat as soon as the parietal-cell secretion becomes admixed with the slightly alkaline secretions from the chief cells and mucous cells. These latter secretions contain a high concentration of neutral chlorides as a result of which the acidity is reduced to a greater extent than is total chloride content. The acidity may also be lowered by regurgitation of alkaline fluid from the intestine and by ingested food, so that the actual acidity of gastric juice as collected usually varies between 0.05 and 0.1 N (0.18 to 0.36 per cent hydrochloric acid). The acidity of the gastric juice is usually expressed in terms of the number of milliliters of 0.1 N sodium hydroxide required to neutralize 100 ml. of gastric juice; this is obviously equivalent to the number of milliliters of 0.1 N hydrochloric acid present in 100 ml. of gastric juice, which corresponds numerically with the concentration of acid expressed in terms of milliequivalents per liter. In clinical practice this value is sometimes called the degree of acidity; thus a gastric juice containing 60 milliequivalents of acid per liter, or requiring 60 ml. of 0.1 N alkali to neutralize 100 ml., is said to have an acidity of 60 degrees.

The hydrochloric acid of the gastric juice forms a medium in which the pepsin can most satisfactorily digest the protein food, and at the same time it acts to some extent as an antiseptic or germicide which prevents putrefactive processes in the stomach. When the hydrochloric acid of the gastric juice is diminished in quantity (hypoacidity) or absent, as it

Babkin: Am. J. Digestive Diseases Nutrition, 5, 107 (1937); 8, 467 (1938).

^{*} Thomas: J. Am. Med. Assoc., 126, 785 (1942).

may be in many cases of functional or organic disease, there is no check to the growth of microorganisms in the stomach. There are, however, certain of the more resistant spores which even the normal acidity of the gastric juice will not destroy. A condition of hypoacidity may also give rise to fermentation with the formation of comparatively large amounts of such substances as lactic acid and butyric acid.

When free hydrochloric acid comes in contact with protein, as in the food, a reaction occurs with the formation of protein hydrochloride. This was formerly called combined hydrochloric acid, but this term is so indefinite in its connotation that it should be abandoned (see p. 336). The formation of protein hydrochloride considerably raises the pH of gastric contents since protein hydrochloride is a much less highly ionized acid than is hydrochloric acid itself. The reduction in hydrogen-ion concentration resulting from the formation of protein hydrochloride may permit processes which are acid-sensitive to proceed during gastric digestion, such as bacterial action or the action of salivary amylase (see p. 310).

Origin of Gastric Acid. The mechanism whereby the stomach produces a secretion which is about three million times more acid than the blood is not known. Many attempts have been made to solve this problem, and various theories have been proposed, none of which has received universal acceptance. One method of studying this problem is by the injection into an animal of dyes or other substances which are excreted by the stomach along with the gastric juice and which indicate the presence of acid by a color change. The mucosa of the living animal may then be examined, or the animal may be sacrificed and histological studies made of the gastric mucosa. In experiments of this type it is usually found that the mucosal cells themselves are essentially neutral in reaction, the presence of free acid not being evident until the secretion reaches the lumen of the gland or even the surface of the mucosa itself. From this it has been concluded that the cell secretion is neutral, and that the acid is formed by processes acting upon the secretion after it has been produced, probably associated with selective reabsorption of certain constituents. Evidence of this type obtained by the use of dyes followed by histological examination of the mucosa is open to the criticism that gastric secretion ceases at the death of the animal, and that during the preparation of the tissue for microscopical study unavoidable changes in dve distribution occur.

An explanation for the formation of acid by the parietal cells which is attracting considerable attention is based upon the discovery by Davenport⁹ that the enzyme carbonic anhydrase (see Chapter 24) is present in large amounts in the parietal cells, almost to the extent of its concentration in red blood cells, and is relatively absent from the other cells of the gastric mucosa. Carbonic anhydrase catalyzes the hydration of carbon dioxide to carbonic acid, which dissociates in solution to yield hydrogen ions and bicarbonate ions:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

[•] See Davenport: Gastroenterology, 1, 383 (1943); Gray: ibid., 1, 390 (1943).

If this reaction is pictured as occurring within the parietal cell, the carbon dioxide coming from metabolic processes, the hydrogen ions may be visualized as being secreted, along with an equivalent number of chloride ions, into the stomach while the bicarbonate ions enter the blood

Here bicarbonate ion replaces chloride ion which diffuses into the parietal cell and is available for excretion along with hydrogen ions into the gastric juice. Thus according to this theory the hydrogen ions of the gastric juice come from carbonic acid, and the chloride ions are derived from the blood. The replacement of blood chloride by bicarbonate should raise the pH of the blood, and in fact it has been shown that blood leaving the stomach during active gastric secretion is significantly more alkaline than the entering blood.

It is an interesting consequence of this theory that the extra bicarbonate of gastric venous plasma as compared to gastric arterial plasma is the result of the direct entrance of bicarbonate as such into the plasma, and not the result of the entrance of anhydrous carbon dioxide into the blood, followed by its hydration to carbonic acid in the red cell and diffusion from the red cell into the plasma; processes which are known to account for the extra bicarbonate of venous plasma over arterial plasma in other parts of the body. Now in ordinary venous plasma the increase in plasma bicarbonate due to diffusion of bicarbonate from the red cell into the plasma is associated with a chloride shift (see Chapter 24). chloride ions leaving the plasma and entering the red cell. In gastric venous plasma the increased plasma bicarbonate brings about a reversed chloride shift by diffusion into the red cell at the expense of chloride ions which diffuse out into the plasma. This has been cited as further evidence concerning the role of carbonic anhydrase in the formation of gastric acid. It should be remembered, however, that while this theory accounts for the production of acid by the parietal cell, no direct evidence concerning the actual mechanisms of formation and secretion is as yet available. and other theories 10 are not as yet untenable.

Pepsin. The most characteristic of the enzymes of the gastric juice is the proteolytic enzyme pepsin. Pepsin is a representative of a large group of enzymes, many of which are found in the gastro-intestinal tract and all of which catalyze the hydrolytic splitting of the peptide bond, -CO-NH- to produce a free amino and a free carboxyl group. Within this group of peptide-splitting enzymes, two general types may be distinguished (Bergmann): (1) the proteinases or endopeptidases, and (2) the peptidases or exopeptidases. The endopeptidases act upon peptide linkages in both the central portion and the terminal portion of a polypeptide chain; the exopeptidases split peptide linkages in the terminal portion of the chain only. Differences between the various endo- and exopeptidases of the gastro-intestinal tract are attributed largely to differences in the type and location of the amino acids united in the peptide bond, as will be evident in this and subsequent chapters. According to this classification, pepsin is an endopeptidase, since it can act upon peptide linkages within the large protein or polypeptide molecule as well as upon synthetic peptides (see below).

¹⁰ See Hollander: Gastroenterology, 1, 401 (1943).

Pepsin is apparently formed by the action of the hydrogen ions of the gastric juice on a precursor or zymogen called pepsinogen originating in the chief cells of the gastric mucosa. Both pepsin and pepsinogen are proteins and have been prepared in crystalline form; 11 crystalline pepsin appears, however, to be a mixture of enzymes rather than a single substance. Pepsinogen is more resistant to alkali than pepsin. It does not clot milk at pH 5 nor liquefy gelatin at pH 4.7, while pepsin is active under these conditions. The formation of pepsin at pH 4.6 appears to be an autocatalytic reaction; i.e., the pepsin as it is formed acts upon further pepsinogen to yield still more pepsin. Since pepsin is known to act only on peptide linkages with a specific amino acid configuration (see below), it would appear that the activation of pepsinogen may involve the breaking of such linkages. The isoelectric point of pepsin is at such a low pH that it has not been accurately established.

Pepsin contains phosphorus. It is denatured and coagulated by heat, with the loss of peptic activity running parallel with the degree of denaturation. It is also inactivated and denatured in alkaline solutions (pH 10). In such cases there is some return of activity on acidification and standing; thus there has been a reversal of the denaturation of the pepsin protein. Pepsin is digested by trypsin in solutions more alkaline than pH 5.5. In more acid solutions trypsin is digested by pepsin.

Pepsin acts very well at 40° C. The optimum pH is about 2.0, but this has been shown to be more related to the ionization of the substrate protein than to any effect on the enzyme itself. A variety of mineral and organic acids may be used to attain this pH with practically identical effects on the enzyme activity. At pH 4 its activity is very slight. At pH 5 it is stable but inactive. At pH values of 6.0 or greater it is unstable and above pH 8 it is rapidly destroyed by OH ions.

Products of Peptic Hydrolysis. The gastric acid acting on food proteins at body temperature produces denatured proteins ("acid metaprotein"). Pepsin acts upon such denatured protein as well as upon native protein with the formation largely of protein derivatives of relatively low molecular weight (not over 1,000, according to Tiselius and Eriksson-Quensel¹²); such split products belong to the ill-defined class of the proteoses and peptones. In the normal time of gastric digestion, substances of this nature appear to be the chief end-products of peptic action. Free tyrosine is also a frequent product of peptic digestion. The nature of the action of pepsin has been considerably clarified by the work of Bergmann. Fruton, and associates. They have studied the action of crystalline pensin on synthetic substrate peptides of known chemical constitution. All synthetic substrates which were hydrolyzable by pepsin contained either tyrosine or phenylalanine in the molecule, with the peptide linkage specifically involving the amino group of these amino acids. If the tyrosine or phenylalanine were at the end of the peptide chain, hydrolysis proceeded more rapidly and the free amino acid was liberated, but peptic action

¹¹ For discussion of crystalline pepsin see pp. 265 and 287. For preparation of crystalline pepsinogen see Herriott and Northrop: Science, 83, 469 (1936); and Herriott: J. Gen. Physiol., 21, 501 (1938).

¹² Biochem. J., 23, 1752 (1939).

was not limited to the presence of the amino acid at the end of a chain. Thus one may conclude that pepsin acts on peptide linkages associated with the presence of tyrosine or phenylalanine (although the possibility of other amino acids being concerned in peptic action is not necessarily excluded); the end-product of the action will depend upon the relative position of these amino acids in the long chain of amino-acid residues in the protein substrate. Pepsin acts upon practically all native proteins with the exception of keratin and the protamines; its lack of action in the case of keratins is believed to be due to the close packing of the polypeptide chains in the keratin molecule; in the case of protamines, because of their deficiency in tyrosine and phenylalanine.

In the preparation of crystalline pepsin from amorphous preparations an enzyme is separated from it which has a higher digestive power on gelatin but a lesser action on other proteins. The significance of this "gelatinase" is as yet uncertain.

Rennin. Rennin is what is known as a milk-curdling or protein-coagulating enzyme. It is a proteinase which, acting upon the casein of milk, is believed to form first a soluble paracasein and a peptone-like body. In the presence of ionized calcium salts there is then formed an insoluble calcium paracaseinate which separates out as a curd. Rennin is commonly obtained from the mucosa of the fourth stomach of the calf and is used to curdle milk in cheese-making.

While the matter was the subject of a long controversy¹³ it appears now to be clear that the enzyme, rennin, is an entity quite distinct from pepsin. It has very high milk-curdling power but practically no protein-digesting activity. In certain animals the curdling of milk is caused by pepsin. Pepsin can coagulate milk in practically neutral solution as contrasted with the high acidity required for its action on proteins in general.

Rennin acts best at a pH of 6.0 to 6.5 and at a temperature of about 45° C. Tauber and Kleiner have obtained a preparation curdling 4,550,000 times its weight of milk at pH 6.2 in 10 minutes at 40° C. The preparation has an isoelectric point of 5.4. It is apparently a diffusible proteose containing sulfur and is not coagulated by heat. It does not give the Millon and Hopkins-Cole tests. Rennin appears to exist in the calf's mucosa as prorennin, which is activated by the gastric acidity.

Gastric Lipase. A third enzyme of the gastric juice is a fat-splitting enzyme. It possesses but slight activity when the gastric juice is of normal acidity, but evinces its action principally at such times as a gastric juice of low acidity is secreted either from physiological or pathological cause. It thus may be of importance in the young animal where gastric acidity is considerably lower than for the adult. The digestion of fat in the stomach is, however, at most, of but slight importance as compared with the digestion of fat in the intestine through the action of the lipase of the pancreatic juice (see p. 358).

Boldyreff has shown trypsin to be present in stomach contents, due to regurgitation of intestinal contents through the pylorus. This claim has been verified by others (see Chapter 15, Gastric Analysis).

¹⁸ For a further discussion of the rennin-pepsin controversy see Sumner and Somers: "Chemistry and Methods of Enzymes," New York, Academic Press, 1943.

NORMAL GASTRIC RESPONSE TO STANDARD FOODS

On the basis of extensive studies made in the senior author's laboratory¹⁴ the following table was constructed which contains data relative

EVACUATION TIMES AND HIGHEST TOTAL ACIDITIES FOR VARIOUS ARTICLES OF DIET

Articles of Dict (100-g. portions unless otherwise stated)	Number of Observa- tions	Highest Total Acidity (average) (ml. 0.1 N alkali to neutralize 100 ml. juice)	Evacuation Time (hours and minutes, average)

to the evacuation time and the highest total acidity after the ingestion of certain standard foods by normal men. In the tests here summarized 100-g. portions of food (unless otherwise stated) were fed to normal men and the gastric response determined by the fractional method (see

¹⁴ See "Researches and Writings," Philip B. Hawk and collaborators, published and distributed privately, 1942.

p. 339). It will be noted in general that foods such as meats which are high in protein, and for which gastric digestion is hence of the greatest importance, remain longest in the stomach (3 to 4 hours) and give rise to the highest acidities (120 or higher). Foods low in protein, as fruits and many vegetables, leave the stomach soon (1.5 to 2 hours) and give

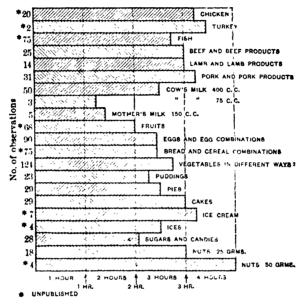

Fig. 91. Evacuation times of standard foods. (Courtesy, Hawk, Rehfuss, and Bergeim: Am. J. Med. Sci., 171, 359 (1926).)

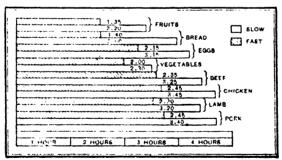

Fig. 92. The evacuation times of fast and slow stomachs. (Courtesy, Hawk, Rehfuss, and Bergeim: Am. J. Mcd. Sci., 171, 359 (1926).)

rise to much less secretion. Foods intermediate in protein content, as cereal foods, show intermediate acidities and emptying times. Milk has considerable buffer action. Water leaves the stomach rapidly.

The relationship of the average evacuation times of the various toods is shown graphically in Fig. 91, whereas the variation in the evacuation time of the same food by fast and slow stomachs is shown in Fig. 92.

COLLECTION OF HUMAN GASTRIC JUICE

Have one or more volunteers from the class take the Rehfuss stomach tube as directed on p. 339. The subjects must omit breakfast if the tube is taken in the morning or luncheon if taken in the afternoon. Empty the stomach (see pp. 341-342) and, with the tube still in place, allow each subject to drink 250 ml. of water. The water will stimulate the flow of gastric juice and will itself quickly leave the stomach. In many instances fairly concentrated gastric juice may be obtained from the stomach in from 30 to

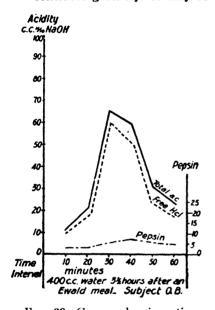

Fig. 93. Curves showing stimulatory power of water. (Courtesy, Bergeim, Rehfuss, and Hawk: J. Biol. Chem., 19, 345 (1914).)

45 minutes after the introduction of the water. Remove this gastric juice according to procedure outlined on pp. 342-343. For the composition of human gastric juice see p. 317. See also Exp. 11, p. 329. If thought desirable, the gastric juice resulting from psychical stimulation (see p. 329) or following histamine injection (see p. 342) may be collected instead of that following the chemical stimulation of water. (Curves showing the stimulatory power of water are given in Fig. 93.)

PREPARATION OF AN ARTIFICIAL GASTRIC JUICE

Dissect the mucous membrane of a pig's stomach from the muscular portion and discard the latter. Divide the mucous membrane into two parts (four-fifths and one-fifth). Cut up the larger portion, place it in a large-sized beaker with at least 4 volumes of 0.4 per cent hydrochloric acid, and keep at 38° to 40° C. for at least 24 hours. Add more HCl as needed to keep the mixture acid to Congo red paper, otherwise putrefaction may

occur. Filter off the residue, consisting of nuclein and other substances, and use the filtrate as an artificial gastric juice. This filtrate contains pepsin, and the products of the digestion of the stomach tissues; i.e., denatured protein, proteoses, and peptones.

PREPARATION OF A GLYCEROL EXTRACT OF PIG'S STOMACH

Take the one-fifth portion of the mucous membrane of the pig's stomach not used in the preparation of the artificial gastric juice, cut it up finely, place it in a small-sized beaker, and cover the membrane with glycerol. Stir frequently and allow to stand at room temperature for at least 24 hours. The glycerol will extract the pepsinogen. With a pipet or by other means separate the glycerol from the pieces of mucous membrane and use the glycerol extract as required in the later experiments.

PRODUCTS OF GASTRIC DIGESTION

Into the artificial gastric juice, prepared as above described, place the protein material (fibrin, coagulated egg white, or lean beef) provided for you by the

instructor, add 0.4 per cent hydrochloric acid as suggested by the instructor, and keep the digestion mixture at 40° C. for two to three days. Stir frequently and keep free hydrochloric acid present in the solution as indicated by a blue color with Congo red paper.

The original protein has been digested and the solution now contains the products of peptic proteolysis; i.e., denatured protein, proteoses, peptones, etc. The insoluble residue may include nuclein and other substances. Filter the digestion mixture and after testing for free hydrochloric acid neutralize the filtrate with sodium hydroxide solution. If any of the denatured protein is still untransformed into proteoses, it will precipitate upon neutralization. If any precipitate forms, heat the mixture to boiling and filter. If no precipitate forms, proceed without filtering.

We now have a solution containing a mixture consisting principally of proteoses and peptones. Separate and identify the proteoses and peptones according to the directions given on p. 182.

PREPARATION OF PURIFIED PEPSIN

Preparation of Pepsin:15 Method of Fenger and Andrew:

Principle: Pepsin is extracted with dilute HCl and precipitated with acetone at the proper pH.

Procedure: Dissect off mucosa from hogs' stomachs. Wash and brush in cold water and mince fine. (All work is best carried out in a room at 0°.) To 1 kilo of the material add 400 ml. of 2 per cent HCl. Let stand over night. Add 1250 ml. of acetone. Strain and filter. The reaction of the filtrate should be pH 3.4 to 3.6. Add 625 ml. of acetone. Decant most of the supernatant fluid, centrifuge, and dry the precipitate in vacuo at a low temperature. Dissolve some of this pepsin in acidulated water and adjust the reaction with HCl to pH 1.8 to 2.0. Filter. Dialyze rapidly against cold running water (5° to 10°). When the pH reaches 2.5, pepsin precipitates out. Centrifuge at high speed. Wash several times by centrifugation with HCl of pH 2.5 and finally with water. Dry in vacuo at room temperature. The pepsin should be ash-free and have a proteolytic activity of 60,000 according to the U. S. Pharmacopoeia XII assay. More pepsin nearly as active as this may be obtained by continuing dialysis to pH 3.0 or 3.8.

GENERAL EXPERIMENTS ON GASTRIC DIGESTION

- 1. Conditions Essential for the Action of Pepsin: Prepare four test tubes as follows:
 - a. Five ml. of pepsin solution.
 - b. Five ml. of 0.4 per cent hydrochloric acid.
 - c. Five ml. of pepsin-hydrochloric acid solution. 10
 - d. Two or 3 ml. of pepsin solution and 2 to 3 ml. of 0.5 per cent sodium carbonate solution.

Into each tube introduce a small piece of fibrin and place tubes in the incubator or water bath at 40° C. for one-half hour, carefully noting any changes which occur.¹⁷ (Carmine-fibrin¹⁸ may be used to advantage in this and the following tests under Gastric Digestion. In this case, however, the experiments should be conducted at room temperature.) Now

16 0.5 per cent commercial pepsin in 0.2 per cent HCl may be used.

¹⁹ For preparation of a crystalline product, see p. 287.

¹⁷ Digestion of fibrin in a pepsin-hydrochloric acid solution is indicated first by a swelling of the protein due to the action of the acid, and later by a disintegration and solution of the fibrin due to the action of the pepsin-hydrochloric acid. If uncertain at any time whether digestion has taken place, the solution under examination may be filtered and the biuret test applied to the filtrate. A positive reaction will signify the presence of proteoses (albumoses) or peptones, the presence of which would indicate that digestion has taken place. The biuret reaction must be more positive than that given by the pepsin-hydrochloric acid solution alone.

¹⁸ See Appendix.

combine the contents of tubes (a) and (b) and see if any further change occurs after standing at 40° C. for 15 to 20 minutes. Explain the results obtained from these five experiments.

- 2. Influence of Different Temperatures: In each of four test tubes place 5 ml. of pepsin-hydrochloric acid solution. Immerse one tube in ice water, keep a second tube at room temperature, and place a third in the incubator or water bath at 40° C. Boil the contents of the fourth tube for a few moments, then cool and also keep it at 40° C. Into each tube introduce a small piece of fibrin and note the progress of digestion. In which of the tubes does the most rapid digestion occur? Explain this.
- 3. The Most Favorable Acidity: Prepare three tubes as follows:
 - a. 3 ml. of pepsin solution + 3 ml. of 0.4 per cent HCl. (Acidity about 0.2 per cent HCl or pH 1.3.)
 - b. 3 ml. of pepsin solution +1 ml. of 0.4 per cent HCl + 2 ml. of water. (Acidity about 0.067 per cent HCl or pH 1.8.)
 - c. 3 ml. of pepsin solution + 4 drops or 0.2 ml. of 0.4 per cent HCl + 3 ml. of water. (Acidity about 0.013 per cent HCl or pH 2.5.)

Introduce a small piece of fibrin into each tube, keep them at 40°, and note the progress of digestion. In which acidity does pepsin act best on fibrin? The acid decreases during digestion due to its combination with protein, so that as a determination of optimum pH this procedure is not exact. The optimum for pepsin is about pH 1.8 under the conditions of this experiment.

- 4. Differentiation Between Pepsin and Pepsinogen: Prepare five tubes as follows:
 - a. Few drops of glycerol extract of pepsinogen +2 to 3 ml. of water.
 - b. Few drops of glycerol extract of pepsinogen + 5 ml. of 0.2 per cent hydrochloric acid.
 - c. Few drops of glycerol extract of pepsinogen + 5 ml. of 0.5 per cent sodium carbonate.
 - d. Two or 3 ml. of pepsin solution + 2 to 3 ml. of 1 per cent sodium carbonate.
 - e. Few drops of glycerol extract of pepsinogen + 5 ml. of 1 per cent sodium carbonate.

Add a small piece of fibrin to the contents of each tube, keep the five tubes at 40° C. for one-half hour, and observe any changes which may have occurred. To (a) add an equal volume of 0.4 per cent hydrochloric acid, neutralize (c), (d), and (e) with hydrochloric acid, and add an equal volume of 0.4 per cent hydrochloric acid. Place these tubes at 40° C. again and note any further changes which may occur. What contrast do you find in the results from the last three tubes? On the basis of these tests, what is the relative resistance of pepsin and pepsinogen to alkalies?

5. Comparative Digestive Power of Pepsin with Different Acids: Prepare a series of six test tubes each containing 5 ml. of a solution of one of the following acids, 19 each solution having the same acidity of pH 2: (1) HCl, (2) H_SO₄, (3) H₂PO₄, (4) oxalic acid, (5) lactic acid, (6) acetic acid. Add 2 ml. of 0.5 per cent pepsin solution or 1 ml. of the glycerol extract of the hogs' stomach and a small piece of fibrin. Put in a water bath and keep at 40° C. Note the progress of digestion. Can you confirm the findings of other observers: that it is the hydrogen-ion concentration (pH) rather than the nature of

¹⁶ HCl 0.037 per cent, H_2SO_4 0.059 per cent, H_2PO_4 0.2 per cent, oxalic acid crystals 0.15 per cent, lactic acid 7.2 per cent, and acetic acid 18 per cent. These solutions are best checked for pH by adding a few drops of thymol blue solution to 5 ml. of each in test tubes and if necessary adding more acid to get the same color as obtained with the oxalic acid which can be weighed out accurately.

Northrop: J. Gen. Physiol., 1, 607 (1919); 5, 263 (1922). This author finds, however, that acetic acid is slightly less effective than the others apparently because of some action of the acetic acid not on the ensyme but on the protein.

the acid present which is the controlling factor in the influence of acids on peptic digestion?

Titrate 10 ml. of each of these acids (lactic and acetic acids only 1 ml.) with 0.1 N NaOH, using phenolphthalein as an indicator. Caclulate the normality of each. Six students may conveniently work together on this part of the experiment, each student then assembling the entire data. What does this experiment teach as to the relationship of hydrogen-ion

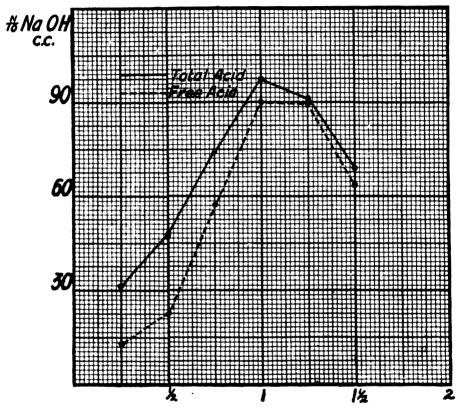

Fig. 94. Curves showing stimulatory power of beef extract. (From unpublished data collected in the senior author's laboratory by Dr. Chester C. Fowler.)

concentration to titratable acidity and as to the biological significance of each?

- 6. Quantitative Determination of Peptic Activity: See Chapter 15, Gastric Analysis.
- 7. Demonstration of Antipepsin in Intestinal Worms: Grind up a number of intestinal worms (ascaris)²¹ with sand in a mortar. Add a little 0.9 per cent NaCl solution. Mix and filter.

Into each of two test tubes introduce 5 ml. of pepsin-hydrochloric acid solution and a little fibrin. To one add 2 ml. of the ascaris extract and to the other 2 ml. of water. Keep at 40° C. and observe the digestion of fibrin. The antipepsin of the extract should prevent digestion of the fibrin in the first tube. This extract also has antitryptic properties.

²¹ These worms are readily obtained from pige at the slaughterhouse,

- 8. Influence of Gastric Rennin on Milk: Prepare a series of five tubes as follows:
 - a. Five ml. of fresh milk + 0.2 per cent hydrochloric acid (add slowly until precipitate forms).
 - b. Five ml. of fresh milk + 5 drops of rennin solution.22

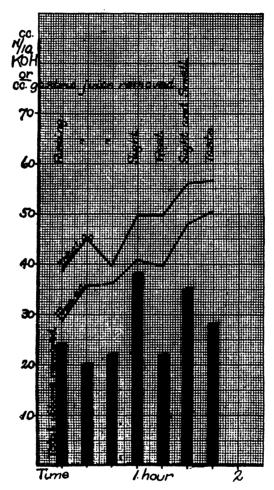

Fig. 95. Curves showing psychical stimulation of gastric secretion. (From unpublished data collected in the senior author's laboratory by Dr. Raymond J. Miller.)

- c. Five ml. of fresh milk + 10 drops of 0.5 per cent sodium carbonate solution.
- d. Five ml. of fresh milk + 10 drops of a saturated solution of ammonium oxalate.
- e. Five ml. of fresh milk + 5 drops of 0.2 per cent hydrochloric acid. Now to each of the tubes (c), (d), and (e) add 5 drops of rennin solution. Place the whole series of five tubes at 40° C. and after 10 to 15 minutes note what is

²² Any good commercial rennin or rennet preparation may be used in preparing this solution.

occurring in the different tubes. Give a reason for each particular result. How do ammonium oxalate and sodium carbonate prevent coagulation?

- 9. Quantitative Determination of Rennin: Prepare a standard milk of pH 5.0 by mixing equal volumes of fresh milk and M acetate buffer of pH 5.0. Introduce 10-ml. portions of this milk into a series of test tubes and keep at 20° C. Add 1-ml. portions of various dilutions of the rennin solution. Mix and note the time of clotting. The amount of rennin that clots 1 ml. of the buffered milk in 10 minutes at 20° C. is called one unit of rennin.
- 10. Characteristics of Human Gastric Juice: Take some of the human gastric juice collected as described on p. 324 and show that it is acid in reaction, that it contains chlorides, and that it has the power to digest protein material and to curdle milk.
- 11. Chemical Stimulation of Gastric Secretion: Have one or more volunteers from the class swallow the Rehfuss stomach tube as directed on p. 339. The subjects must omit breakfast if the tube is taken in the morning or luncheon if taken in the afternoon. Empty the stomach (see pp. 341-342) and, with the tube still in position, allow each subject to drink 250 ml. of bouillon prepared by dissolving one bouillon cube in hot water. Collect samples of gastric contents at intervals until the stomach is empty as described under 5 on p. 342. The samples thus collected may be examined qualitatively for acid, chlorides, pepsin, and rennin, or they may be submitted to the quantitative procedure given under 6 on p. 342. If the examination is made quantitative the data may be recorded in the form of a curve such as shown in Fig. 94.
- 12. Psychical Stimulation of Gastric Secretion: Have one or more volunteers from the class take the Rehfuss stomach tube as directed on p. 339. The subjects must omit breakfast if the tube is taken in the morning or luncheon if taken in the afternoon. Empty the stomach (see pp. 341-342), and while the tube is still in position permit the subjects to see and smell an appetizing beefsteak while it is being cooked. They may also be permitted to taste some of the material provided care is taken that none is swallowed. Empty the stomach completely at 10-minute intervals as described under 5 on p. 342. Measure the volume of each sample and examine them qualitatively for acid, chlorides, pepsin, and rennin. If preferred, the quantitative procedure given under 6 on p. 342 may be substituted for the qualitative examination. On the basis of the quantitative data a curve as shown in Fig. 95 may be constructed.

Gastric Analysis

The method of gastric analysis which was in vogue clinically for years entailed the feeding of a standard test meal, the removal of the complete stomach contents at the end of a one-hour period, and the analysis of the material so removed. That this method is inaccurate has been repeatedly demonstrated in the senior author's laboratory and elsewhere. Furthermore, owing to the bulk of the old form of stomach tube and the discomfort occasioned by its use, it is impossible to follow the whole cycle of digestion and estimate, step by step, the exact changes which take

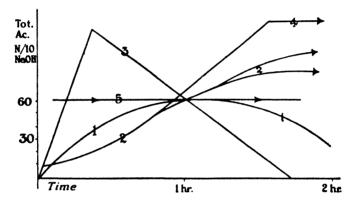

Fig. 96. Normal and pathological curves after an Ewald meal. (1) Normal curve, (2) delayed digestion with late hyperacidity, (3) larval hyperacidity, (4) tardive hyperacidity, and (5) marked continued secretion from obstruction.

place in the stomach after the introduction of definite food mixtures into that organ.

Realizing the inadequacy of the procedure entailed in the old method of gastric analysis, an improved procedure was developed by Dr. Martin E. Rehfuss in the senior author's laboratory. This so-called "Fractional Method" entails the analysis of samples of material withdrawn from the stomach (by syringe) at short intervals for a period of two hours or more (until the stomach is empty) after the ingestion of the test meal. By this means the observer is able to follow the entire cycle of gastric digestion and is not limited, as in the old method, to information derived from the analysis of a single sample of stomach contents withdrawn at the end of one hour. That the acid values obtained by the old method may be grossly misinterpreted and lead to an incorrect diagnosis is indicated by the diagram shown in Fig. 96.

It is set forth in Fig. 96 that various types of abnormal gastric secretion would be considered normal on the basis of a single examination at the end of one hour, whereas the application of the fractional method reveals an abnormality of the secretion. The removal of samples of gastric contents at short intervals, for a period of two hours or more after a test meal, is made possible by the use of a modified stomach tube¹ of small

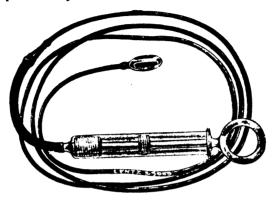

Fig. 97. Rehfuss stomach tube.

diameter (No. 12 French tubing) and fitted with a metal tip. The tip is slotted with large perforations, the diameter of each being equivalent to the maximum bore of the tubing. Such a tube can be left in the stomach through the entire cycle of gastric digestion without inconvenience to the patient. The Rehfuss stomach tube is shown in Fig. 97.2 Lyon suggested a modified tip.

A tube much favored in England is that devised by Ryle. This consists of a small-bore rubber tube with a blind end, into which is inserted an

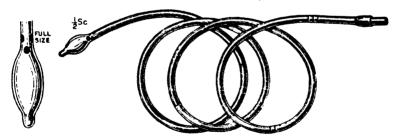

Fig. 98. Ryle's gastric tube. (Courtesy, Ryle: "Gastric Function in Health and Disease," London, Oxford University Press, 1926.)

oval weight of lead (see Fig. 98). Holes are punched in the rubber tube just above the weight. Ryle claimed the following advantages over a metal-tipped tube: (1) More easily swallowed and withdrawn, (2) blockage with mucous plugs generally avoided, (3) impossible to detach end, (4) less likelihood of damaging the gastric mucosa, (5) cheaper. For further discussion of the Fractional Method, see p. 339.

¹ Rehfuss: Am. J. Med. Sci., 147, 848 (1914).

¹ This tube is manufactured by Charles Lents and Sons, Philadelphia.

An apparatus (Fig. 99) has also been devised for the determination of intragastric conductance and temperature. The apparatus is also provided with an aspiration tube similar to that of the Rehfuss tube which makes possible the removal of samples of gastric contents for chemical analysis. Curves showing the relationship of conductance to acidities are shown in Fig. 100.

For a long time, based principally upon the work of the Pavlov school, the consensus was to the effect that the gastric juice of normal man had an average acid concentration of 0.2 per cent hydrochloric acid, whereas

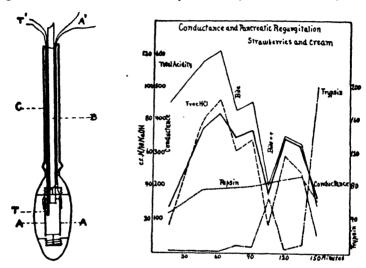

Fig. 99. (Left) Bergeim intragastric conductance apparatus. Diagrammatic cross-section showing platinum electrodes A, A, with leads A'; thermocouple T with leads, T'; tube for aspiration B; and outer protecting tube C.

Fig. 100. (Right) Curves showing relationship of conductance to acidities. (Courtesy, Bergeim: Am. J. Physiol., 45, 1 (1917).)

the gastric juice of the dog and cat had an average acid concentration of 0.4 to 0.5 per cent hydrochloric acid. These experiments were based principally upon the examination of the pure gastric juice of the lower animals as compared with the stomach contents of man. Later experiments, however, demonstrated that the acid concentration of the freshly secreted gastric juice of man is similar to that of the dog; i.e., 0.4 to 0.5 per cent. Boldyreff claimed that this initial high acidity of the human gastric juice is normally lowered to the "optimum acidity" of 0.15 to 0.2 per cent hydrochloric acid by regurgitation of alkaline fluids (bile, pancreatic and intestinal juices) from the intestine. This constitutes what Boldyreff termed "the automatic regulation of gastric acidity." This claim has been substantiated by experiments made in the senior author's laboratory and elsewhere. Both bile and trypsin are easily identified in the stomach contents of man after the introduction of 0.5 per cent hydrochloric acid

^{*} Bergeim: Am. J. Physiol., 45, 1 (1917).

into the empty organ. The above points are illustrated by the chart shown in Fig. 101.

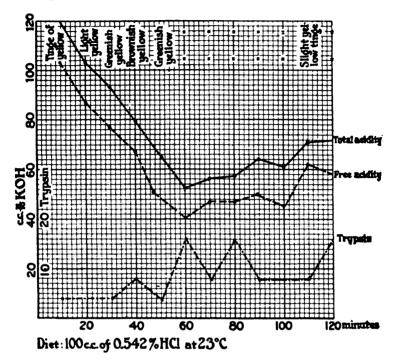

Fig. 101. Influence of acid introduced into the normal human stomach. (Courtesy, Spencer, Meyer, Rehfuss, and Hawk: Am. J. Physiol., 39, 459 (1916).)

The composition of human gastric juice and of the residuum (see p. 341) is given in the following table:

Properties and Composition of Human Gastric Juice

	Appetite Juice	Residuum
Specific gravity	1.007	1.006
Freezing point depression, °C	-0.55°	-0.47°
Total acidity, per cent HCl	0.45	0.30
Total solids, g. per 100 ml	0.55	0 98
Organic solids, g. per 100 ml		0.53
Inorganic solids, g., per 100 ml	0.14	0.45
Total nitrogen, g. per 100 ml		0.066
Total phosphorus, g. per 100 ml		0.005
Total sulfur, g. per 100 ml		0.007
Ammonia N, g. per 100 ml		
Amino-acid N, g. per 100 ml		• • •
Chlorides (as Cl), g. per 100 ml		

THE USE OF INDICATORS IN GASTRIC ANALYSIS

Indicators are used in gastric analysis for two main purposes: (1) For the colorimetric determination of the pH of gastric contents, and (2) as an aid in the measurement of gastric acidity by titration. The use of indicators for the first purpose is identical in principle with their use in this connection with other fluids, and is described in detail on p. 28. The practical details in connection with gastric analysis are presented on p. 335.

The primary objective in the titration of gastric acidity is to determine the amount of unneutralized hydrochloric acid present ("free hydrochloric acid"), in the possible presence of other acids which while titratable are nevertheless so much less highly ionized than hydrochloric acid that they contribute little or nothing to the hydrogen-ion concentration of the solution. It is the hydrogen-ion concentration (i.e., the pH) of the gastric contents which to a large extent determines whether or not the physiological functions of the gastric secretion will be served, and hydrogen ions in concentration sufficient to maintain a normal pH can come only from a highly ionized acid such as hydrochloric acid. Thus gastric function can be evaluated in terms of the presence and amount of free hydrochloric acid. Since the concentration of free hydrochloric acid determines the pH, it is clear that a pH measurement will frequently give as much information as a titration, and increasing use of pH determination in this connection is being made clinically, particularly in view of the ease with which precise pH determinations may be made with the modern electronic pH meters (see Chapter 1).

The establishment by titration of the presence and amount of free hydrochloric acid in the presence of other titratable acids is based on the fact that hydrochloric acid is completely dissociated in solution, the hydrogen ions from this dissociation reacting with the added OH ions before any undissociated acid present can ionize and so react. Thus the amount of alkali added up to the point of practically complete neutralization of the hydrochloric acid present should be distinguishable from that necessary for the remaining acid or acids. That this is so is evident from an inspection of the titration curve for hydrochloric acid as compared with that for a typical weak acid such as acetic acid; such curves are shown in Fig. 10 of Chapter 1. From an inspection of these curves it can be seen that as standard alkali is added to a solution containing hydrochloric acid, the pH of the solution changes relatively little until most of the acid is neutralized, increasing from pH 1 to about pH 2, when about threefourths of the acid has been neutralized. As the titration continues, at about pH 3.5 or so it is clear that practically all of the acid has been titrated; stopping the titration at this point gives a value for the acid present which is almost indistinguishable from the value obtained if the titration were carried to the end-point with such indicators as methyl orange, litmus, or phenolphthalein.

The situation is quite different if a weak acid, such as acetic acid for example, is being titrated. In the case of acetic acid, the solution has a

pH of about 3 before any alkali has been added, this pH corresponding to the relatively small (about 1 per cent) ionization of the acetic acid molecules. As the pH is increased by the addition of alkali, more of the acetic acid dissociates to give hydrogen ions which are capable of reacting with the added OH ions, until ultimately sufficient alkali has been added to neutralize all of the acid initially present. But it will be noted that the end-point of this titration (i.e., the pH at which equivalent amounts of alkali and acid are present) is not pH 7 but rather nearer pH 8.5. Thus, in order to titrate such an acid as this, it is necessary to use an indicator which changes color at about pH 8.5; phenolphthalein is such an indicator.

From what has just been said, it follows that if a mixture of hydrochloric acid and some weak acid or acids is being titrated with standard alkali, the buret reading at pH 3.5 or thereabouts will be a measure of the hydrochloric acid present, while the reading at pH 8.5 will be a measure of the total acidity of the solution. It is thus possible to distinguish quantitatively between these two types of acidity provided that means of indicating the pH of the solution are available. This may be done using a pH meter; it is much more common to select an indicator whose color change lies at the pH range desired. Of the various indicators which have been proposed for this purpose in gastric analysis, Töpfer's reagent (dimethylaminoazobenzene) and phenolphthalein are almost universally used. Töpfer's reagent has a color change from red to yellow over the pH range 2.9 to 4.0 (see table), the intermediate color of salmon pink being noticeable at approximately pH 3.3. Thus if gastric contents are titrated with alkali to the color change with Töpfer's reagent, a measure of the free hydrochloric acid present will be obtained, the value being uninfluenced by any weak acids which may be present. If the titration is then continued to the color change with phenolphthalein (pH 8.5), the total acidity is determinable.

Töpfer's reagent has a number of disadvantages; the color change is not sharp and requires a certain amount of familiarity before the proper end-point is routinely obtainable; furthermore, the color fades rapidly at the end-point and thus precludes the setting up of pH controls for the more precise establishment of the end-point. Other indicators have been proposed, such as thymol blue (red, becoming yellow at pH 2.8), and bromphenol blue (yellow, beginning to turn blue at pH 3.4 or so), but in the authors' experience of teaching medical students and technicians the routine of gastric titrations, neither of these has proved so satisfactory as Töpfer's reagent.

In the above discussion acetic acid was used as an example of a typical weak acid, to illustrate the principles involved in a gastric titration. In actual practice the weak acids which may be found in gastric contents include protein hydrochloride (so-called "combined hydrochloric acid"), acid phosphates, and various organic acids such as lactic, citric, etc., after fermentation or the ingestion of certain foods. At one time the mistaken notion prevailed that by the suitable use of various indicators it was possible to differentiate between these components of the weak acid fraction of gastric contents. This is not true, since the titration curves of these

various components overlap to such an extent that it is impossible to differentiate between the contribution of each to the total acidity, and the concept should be abandoned. Even the distinction between free mineral acid and weak organic acids becomes less sharp if the organic acids have an appreciable ionization at pH 3 or so, as is the case for example with lactic acid. The presence of significant amounts of such organic acid in gastric contents is quite unusual; should it occur, the determination of volatile chloride (see chloride partition, p. 351) is of value in establishing the extent of acidity due to hydrochloric acid.

It is occasional practice in the titration of relatively pure gastric contents to subtract the value for the free acidity from that of the total acidity and call the difference the "combined acid." The validity of this is questionable; even assuming that the difference between free and total acid is partly due to acid which has reacted with protein to form protein hydrochloride, it is clear that the amount of acid which has so reacted is measurable only by titrating the solution to the isoelectric point of the protein: further titration beyond this pH represents the formation of alkali salt of protein and will depend on the amount and nature of protein present, without reference to how much hydrochloric acid has been "combined" with the protein. Actually, the difference between free and total acid is more a measure of the buffer power of the gastric juice than anything else. From a practical point of view, therefore, it would appear that the requirements of gastric analysis, at least in so far as gastric acid is concerned, are largely met by measurement of either the free acid or the pH.

Indicator	pH range	Color change
Thymol blue (acid range)	1.2-2.8	Red-yellow
Töpfer's reagent	2.9-4.0	Red-yellow
Bromphenol blue	3.0-4.6	Yellow-blue
Congo red	3.0 - 5.0	Blue-red
Methyl orange	3 1-4.4	Orange red-yellow
Bromeresol green	4.0-5.6	Yellow-blue
Methyl red	4.2-6.3	Red-yellow
Litmus	4.5 - 8.3	Red-blue
Chlorphenol red	5.0-6.6	Yellow-red
Alizarin red		Yellow-red
p-Nitrophenol		Colorless-yellow
Bromcresol purple	5.4-7.0	Yellow-purple
Bromthymol blue	6.0-7.6	Yellow-blue
Phenol red	6.6-8.2	Yellow-red
Neutral red	6.8-8.0	Red-vellow
Cresol red	7.2-8.8	Yellow-red
Metacresol purple	7.6-9.2	Yellow-purple
Thymol blue (alkaline range)	8.2- 9.8	Yellow-blue
Phenolphthalein	8.3-10.0	Colorless-red
Alizarin yellow	10.0-12.0	Coloriess-yellow
Tropeolin O	11.1-12.7	Yellow-orange

The table on p. 336 lists the characteristics of those indicators which have found application in gastric analysis and for other purposes. Experiments which follow illustrate the application of the principles just presented.

Tests with Indicators: Prepare a series of solutions of varying acidities as outlined in the following table, p. 338. Introduce 5- or 10-ml. portions of each of these into a series of test tubes and to each add a few drops of a solution of thymol blue. Make a note of the colors produced, in the spaces left for this purpose. In the same way test the other indicators mentioned, in order, in each case using a few drops of the indicator solution.

Are the following assumptions, on which the use of certain of these indicators in gastric analysis is based, borne out by your findings?

- 1. That Töpfer's reagent (dimethylaminoazobenzene) gives its characteristic pinkish-red color only in the presence of free HCl.
- 2. That Congo red can be used to distinguish between strong acids, moderately weak acids, and very weak acids.
- 3. That thymol blue may be used as an indicator in the titration of both free and total acid.
- 4. That alizarin may be used in titrations where the end-point is at a pH just acid to pH 7 rather than just beyond pH 7.
- 5. That phenolphthalein can be used in titrating total acidity, that is, acidity due to mineral and organic acids, acid salts, and combined acid.
- 6. That Günzberg's test is in certain respects the most satisfactory one for free HCl.
- 7. That "combined acid" (protein hydrochloride) is an acid of approximately the strength of acetic acid.

Special Test for Free HCl (Günzberg's Test): Perform the following test on solutions one to four of the table and tabulate the results. Place 1 to 2 drops of Günzberg's reagent' in a small porcelain evaporating dish and carefully evaporate to dryness over a low flame. Insert a glass stirring rod into the mixture to be tested and draw the moist end of the rod through the dried reagent. Warm again gently and note the production of a purplish-red color in the presence of free hydrochloric acid. This test differs markedly from the use of indicators in that the reaction is not determined by the pH of the solution, but is based on the fact that hydrochloric acid of any strength whatever reaches a "constant boiling" concentration of about 20 per cent on evaporation. At this strength of acid the ingredients of the reagent condense to form a purplish-red compound. The reaction is thus highly specific for hydrochloric acid in gastric juice.

Differential Titration of a Mixture of Strong and Weak Acids: (a) Titrate a 5-ml. portion of 0.1 N acetic acid with 0.1 N sodium hydroxide, using phenolphthalein as indicator. (b) Titrate a 5-ml. portion of 0.1 N hydrochloric acid, using phenolphthalein. (c) Titrate a 5-ml. portion of 0.1 N hydrochloric acid, using Töpfer's reagent (one drop) as indicator. The endpoint is a "salmon pink" shade, intermediate between red and yellow. Is there any significant difference in the titer of the hydrochloric acid as compared with the value obtained in part (b)? (d) Now mix 5-ml. portions of 0.1 N acetic acid and 0.1 N hydrochloric acid in a flask, add Töpfer's reagent, and titrate with alkali to the "salmon pink" end-point. Read the buret, add a drop of phenolphthalein to the contents of the flask, and

⁴ See Appendix.

Methyl ml. of with a lot only or far from a reagent, 0.5 g. of dimethylaminentee in 100 ml. of 85 per cent alcohol. Congo red, 0.5 g. in 90 ml. of water and add 10 ml. of 95 per cent alcohol. Aitzaria. I g. of secdium sulfaminete in 100 ml. of water Phenolphenol

Congo red paper.

Make up solutions of potassium dibydrogen phosphate and of disodum hydrogen phosphate of M/15 strength. See p. 23. To prepare the acid phosphate solution used in the test mix 1 part of the solution of the disodum sale with 9 parts of the solution of the disodum sale with a part of the solution of pll 7, the proportions are 0: 4. Do not attempt to use distilled H-O alone as a pH 7 solution (Why not?)

Borate-NaOH solution. Frepare a borate solution by dissolving 12-414 g. of pure borie acid (0.2 not.) in 100 mL of N NaOH solution and dilute with water to a lifer. Prepare the borate-NaOH solution by mixing 6 parts of the borate solution with 4 parts of 0.1 N NaOH.

continue the titration with alkali until the pink color of the phenol-phthalein end-point can be seen to be superimposed on the clear yellow color of the Töpfer's reagent. Read the buret again. This reading represents the "total acidity." The first reading is a measure of the HCl present, and the difference between the first and final readings represents the acidity due to the weak acid (acetic, in this case). Compare the values you obtain in this differential titration with those obtained by separate analysis in parts (a) and (c) above.

THE FRACTIONAL METHOD OF GASTRIC ANALYSIS

Since 1914, when the first experiments entailing the use of the fractional method were reported from the senior author's laboratory, the method has been widely adopted both in this country and abroad. This widespread use by a large number of workers has resulted in much discussion of the method. On the basis of this large experience certain modifications in the original technique are here presented. In its major details, however, the method remains as originally carried out, and in the opinion of the authors constitutes the best available method for the clinical examination of the stomach.

PROCEDURE IN GASTRIC ANALYSIS BY THE FRACTIONAL METHOD

- 1. Introduction of the stomach tube (see p. 339).
- 2. Removal of the residuum (see p. 341).
- 3. Feeding the test meal (see p. 341).
- 4. Feeding the retention meal (in special cases), (see p. 342).
- 5. Removing samples of stomach contents for analysis (see p. 342).
- 6. Examination of the samples for:
 - (a) Total acidity (see p. 343).
 - (b) Free acidity (see p. 343).
 - (c) Hydrogen-ion concentration (see p. 346).
 - (d) Pepsin (see p. 347).
 - (e) Trypsin (not a routine procedure; see p. 349).
 - (f) Lactic acid (see p. 350).
 - (g) Occult blood (see p. 351).
 - (h) Bile (see p. 351).
 - (i) Microscopic constituents (see p. 351).
 - (j) Chloride partition (not a routine procedure; see p. 351).

1. Introduction of Stomach Tube. Whereas the large tube is directly inserted by propulsion, the Rehfuss tube is swallowed in the natural manner with the aid of gravity. The tube may be passed in one of three ways, viz.: (1) Lubricated, (2) with the aid of fluid; (3) after the throat is cocainized. When passed by the first method the tip of the tube, after thorough lubrication with glycerol or liquid petrolatum is held between the thumb and forefinger and placed on the tongue. Then with the aid of the forefinger the tip is pushed backward until it reaches the root of the tongue and is engaged in the oropharynx. Then the patient is encouraged to breathe deeply through the nose and to swallow persistently while the tube is slowly fed into the mouth. After slight discomfort in

the pharynx and its passage past the level of the cricoid cartilage, practically no discomfort is felt. This method is used when it is essential that the pure gastric secretion or residuum be obtained. Ordinarily, however, it is much easier to swallow the tube by the second method. This method consists in placing the tip in the oropharynx and then giving the patient a measured quantity of water or tea to swallow. The movements induced by the swallowing carry the tube rapidly to the stomach with a minimum

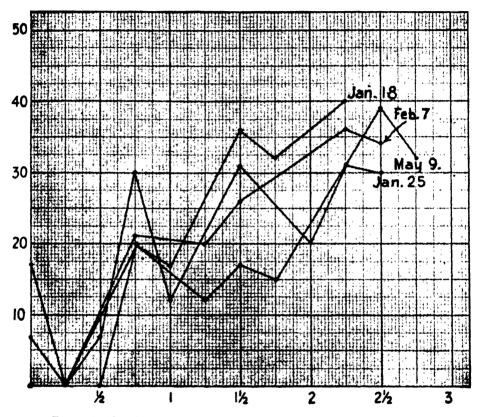

Fig. 102. Showing gastric response of same individual on four different occasions. (After Ryle: "Gastric Function in Health and Disease," London, Oxford University Press, 1926.)

of discomfort. When an Ewald meal (see p. 341) is given, part of the tea may be reserved for swallowing the tube. This procedure makes it scarcely more arduous than the swallowing of food. Should the patient, however, be extremely neurotic or the unfortunate possessor of marked pharyngeal hyperesthesia, cocaine hydrochloride in 2 per cent aqueous solution may be applied to the throat, rendering the passage of the tube practically insensitive. When the tube has entered the stomach, aspiration of the material shows the characteristic gastric contents. Should the tip remain in the esophagus through transient cardiospasm or other cause, aspiration

results in the removal of only a very small specimen having all the characteristics of the pharyngeal and esophageal secretions.

The clinician should see to it that the tube is so placed that the tip reaches the lower pole of the stomach. Furthermore, the tip should remain in his position throughout the duration of the test. By placing the tube in this manner, representative specimens and accurate data may be obtained.

That the gastric response to the fractional method when properly performed is similar for the same individual on different days is shown in Fig. 102.

Bloomfield and Keefer have suggested a method for the "continuous quantitative estimation of gastric secretion and discharge in man."

2. Removal of Residuum. If the so-called "empty" stomach is examined in the morning before any food or drink has been taken it will be found to contain considerable material, which is termed "residuum." Before a test meal is introduced into the stomach, this organ should be emptied. If this is not done we cannot consider the samples withdrawn after the test meal is eaten as representing the secretory activity of the gastric cells under the influence of the stimulation of the test meal. It has been generally recognized, clinically, that a residuum above 20 ml. is pathological. Such a volume has been considered as indicative of hypersecretion, and this in turn in many cases indicates an organic lesion. The observations indicating that a residuum of over 20 ml. was pathological were made upon residuums removed by means of the old type of stomach tube which does not completely empty the stomach. When the residuum is completely removed by means of the Rehfuss tube it has been demonstrated that the normal residuum is practically always over 20 ml.. the average for both men and women being about 50 ml. The normal residuum has been found to possess all the qualities of a physiologically active gastric juice with an average total acidity of 30 and an average free acidity of 18.5. The residuum is often colored by bile. This is particularly true if the fluid has a relatively high acidity. Trypsin is also generally present. These findings indicate regurgitation (see p. 349). Pathological residuums may contain blood, pus, and mucus and may also show food retention, indicative of delayed evacuation. In carcinoma the residuum frequently has a foul odor. The quantity may also be much increased due to hypersecretion. A residuum of large volume possessing a total acidity value of 70 or over may indicate ulcer.

Analysis of Residuum: Remove the residuum as directed under (5) on p. 342, and analyze the fluid according to methods outlined on p. 343 et seq.

3. Feeding the Test Meal. Before making an analysis of the stomach contents it is customary to introduce something into the stomach which will stimulate the gastric cells. The response to this stimulation is then measured clinically by the determination of total acidity, free acidity, and pepsin in the stomach contents. Many forms of test meal have been used.

The test meal most widely employed is the Ewald test meal. This consists of 2 pieces (35 g.) of toast and 8 ounces (250 ml.) of tea.

Inasmuch as it was demonstrated in the senior author's laboratory that water gave a similar gastric stimulation to that produced by the Ewald meal, it was suggested that a simple water meal might be substituted for the Ewald meal. This water meal also has the added advantage of enabling one to determine the presence of food rests and to test more accurately for lactic acid, blood, and bile. Ryle's prefers to use oatmeal gruel (1 pint). Doses of 0.5 to 1 mg. of histamine hydrochloride injected subcutaneously are effective in stimulating gastric secretion and may help to differentiate between true and "apparent" achylia gastrica.

- 4. Feeding the Retention Meal. In order to obtain more information regarding gastric motility than is furnished by the ordinary test meal described above, the patient may be fed a so-called retention meal. This meal is fed in place of the regular evening meal and contains substances readily detected. In the morning before breakfast (7 to 8 A.M.), remove the stomach contents (residuum, see p. 341) by aspiration and examine for food rests. The normal stomach should give no evidences of food retention. A satisfactory retention meal consists of 4 ounces each of boiled string beans and rice. Diets containing prunes, raspberry marmalade, lycopodium powder, etc., have also been employed. In many instances an ordinary mixed diet will serve the purpose.
- 5. Removal of Samples of Stomach Contents for Analysis. At intervals of exactly 15 minutes from the time the test meal is eaten until the stomach is empty, 5- to 6-ml. samples of gastric contents are withdrawn from the stomach by means of aspiration and a few milliliters of air blown down the tube in order that the tube shall be empty when the next sample is drawn. If the stomach is not empty at the end of three hours, the remaining stomach contents may be withdrawn and measured.

In order to facilitate the mixing of the stomach contents and the withdrawal of a more representative sample, the stomach contents should be aspirated back and fourth four times before taking the sample for analysis. Some clinicians advise that the stomach contents be mixed by physical manipulation just prior to aspiration.

In the removal of samples from the stomach, it is essential that very little traction be employed. To completely empty the stomach, aspiration is practised in four positions: (a) On the back, (b) on the stomach, (c) on the right side, (d) on the left side. This results in complete evacuation of the stomach. Three tests may be employed to determine whether the stomach is empty: (1) No more material can be aspirated in any position; (2) injection of air and auscultation over the stomach with a stethoscope reveals a sticky râle and not a series of gurgling râles such as is heard when there is material in the stomach; (3) lavage or irrigation through the tube shows the absence of all food in the stomach.

6. Examination of the Samples. The old methods of gastric analysis involved the collection (by analysis and calculation) of data regarding several types of acidity. It has already been pointed out (p. 336) that the validity of such data is questionable. The modern tendency among clini-

⁵ Boil 2 thep, of catmeal in a quart of water until the total bulk is reduced to 1 pint. Strain through coarse muslin. Season with salt as desired.

cians is to lay particular emphasis upon the values for total acidity, free acidity, and pH. Chloride partition may also give some information. The determination of the peptic activity is also of occasional value as well as the demonstration of the presence or absence of occult blood, lactic acid, mucus, food rests, etc.

Procedure: Strain each sample through fine-mesh cheesecloth. Examine the residue for mucous, blood, and food rests. Use the strained stomach contents for the determination of total acidity, free acidity, and peptic activity by methods which follow.

a. Determination of Total Acidity:

Principle: The indicator used is phenolphthalein. Since the indicator reacts with mineral acid, organic acid, combined acid, and acid salts the values obtained represent the *total acidity* of the solution.

Procedure: Measure 1 ml. of the strained stomach contents by means of an Ostwald pipet and introduce it into a low-form 60-ml. porcelain evaporating dish. Dilute with 15 ml. of distilled water. Add 2 drops of a 1 per cent alcoholic solution of phenolphthalein and titrate with 0.01 N sodium hydroxide until a faint pink color is obtained which persists for about 2 minutes. Take the buret reading and calculate the total acidity.

Calculation: Note the number of milliliters of 0.01 N NaOH required to neutralize 1 ml. of stomach contents, and multiply it by 10 to obtain the number of milliliters of 0.1 N NaOH necessary to neutralize 100 ml. of stomach contents. This is the method of calculation most widely used.

b. Determination of Free Acidity:

Principle: An indicator is selected which changes color at sufficiently low pH values so that the end-point corresponds to the neutralization of all highly ionized acid only, as discussed on p. 334. The indicator most widely used is Töpfer's reagent; its advantages and disadvantages have been presented on p. 335. The use of Sahli's reagent, a mixture of potassium iodide and iodate which liberates free iodine in the presence of a sufficiently high concentration of hydrogen ions, has been suggested in place of Töpfer's reagent. The liberated iodine is titrated with thiosulfate solution and the end-point is very sharp. Unfortunately, Sahli's reagent reacts to a certain extent with weak organic acids so that high values are obtained for example after the ingestion of acid fruits. A procedure using Sahli's reagent is given in the Eleventh Edition of this book.

Procedure: By means of an Ostwald pipet measure 1 ml. of the strained stomach contents and introduce it into a low-form 60-ml. porcelain evaporating dish. Dilute with 10 ml. of distilled water. Add 2 drops of Töpfer's reagent (0.5 per cent alcoholic solution of dimethylamine azobenzene) and titrate with 0.01 N sodium hydroxide to a salmon-pink color. If the sample gives a yellow color on the addition of Töpfer's reagent, it has no free acid present. The end-point may require practice in identification. The use of comparative buffered colorimetric standards to control the end-point has been suggested. Care should be taken against the possibility of color fading. The reading of the buret at the end-point is a measure of the free acidity.

It is common clinical practice to use this same sample for the determination of total acidity. To do this, add 2 drops of a 1 per cent alcoholic solution of phenolphthalein, and continue the titration until the pink color change of the phenolphthalein is superimposed on the yellow color of the Töpfer's reagent. The buret reading at this point is a measure of the total acidity.

^{*}The examination for microscopic constituents (see p. 351) should be made on the original (unstrained) gastric contents. Tests for occult blood may be made on the sediment if desired.

The detection of blood is rather more satisfactory in the residue than in the strained

Berk, Thomas, and Rehfuss: Am. J. Digestive Discuses, 9, 106 (1942).

Calculation: Note the number of milliliters of 0.01 N sodium hydroxide required to reach the end-point color with Töpfer's reagent. Multiply this by 10 to obtain the number of milliliters of 0.1 N sodium hydroxide necessary to neutralize the

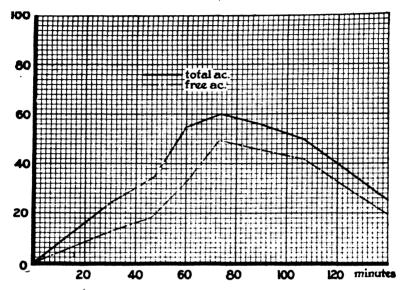

Fig. 103. Acidity curves of normal human stomach.

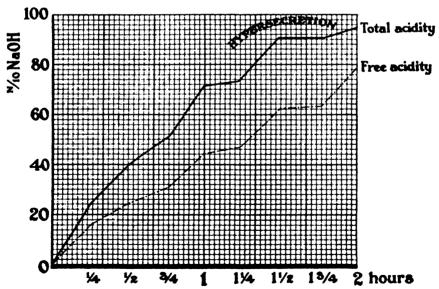

Fig. 104. Acidity curves from a case of hypersecretion.

free acid in 100 ml. of gastric contents. This value also corresponds to the free acidity expressed in degrees or in milliequivalents of acid per liter. In a similar way, the buret reading at the phenolphthalein end-point can be used to calculate the total acidity.

CURVES OBTAINED BY THE FRACTIONAL METHOD

When an Ewald test meal is given to normal individuals a curve such as that indicated in Fig. 103 is usually obtained. The curve may vary within certain limits depending on individual idiosyncrasies, but it is

usually found to follow the curve depicted, and the meal normally leaves the stomach in two and onehalf hours. Pathologically every variation occurs, in time of evacuation as well as in the character of the curve and the quantity of the secretion elaborated. Fig. 96 represents some of the possibilities of pathological cases, but a consideration of their interpretation is outside the purpose of the present volume. It will be evident, however, from a consideration of Fig. 96 that the cycle of gastric digestion is a constantly changing one, and no information concerning the trend of digestion can be obtained by an examination at only a single stage of digestion. Marked changes may precede or follow that stage and the possibilities suggested in Fig. 96 are all ob-

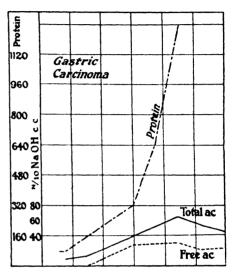

Fig. 105. Acidity and protein curves in gastric carcinoma. (Courtesy, Clarke and Rehfuss: J. Am. Med. Assoc., 64, 1737 (1915).)

served clinically and are of varying significance. Typical curves from cases of hypersecretion, gastric carcinoma, and achylia are shown in Figs. 104, 105, and 106, respectively.

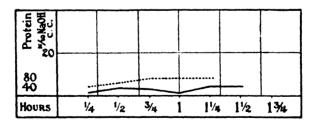

Fig. 106. Total acidity and protein curves in benign achylia (solid line represents acidity). (Courtesy, Clarke and Rehfuss: J. Am. Med. Assoc., 64, 1737 (1915).)

Besides carcinoma low acidities may be found in atonic dyspepsia and pernicious anemia. A tendency toward high acidities may be found, though not constantly, in cases of gastric and duodenal ulcers, especially those occurring in the neighborhood of the pylorus and inducing some degree

of obstruction. High acidities may be induced reflexly in gallbladder disease and appendicitis.

c. Determination of Hydrogen-ion Concentration of Gastric Contents:

Principle: Inasmuch as the hydrogen-ion concentration of the gastric contents is a determining factor in peptic digestion the estimation of pH is coming into wider use in gastric analysis. Simple colorimetric methods are available for this purpose, as is the convenient electrometric pH meter. The measurement of pH gives information of real value and the test paper method especially is so convenient that it may often be the method of choice. Determinations of pH do not, however, displace titration methods as the latter give additional information.

(1) Colorimetric Method of Shohl and King:

Procedure: Prepare Clark and Lubs standard solutions for pH 1.4, 1.6, 1.8, 2.0, 2.4, 3.0 (see Chapter 1). Transfer 2 ml. of filtered or centrifuged gastric contents to a test tube 11 mm. in diameter. Add 2 drops or 0.04 ml. of 0.2 per cent thymolsulfonephthalein in 95 per cent alcohol. Compare with equal amounts of standard solutions treated in the same way in similar test tubes (see Plate III). If the sample is more acid than pH 1.4, lower standards may be prepared. Using the Ewald test meal it may be said in a general way that pH 1.4 represents a high acidity; from 1.6 to 1.8, moderate normal acitity; from 2.0 to 2.4, low acidity; and 3.0 or higher, anacidity.

(2) Method of Denis and Silverman Using Test Papers:

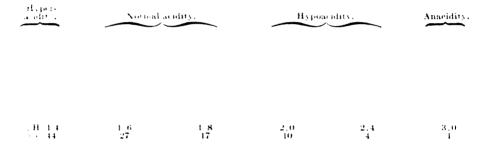

Procedure: Prepare test papers as follows. A solution of dye (dimethylaminoazobenzene 0.5 per cent or 0.1 per cent thymol blue) is poured over a sheet of filter paper six inches in diameter, the excess dye allowed to drain off, and the paper dried quickly by holding it in front of a rapidly revolving electric fan. Prepare the two kinds of paper and cut in strips approximately 1 by '4 inch and place in a stoppered bottle. Keep away from light and laboratory fumes. Smooth, ashless quantitative paper of the highest grade should be used.

Pour some of the material to be tested over the end of a test paper. The colors may be compared with those obtained from similar papers dipped in the standard solutions mentioned in the method of Shohl and King above. However, with some practice this will be unnecessary. All readings should be made at once. The table given below will serve as a guide in the interpretation of results. It gives test paper results as compared with number of ml. of 0.1 N NaOH that would be required to neutralize 100 ml. of a solution of the H-ion concentration found, if all the acid were free HCl.

Indicator	pll	Color	Ml. 0.1 N NaOH Required	Remarks
Töpfer's reagent Töpfer's reagent Töpfer's reagent Töpfer's reagent Thymol blue Thymol blue Thymol blue	1.6 1.8 2.0 2.0 2.4	Deep red Reddish-orange Orange Yellowish-orange Purple-red Faint pink Yellow	11 27 17 10 10 4	Hyperacidity Normal acidity Normal acidity Hypoacidity Hypoacidity Hypoacidity Anacidity

^{*} Prepared outfits for both the indicator solution and test paper methods may be obtained from most larger laboratory supply houses.

PLATE III

Color numbers of standard solutions containing 0.02 mL of 0.2 per cent alcoholic thymol sulfonephthalein (thymol blue) per mL of solution, and also the corresponding value in terms of pH and in mL of 0.1 X hydrochloric acid per 100 mL of gastric contents. (Courtesy, Shohl and King: Ball, Johns Hopkins Hosp., 31, 158 (1920).)

d. Determination of Peptic Activity:

- (1) Photometric Method of Riggs and Stadie: 10 In this method the enzyme activity is measured photometrically as the decrease in turbidity of a standardized, homogenized suspension of coagulated egg white under specified conditions. Accurate measurement is possible down to a level equivalent to 1 γ of crystalline pepsin. Protein hydrolysis so measured follows a monomolecular course and hence the enzyme activity is expressed as a velocity constant. This method is particularly adapted to clinical studies. For details of procedure see the original article. 10
- (2) Method of Mett as Modified by Nirenstein and Schiff:

Principle: Small glass tubes filled with coagulated egg albumin are introduced into the solution to be tested, and kept for a definite length of time in the incubator. The protein column is digested at both ends of the tube to an extent depending upon the amount of pepsin present. The method is not strictly accurate but is most satisfactory for clinical purposes on account of its simplicity. Nirenstein and Schiff showed that human gastric juice contained inhibiting substances the effect of which is overcome by the dilution recommended.

Procedure: Introduce into a small Erlenmeyer flask 1 ml. of gastric juice and 15 ml. of 0.05 N HCl (= 0.18 per cent HCl). Add two Mett tubes prepared as indicated below, stopper the flask to prevent evaporation, and place in an incubator at 37° C. for 24 hours. By means of a low-power microscope and a millimeter scale (graduated to half millimeters), determine accurately the length of the column of albumin digested at each end of the tubes. It is well to run the determination in duplicate in which case the result is the average of the eight figures obtained. Ordinarily from 2 to 4 mm. of albumin are digested by normal human gastric juice.

Calculation: The peptic power is expressed as the square of the number of millimeters of albumin digested. This is based on the Schütz-Borissow law that the amount of proteolytic enzyme present in a digestion mixture is proportional to the square of the number of millimeters of albumin digested. Therefore a gastric juice which digests 2 mm. of albumin contains four times as much pepsin as one which digests only 1 mm. of albumin. For example, if the microscopical reading gives an average of 2.2 mm. of albumin digested, the pepsin value for the diluted juice would be 2.2² = 4.84, and for the pure undiluted juice, 4.84 × 16 = 77.44.

Preparation of Mett Tubes (Christiansen's Method): The liquid portions of the whites of several eggs are mixed and strained through cheesecloth. The mixture should be homogeneous and free from air bubbles. It is best to allow the egg white to stand for two or three hours in a vacuum desiccator to more completely remove air. A number of thin-walled glass tubes of 1 to 2 mm. internal diameter are thoroughly cleaned and dried and cut into lengths of about 10 inches. These are sucked full of the egg white and kept in a horizontal position. Into a large evaporating dish or basin 5 to 10 liters of water are introduced and heated to boiling. The vessel is then removed from the fire and stirred with a thermometer until the temperature sinks to exactly 85° C. The tubes filled with egg white are immediately introduced and left in the water until it has cooled. The tubes thus prepared are soft boiled, more easily digested than hard-boiled tubes, and free from air bubbles. The ends are sealed by dipping in melted paraffin or sealing wax (preferably the latter), and the tubes can be kept thus for a long time. When ready for use mark with a file and break into pieces about 1/2 inch long. After cutting, the tubes should be immediately introduced into the digestion mixture or may be kept a short time under water. Tubes whose ends are not squarely broken off must be rejected.

The digestibility of different egg whites varies widely. Hence in making up a new set of tubes, if the results are to be comparable, these tubes must be standardized against those first prepared. This may be done by running simultaneous tests with tubes from the two series, using the same gastric

¹⁶ Riggs and Stadie: J. Biol. Chem., 150, 463 (1943).

juice and comparing the lengths of columns digested in each case. Christiansen's method of preparing tubes of the same digestibility is to be preferred. She proceeds as in the original preparation of the tubes except that as the water cools from 90° to 80° C. a single tube containing the new egg white is dropped in at each degree change of temperature—that is, at 90°, 89°, etc. Pieces of each of these tubes as well as of the original standard tubes are then allowed to digest simultaneously in portions of the same gastric juice. One of these tubes should show a digestibility equal to that of the standard tubes. For example the tube coagulated at 88° C. may show the proper digestibility. Then the new series of tubes should be made in the same manner as this one—that is, introduced at 88° C. The tubes thus prepared should be again checked up with the standard to see that no mistake has been made.

(3) Method of Volhard and Löhlein:

Principle: The pepsin is added to casein solution. The unaltered casein is salted out. The filtrate from this contains the digestion products of casein which can be estimated by titration.

Procedure: Into each of three flasks (graduated at 300 and at 400 ml.) introduce 11 ml. of N HCl and add water to make not quite 150 ml. With constant shaking add 100 ml. of the casein solution. Any turbidity must quickly disappear. Add different known amounts of pepsin-containing solution to the three flasks and make up to 300 ml. Keep at 40° for one hour. Add 20 per cent sodium sulfate solution to the 400-ml. mark. Filter and titrate 100 ml. of filtrate with 0.1 N NaOH, using phenolphthalein as an indicator.

Calculation: Multiply the titration by 4. Correct for blank run without pepsin and for any acidity of the pepsin solution. The square of the result gives units of pepsin. In any pepsin method it is best to determine the amount of unknown required to bring about, in a definite time, the same amount of digestion as a definite amount of a standard solution of pepsin.¹²

(4) Hemoglobin Method of Anson and Mirsky:

Principle: The pepsin is added to a hemoglobin solution. Unaltered protein is removed with trichloroacetic acid. The amount of digestion products is determined colorimetrically, using phenol reagent, which reacts with tyrosine, tryptophane, and cysteine groups, tyrosine being used as a standard.

For a discussion of the determination of pepsin by viscosimetric and other methods and of pepsin units see Northrop.¹¹

Procedure: Pipet 5 ml. of a 2 per cent solution of dialyzed ox carbon monoxide hemoglobin¹⁴ in 0.06 N HCl into a 175 by 20 mm. test tube and bring to 35.5° or 25° C. Add 1 ml. of enzyme solution and mix by whirling

¹¹ Introduce 100 g, of pure casein into a 2-liter flask, Add 1000 ml, of water, shake, and let stand some hours. Add 80 ml, of N NaOH, make up to 2000 ml,, and warm gradually until clear. Then heat rapidly to 85°-90° to destroy any proteinases and preserve in a stoppered bottle with a little toluol. This solution keeps for a long time.

¹² Treat 10 g. of a good pepsin preparation with 100 ml. of 10 per cent NaCl. Let stand one week at room temperature. Filter. Add an equal volume of glycerol and keep in the ice box. The solution keeps indefinitely.

13 Northrop: J. Gen. Physiol., 16, 41 (1932).

14 Bubble CO through whipped ox blood. Centrifuge. Siphon off the serum and cells. Wash the corpuscles four times with cold 0.9 per cent NaCl. Add an equal volume of water and a sixth of the total volume of toluol. Bubble the CO through the solution. Shake vigorously. Let stand in the cold over night. Siphon off the hemoglobin layer. Mix gently with a tenth the volume of centrifuged alumina cream (see Appendix). Filter through coarse paper. Dialyse over night in the cold and keep under CO in the cold with toluol as a preservative. Determine N by the Kjeldahl method. Use 17.7 as per cent of N in the hemoglobin. Use mercury instead of copper in the determination and evaporate before digestion to avoid serious foaming. To 3 volumes of 0.1 N HCl add 2 volumes of 5 per cent hemoglobin. This solution may be kept in the cold for 10 days.

The tyrosine used should have been recrystallised and the concentration also determined by the Kieldahl method, N = 7.74 per cent.

tube. After 5 minutes add 10 ml. of 4 per cent trichloroacetic acid from another test tube and pour back and forth to mix. Filter through fine paper. To 3 ml. of filtrate in a 50-ml. Erlenmeyer flask add 20 ml. of water, 1 ml. of 3.85 N NaOH, and 1 ml. of phenol reagent (Folin and Ciocalteu. See Chapter 32). The standard consists of 3 ml. of 0.1 N HCl containing 0.15 mg. of tyrosine. (A copper sulfate standard can be used with a red color filter.) Compare colors after 5 to 10 minutes with the standard at 20.

Calculation:16 If X is the reading of unknown:

Pepsin Units =
$$\frac{0.0194}{X} - 0.000147$$

If carried out at 25° multiply by 1.82.

e. Determination of Tryptic Activity. Trypsin is not a gastric enzyme but occurs in the pancreatic juice (see p. 355). In case of regurgitation of intestinal contents through the pylorus, trypsin would be passed into the stomach. This regurgitation is doubtless of frequent occurrence and may even be a normal mechanism by which gastric acidity is regulated (see p. 332). Trypsin is, therefore, generally present in the contents of the normal human stomach. However, inasmuch as trypsin is destroyed by the pepsin-hydrochloric acid of the gastric juice, determinations of this enzyme must be carried out immediately after aspirations of the gastric contents, particularly where the acidity of the latter is high.

Spencer's Method:16 (a) Prepare five reagent tubes, Nos. 1, 2, 3, 4, and 5; more if desired.

To tubes 1 and 2 add 0.5 ml. of gastric contents (filter if cloudy).

- (b) To tubes 2, 3, 4, and 5 add 0.5 ml. of distilled water.
- (c) From tube 2 remove 0.5 ml. of its mixed contents and add to tube 3.
 Mix thoroughly and add 0.5 ml. from tube 3 to tube 4. Repeat for tube 5.
 We now have dilutions of gastric contents of 1, 1/2, 1/4, 1/8, and 1/16.
- (d) To each tube add one drop of phenolphthalein solution (phenolphthalein 1 g.; alcohol (95 per cent) 100 ml.); then drop by drop add a 2 per cent sodium bicarbonate solution until a light pink color is produced.
- (e) To tubes 1, 2, 3, and 4 add 0.5 ml. of casein solution. Tube 5 must receive 1 ml. of casein solution, since it contains 1 ml. of the diluted gastric contents. For the casein solution, dissolve 0.4 g. of casein in 40 ml. of 0.1 N NaOH. Add 130 ml. of distilled water, then 30 ml. of 0.1 N HCl. This leaves

¹⁹ In addition to the 0.15 mg, of tyrosine the standard contains from the reagents an amount of color-producing material equivalent to 0.015 mg, of tyrosine. The color-producing substance in the 3 ml, of filtrate is, therefore, equivalent to $\frac{20}{X}$ (0.15 + 0.015) mg, of tyrosine. Of this 0.015 mg, are due to the color-producing substance in the reagents and 0.01 mg.

to the color-producing substance present in the trichloroacetic acid filtrate even when no enzyme is added. The digested hemoglobin in the 3 ml. of filtrate is, therefore, equivalent to $\frac{20}{X}$ (0.15 + 0.015) = 0.015 = 0.01 mg. of tyrosine. This value must be multiplied by $^{16}3$ to obtain the digested hemoglobin in the whole 16 ml. of filtrate instead of the 3 ml, taken for

obtain the digested hemoglobin in the whole 16 ml, of filtrate instead of the 3 ml, taken for analysis; it must be divided by 5 to obtain the amount of nonprecipitable digested hemoglobin produced in one minute instead of in 5 minutes; it must be divided by 181, the molecular weight of tyrosine, to obtain the tyrosine equivalent as milliequivalents instead of as milligrams. The relation between the number of pepsin units in 1 ml, of enzyme solution and the colorimeter reading X is thus:

P.U. =
$$\left[\frac{20}{X}(0.15 + 0.015) - 0.015 - 0.01\right] \frac{16}{3} \times \frac{1}{5} \times \frac{1}{181} = \frac{0.0194}{X} - 0.000147$$

¹⁶ Elaborated by Spencer in the senior author's laboratory for the specific purpose of determining trypsin in gastric juice. For other trypsin methods see Eleventh Edition of this book.

the solution alkaline to the extent of 10 ml. of 0.1 N NaOH, minus about 3 ml. neutralized by the casein.

(f) Incubate for five hours at 40° C.

(g) Precipitate the undigested casein by the dropwise addition of a solution of the following composition: glacial acetic acid 1 ml., alcohol (95 per cent) 50 ml., distilled water 50 ml. The tubes in which digestion has been complete remain clear; others become turbid.

(h) The tryptic values are expressed in terms of dilution. Thus, complete digestion in tube 3 (a dilution of $\frac{1}{2}$) shows four times the tryptic power of undiluted gastric juice; taking this dilution as unity, the undiluted juice

has a tryptic value of 4.

(i) Controls of boiled gastric contents plus casein solution, and of distilled water plus casein solution, treated as above stated, must show no digestion, and become turbid on addition of the precipitating solution.

f. Detection of Lactic Acid. When the acidity of the stomach contents is reduced to a low value there may occur considerable fermentation of carbohydrates which have been introduced into the stomach in the ingested food. This fermentation yields various organic acids, among which lactic acid is particularly prominent. It is important, therefore, in case of low gastric acidity that the stomach contents be examined for lactic acid.

Tests:

(1) Ether-Ferric Chloride Test (Strauss): A satisfactory deduction regarding the presence of lactic acid can be made only by removing the lactic acid from interfering material (e.g., hydrochloric acid, protein digestion products, etc.) present in the stomach contents. Lactic acid may be extracted from the stomach contents by ether. The following technic not only serves to detect lactic acid but also gives an approximate idea as to the amount of the acid present.

Procedure: Introduce 5 ml. of strained stomach contents into a small graduated separatory funnel, add 20 ml. of ether, and shake the mixture thoroughly. Permit the ether to separate, then allow all the fluid to run out of the separatory funnel except the upper 5 ml. of ether. To this ether extract add 20 ml. of distilled water and 2 drops of a 10 per cent solution of ferric chloride and shake the mixture gently. A slight green color is obtained in the presence of 0.05 per cent lactic acid whereas 0.1 per cent

lactic acid yields a very intense yellowish-green color.

(2) Ferric Chloride Test (Kelling): Fill a test tube with water, add 1 to 2 drops of a 10 per cent solution of ferric chloride and mix thoroughly, making a very faintly colored solution. Divide the solution into two parts and keep one part as a control. To the other part add a small amount of the strained gastric contents and to the control tube add a similar volume of water. Lactic acid is indicated by the immediate development of a distinct yellow color in the tube containing the gastric contents.

The color in this test is due to the formation of ferric lactate.

(3) Uffelman's Reaction: Prepare 25 ml. of Uffelmann's reagent. 17 To 5 ml. of this reagent in a test tube add an equal volume of strained gastric juice. A canary yellow or greenish-yellow color develops if lactic acid is present to the extent of 0.01 per cent or over.

Other organic acids give a similar reaction. Mineral acids such as hydrochloric acid discharge the blue coloration leaving a colorless solution. In other words, the color of the reagent is weakened in the presence of an acid reaction.

¹⁷ See Appendix.

g. Detection of Occult Blood: 18 1. Benzidine Reaction: This is one of the most delicate of the reactions for the detection of blood. Different benzidine preparations vary greatly in their sensitiveness, however. Inasmuch as benzidine solutions change readily upon contact with light it is essential that they be kept in a dark place. The test is performed as follows: To 3 ml. of a saturated solution of benzidine in glacial acetic acid of add 2 ml. of the solution to be tested and then 1 ml. of 3 per cent hydrogen peroxide. A positive test is indicated by a green or blue color.

Confirmatory Test: If the mixture contains fat make neutral or slightly alkaline and extract by shaking with an equal volume of ether. Discard this ether extract. Make the residue acid with acetic acid and again extract with ether. Pour off ether into a small evaporating dish. Put on a hot water bath with flame turned out and evaporate to dryness. Add a few drops of water, a drop of benzidine solution, and a drop of 3 per cent hydrogen

peroxide. A green or blue color indicates blood.

Blood is found in gastric contents in conditions associated with erosion of the mucous membrane, ulcer, and carcinoma. In cases of ulcer the blood may be bright red or may be converted to brown "acid hematin" by the excess of acid which is usually present. In carcinoma the blood forms brownish-black lumps, the so-called "coffeeground" material.

- h. Detection of Bile in Stomach Contents. If we accept Boldyreff's theory as to the automatic regulation of gastric acidity under normal conditions by the regurgitation of alkaline material from the intestine, then the presence of bile in the gastric juice does not possess the clinical significance it has been accorded. However, if an ordinary Ewald meal be fed, and bile in any considerable quantity be found throughout the entire course of digestion, it may indicate, pathologically, a stenosis below the level of the common bile duct. The presence of bile is indicated by a yellowish or greenish color of the specimen, changing to a bright green on standing.
- i. Microscopy of the Gastric Contents. Microscopical examination of the gastric contents is a routine clinical procedure.

When an Ewald meal is given the starch granules in various stages of digestion are observed together with epithelia from the pharynx, esophagus, and occasionally the stomach. Gastric and salivary mucus are seen and readily recognized by their ropy appearance. Pathologically various bacteria are seen: sarcinae, Oppler-Boas bacilli, streptococci, leptothrix, etc. Retained food from previous meals is readily recognized by its histological appearance; meat fibers, vegetable cells, and cellulose may all occur in pathological retention. In certain pathological processes such as ulcer and cancer, red blood cells, pus, and even the cancer cells themselves may be found. For illustrations of the microscopic constituents of gastric contents, see Fig. 107.

Procedure: Examine a drop of the original (mixed) stomach contents unstained under the low and high powers of the microscope. Compare your findings with the microscopical views shown in Fig. 107.

j. Partition of Chlorides in Gastric Contents. Because of the neutralizing effect of duodenal regurgitation or the possible presence of fer-

¹⁸ These tests may be made upon the strained stomach contents or upon the solid residue.
19 Glacial acetic acid is preferable but alcohol acidified with acetic acid may be used.

mentation acids in the stomach, acidity titrations may not give a true measure of HCl secretion. Partition of the total, mineral, and combined chlorides may therefore yield additional or confirmatory information. The following method gives only approximate results, but is suitable for clinical purposes.

Fig. 107. Microscopical constituents of the gastric contents. (A) Starch cells, (B) yeast cells, (C) Oppler-Boas bacilli, (D) staphylococci, (E) streptococci, (F) safcinae, (G) muscle fiber, (H) muscus, (I) red blood cells, (J) leukocytes, (K) snail-like mucous formations, (L) squamous epithelial cells, and (M) cellulose.

Procedure: Introduce 10-ml. portions of gastric contents into each of three silica dishes, (a), (b), and (c). To (a) add 1 ml. of 0.1 N NaOH in excess of that required for neutralization. Evaporate the contents of all three dishes to dryness on a water bath. This causes free HCl in the unalkalinized portions to be volatilized. Now add to (b) 1 ml. of 0.1 N NaOH, evaporate and gently incinerate the residue over a free flame. Without any addition of alkali, evaporate and incinerate the contents of dish (c), thus driving off the "combined HCl" also. Take up the residue in each dish in 10 ml. distilled water, add 5 ml. of concentrated HNO₂, 20 ml. of 0.1 N AgNO₂, and 1 ml. of saturated ferric alum solution. Titrate with 0.1 N KCNS while stirring vigorously, until the red color persists one minute.

Calculation: 0.0365(20 - ml. KCNS used) = Chlorides, as g. HCl per 100 ml. of gastric contents. The values obtained for dishes (a), (b), and (c) represent, respectively, total, combined plus mineral, and mineral (or fixed) chlorides. Chlorides in the form of free HCl may be calculated by subtracting from the total (a) the sum of the mineral plus combined chlorides (b).

Interpretation. Active acidity is represented by free HCl and HCl combined with proteins, i.e., total minus mineral chlorides. Mineral chlorides.

rides afford an index of regurgitation. The difference between free acidity as determined by titration and as calculated from the chloride partition, represents abnormal acidity, e.g., that due to lactic or butyric fermentation. Thus the chloride partition imparts information of clinical importance.

Wolff Technic for the Protein Concentration of the Gastric Contents: Determination of protein has a certain diagnostic value. Under normal conditions the protein concentration follows the acidity rather closely, being low when the acid is low. See curves in case of benign achylia, Fig. 106. In certain cases, however, as in carcinoma, there is an actual increase in the protein concentration of the gastric juice out of all proportion to acidity (see Fig. 105). For procedure see the Ninth Edition of this book.

TÖPFER'S METHOD OF GASTRIC ANALYSIS

This method appeared in previous editions but has been omitted in this revised Twelfth Edition because it is believed to be unreliable.

Pancreatic Digestion

As soon as the food mixture leaves the stomach it comes into intimate contact with the bile and the pancreatic juice. Since these fluids are alkaline in reaction there can obviously be little further peptic activity after they have become intimately mixed with the chyme and have neutralized most of the acidity previously imparted to it by the hydrochloric acid of the gastric juice. The pancreatic juice reaches the intestine through the duct of Wirsung which opens into the intestine near the pylorus.

STIMULATION OF PANCREATIC SECRETION

Secretin and Pancreozymin. Prior to the work of Bayliss and Starling in 1902 it was believed that substances in the intestine stimulated pancreatic secretion through local reflexes from the intestine to the pancreas. This view was based on the observation that the introduction of acid into the intestine was followed by secretion. Bayliss and Starling, however, observed that introduction of acid into a jejunal loop which had been denervated as far as possible still induced secretion. This indicated that the exciting agent acted by way of the blood. Injection of acid directly into the blood did not affect secretion, which must therefore be induced by some substance given off from the mucosa. A substance capable of stimulating secretion by intravenous injection could be extracted from the intestinal mucosa by acid but not by water. Apparently the mucosa contains a substance pro-secretin which is changed by the acid of the gastric chyme into secretin which passes by way of the blood stream to the pancreas causing it to secrete. This view has been confirmed by many observers, and most clearly by Ivy, Farrel, and Lueth who found acid applied to transplanted intestinal loops to cause secretion in the transplanted pancreas.

Secretin was the first hormone to have its function clearly established. Tests on the purest secretin preparation so far obtained show it to be a polypeptide, with a molecular weight of about 5000. It contains no aromatic amino acids and only one atom of sulfur in the molecule. In general, secretin possesses basic properties. The activity of secretin is destroyed by pepsin and trypsin, hence it cannot be given effectively by mouth. Secretin is likewise destroyed on incubation with blood serum, presumably because of the presence of the enzyme secretinase.

Harper and Raper¹ claim that extracts of duodenal mucosa contain two hormonal agencies affecting the external secretory activity of the pancreas. These are (1) secretin, which stimulates the production of fluid and bicarbonate by the pancreatic acini, and (2) pancreozymin, which

¹ Harper and Raper: J. Physiol., 102, 115 (1943).

governs the production of the pancreatic enzymes. This claim has been confirmed by Ivy and associates.²

It might be supposed that a failure of the pancreatic secretion would be noted in achylia where no gastric acid is secreted to bring about the liberation of secretin. This is not the case. Fatty acids formed in fat digestion may cause the passage of secretin into the blood stream. For the same reason bile also has some stimulating action on pancreatic secretion.

PANCREATIC JUICE

The juice as obtained from a permanent fistula differs greatly in its properties from the juice obtained from a temporary fistula, and neither form of fluid possesses the properties of the normal fluid. Pancreatic juice collected from a natural fistula has been found to be a colorless, clear, alkaline fluid (pH 8 or thereabouts) which foams readily. The inorganic salts consist largely of sodium chloride and bicarbonate, in approximately equal amounts; the bicarbonate is responsible for the alkalinity of the juice. It is further characterized by containing albumin, globulin, proteose, and peptone; nucleoprotein is also present in traces. The average daily secretion of pancreatic juice is 650 ml. and its specific gravity is 1.008. The fluid contains 1.3 per cent of solid matter and the freezing point is -0.47° C. The normal pancreatic secretion contains a variety of different enzymes. Among those which have been well characterized are included the following: (1) The peptide-splitting enzymes trypsin, chymotrypsin, and various carboxypeptidases; (2) a polynucleotidase acting on nucleic acids; (3) pancreatic amylase (amylopsin), an amylolytic enzyme; and (4) pancreatic lipase (steapsin), a fat-splitting enzyme. Other enzymes are doubtless present. It will be noted that pancreatic juice contains enzymes capable of acting on all three classes of foodstuffs-proteins, carbohydrates, and fats.

Proteolytic Enzymes of Pancreatic Juice. The major proteolytic enzymes of panereatic juice appear to be (1) trypsin, (2) chymotrypsin, and (3) a carboxypeptidase, each of which has been obtained in crystalline form. The combined activities of these (and possibly other) enzymes was formerly believed to be due to a single enzyme which was called trypsin. This term is now, however, applied to a single enzyme in the group. As a class, these enzymes are similar in that they all catalyze the hydrolytic splitting of the peptide bond. They differ from one another in such respects as the type of peptide linkage required for activity; the type of activation from zymogen precursors, as discussed below; the pH optima, etc.

Trypsin and chymotrypsin may be classified as endopeptidases (Bergmann) acting on peptide linkages either in the central portion or the terminal portion of polypeptide chains. By the use of synthetic peptide substrates, Bergmann and Fruton found that trypsin acts on peptide linkages containing the carboxyl group of either lysine or arginine. Chymotrypsin on the other hand was found to act on peptide linkages involv-

² Greengard, Grossman, Woolley, and Ivy: Science, 99, 850 (1944).

ing the carboxyl group of tyrosine and phenylalanine. Thus the digestive action of trypsin and chymotrypsin on proteins appears to involve the splitting of specific types of peptide linkages in the molecule, the products of the action being, as with pepsin (see p. 320), either low molecular weight polypeptides or free amino acids, depending upon the location of the peptide linkages acted upon. There is some evidence of a synergistic action of these various endopeptidases; the action of one may uncover a linkage previously inaccessible to another. For the crystalline form of trypsin and chymotrypsin, see Figs. 82 and 83, Chapter 12.

Trypsin has its greatest activity at pH 8 to 9, the optimum pH depending somewhat on the nature of the substrate. It has some action in

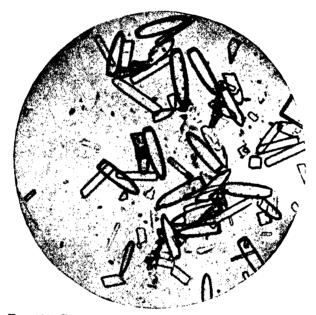

Fig. 108. Crystalline carboxypeptidase, prepared by the method of Anson. (Courtesy, Dr. A. A. Plentl.)

weakly acid solution. In acid solutions it resists temperatures near the boiling point, the denaturation that occurs being rapidly reversible on cooling. Trypsin is fairly stable in acidities as high as pH 2, but is digested by pepsin in acid solutions.

The carboxypeptidase activity of pancreatic juice is doubtless due to a mixture of enzymes, of which only one has been crystallized (Anson). Carboxypeptidase is an example of an exopeptidase. It catalyzes the splitting of a peptide linkage involving the amino group of an amino acid whose carboxyl group is free, i.e., not combined in peptide linkage with another amino acid. The action of carboxypeptidase is thus confined to the terminal portion of a polypeptide chain. If the free carboxyl group is blocked, as by the formation of an ester, the enzyme becomes ineffective. Carboxypeptidase has a pH optimum around 7.0.

ACTIVATION OF TRYPSIN AND CHYMOTRYPSIN. Pancreatic juice obtained from a fistula commonly shows no action on proteins. On entrance into the intestine the juice immediately becomes active. Apparently trypsin and chymotrypsin as found in the pancreas, and as secreted by that gland, exist not as such but as proenzymes called trypsinogen and chymotrypsinogen. These proenzymes have been obtained by Northrop and Kunitz in crystalline form and show protein characteristics. Trypsin appears to be normally activated by the substance enterokinase found in the small intestine. Evidence has been presented to show that enterokinase may be secreted in the pancreatic juice in an inactive form which becomes active on contact with the intestinal juice and may then activate trypsin. The mechanism of the action of enterokinase is not yet clear. According

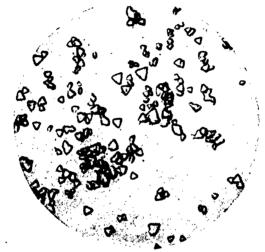

Fig. 109. Trypsinogen crystals. (Courtesy, Dr. John H. Northrop.)

to one view enterokinase brings about an enzymatic change in the trypsinogen, while others hold active trypsin to be a compound of trypsinogen with enterokinase. The former view would seem to be favored by the fact that crystalline trypsinogen can be activated by traces of trypsin, the activation increasing in rapidity as more active trypsin is formed. In less pure trypsin preparations activation appears to be slowed up by the presence of an inhibitor which has been obtained in crystalline form and appears to be a polypeptide. Strong salt solutions may also activate trypsin.

Chymotrypsinogen is apparently activated by active trypsin. Enterokinase thus does not activate chymotrypsinogen directly but indirectly in the presence of trypsinogen.

Pancreatic Amylase. This is an amylolytic enzyme, or more probably a mixture of enzymes, which possesses somewhat greater digestive power than salivary amylase. As its name implies its activity is confined to the

starches and similar compounds, and the products of its amylolytic action are dextrins and ultimately maltose.

It is probable that the saliva as a digestive fluid is not absolutely essential. The salivary amylase is destroyed by the hydrochloric acid of the gastric juice and is therefore inactive when the chyme reaches the intestine. Should undigested starch be present at this point, however, it would be quickly transformed by the active pancreatic amylase. This enzyme is not present in the pancreatic juice of infants during the first few weeks of life, indicating that a starchy diet is not normal for this period.

Pancreatic amylase is practically identical in its action with salivary amylase and is similarly influenced by physical and chemical agents (see Chapter 13). Its optimum pH is 7.1. The purest preparations have been made by Sherman and his collaborators. They possessed protein properties; the report that the enzyme was crystallizable has not been followed up and established by further work. One purified preparation split 20,000 times its weight of starch in 30 minutes at 40° C. In longer experiments it digested 4,000,000 times its weight of starch.

It has been shown that pancreatic amylase will digest raw starch. The raw starch of corn and wheat may be completely digested and absorbed by normal adults in amounts of over 100 g. per day, whereas the raw potato starch is about 80 per cent available.

Pancreatic Lipase. This is a fat-splitting enzyme. It has the power of splitting the neutral fats of the food by hydrolysis, into fatty acid and glycerol. A typical reaction would be as follows:

$$\begin{array}{c} C_{3}H_{5}(\mathrm{OOCC_{15}H_{31}})_{3} + 3H_{2}\mathrm{O} \rightarrow 3(C_{15}H_{31}\mathrm{COOH}) + C_{5}H_{5}(\mathrm{OH})_{3}. \\ \text{Palmitin} & \text{Palmitic acid} & \text{Glycero!} \end{array}$$

Pancreatic lipase is very unstable and is easily rendered inert by the action of acid. For this reason it is not possible to prepare an extract having a satisfactory fat-splitting power from a pancreas which has been removed from the organism for a sufficiently long time to have become acid in reaction.

Pancreatic lipase is undoubtedly the most important fat-splitting enzyme in the digestive tract. In the absence of pancreatic lipase, as when the pancreatic duct is obstructed by disease, the fat of the diet appears in the undigested form in the feces; this condition is known as steatorrhea. The enzyme is water-soluble and presumably a protein, although sufficiently pure preparations to prove this have not as yet been obtained, nor has the enzyme been crystallized. The action of the enzyme on fats is obviously dependent in large extent upon the surface of fat available; thus the more highly emulsified the fat is, the more surface is exposed to the aqueous phase containing the enzyme and the more rapid is lipase action. Emulsification of fats in the digestive tract is facilitated by the presence of bile, because of the lowering of surface tension brought about by the bile salts (see Chapter 18). The bile also aids in fat digestion by aiding in the removal of the end-products of lipase action. It is believed

by some that the bile actually activates pancreatic lipase; it appears more probable that the acceleration in lipase activity in the presence of bile is due to physicochemical action by the bile salts in facilitating closer contact between the water-soluble lipase and the fat globule.

PREPARATION OF AN ARTIFICIAL PANCREATIC JUICE

- After removing the fat from the pancreas of a pig or sheep, finely divide the organ by means of scissors and grind it in a mortar. If convenient, the use of an ordinary meat chopper is a very satisfactory means of preparing the pancreas.
- When finely divided as above, the pancreas should be placed in a 500-ml. flask, about 150 ml. of 30 per cent alcohol added, and the flask and contents shaken frequently for 24 hours. (What is the reaction of this alcoholic extract at the end of this period, and why?) Strain the alcoholic extract through cheesecloth, filter, nearly neutralize with potassium hydroxide solution, and then exactly neutralize it to litmus with 0.5 per cent sodium carbonate.

PRODUCTS OF PANCREATIC DIGESTION OF PROTEIN

- Into a 250-ml. flask introduce 20 g. of casein, 10 ml. of the artificial pancreatic juice prepared as described above, and 100 ml. of 1 per cent sodium carbonate. Allow to digest at 40° C. for 8 to 10 days with the addition of a few milliliters each of chloroform and toluene, the flask being stoppered with cotton. As the chloroform and toluene evaporate they must be renewed. Heat the mixture to boiling and at the boiling point add acetic acid drop by drop until the mixture is acid in reaction. Cool and filter.
- To 5 ml. of the filtrate add bromine water drop by drop. Note the development of a pink color which disappears in the presence of an excess of the reagent. This reaction indicates the presence of tryptophane.
- To another 5-ml. portion of the filtrate add 10 drops of concentrated sulfuric acid and 10 ml. of a 10 per cent solution of mercuric sulfate in 5 per cent sulfuric acid. After mixing and allowing to stand for a few minutes, filter off the yellow precipitate which forms. This is an impure mercury compound of tryptophane. Filter off the precipitate, reserving the filtrate, and wash the precipitate on the filter paper thoroughly with several small portions of water.
- To small portions of the precipitate apply the Hopkins-Cole, xanthoproteic, and Millon tests. Tryptophane gives a positive reaction with the first two of these tests and is responsible for the Hopkins-Cole reaction as applied to protein.
- Test portions of the filtrate from the mercuric precipitate by the Hopkins-Cole, xanthoproteic, and Millon reactions. Tyrosine responds to the latter two tests.
- To the remainder of the original filtrate add a few drops of ammonia' (enough to make slightly alkaline) and evaporate to a volume of 10 to 20 ml., using at first a free flame and completing the evaporation on a water bath. Transfer to a beaker and allow to stand for 1 or 2 days. Examine microscopically the crystals which separate out. Tyrosine crystallizes in sheaves of needles (see Fig. 47). Leucine forms small rosettes. Apply Mörner's reaction for tyrosine (see p. 126).

^{*} It has been claimed that a similar yellow precipitate forms in the presence of tyrosine, cystine, and polypeptides.

⁴ If the solution is alkaline in reaction due to the presence of fixed alkali while it is being concentrated, the amino acids will be broken down and ammonia will be liberated. Ammonia in slight excess does not cause such decomposition.

GENERAL EXPERIMENTS ON PANCREATIC DIGESTION

EXPERIMENTS ON TRYPSIN⁵

- 1. The Most Favorable Reaction for Tryptic Digestion: Prepare five tubes as follows:
 - a. 3 ml. of neutral pancreatic extract + 3 ml. of water. pH 7.
 - b. 3 ml. of neutral pancreatic extract + 3 ml. of water + 1 drop of phenolphthalein solution + 0.5 per cent Na₂CO₃ to first faint pink color. pH 8.3.
 - c. Same as (b) but add Na₂CO₃ until the pink color no longer deepens. pH 10.
 - d. 3 ml. of neutral pancreatic extract + 3 ml. of 2 per cent boric acid solution. pH 5.
 - e. 3 ml. of neutral pancreatic extract + 3 ml. of 0.6 per cent HCl. pH 3.

Add a small piece of fibrin⁶ to the contents of each tube and keep them at 40° C., noting the progress of digestion. In what reactions does trypsin act and what is the optimum pH? How do the indications of the digestion of fibrin by trypsin differ from the indications of the digestion of fibrin by pepsin? Is the same degree of swelling of the protein noted?

- 2. The Most Favorable Temperature: (For this and the following series of experiments under tryptic digestion use the neutral extract plus an equal volume of 0.5 per cent sodium carbonate.) In each of four tubes place 5 ml. of alkaline pancreatic extract. Immerse one tube in ice water, keep a second at room temperature, and place a third in the incubator or water bath at 40° C. Boil the contents of the fourth for a few moments, then cool and also keep it at 40° C. Into each tube introduce a small piece of fibrin and note the progress of digestion. In which tube does the most rapid digestion occur? What is the reason?
- 3. Demonstration of the Action of Enterokinase on Trypsin:
 - a. Preparation of Enterokinase: Grind 5 g. of fresh duodenal mucosa of the hog with a little sand. Gradually add 50 ml. of water during the grinding process. Strain through cheesecloth.

A better preparation is made by drying the mucosa. From the upper three feet of the intestine of the hog scrape off the mucous membrane with a knife, or, better, a glass plate. Shake with three volumes of acetone. Let stand two hours. Filter. Wash the residue again with the same amount of acetone, then with a mixture of acetone and ether, and finally twice with ether. Dry in air and pulverize. A 1:50 extract of this powder in water may be used. The powder keeps indefinitely. The enterokinase may be further purified.

- b. Preparation of Kinase-free Trypsin Solution: Immediately after killing the animal, grind hog pancreas in a meat chopper and dry with acetone and ether as in preparation of enterokinase (see above). Glycerol extracts of this dried pancreas (1:10) may be used. Kinase-free trypsin may also be further purified.
- c. Demonstration of Action of Enterokinase: Prepare five tubes as follows:
- (1) 2 ml. of pancreas extract + 5 ml. of water.
- (2) 2 ml. of pancreas extract + 1 ml. of duodenal extract + 4 ml. of water.
- (3) 1 ml. of duodenal extract + 6 ml. of water.
- (4) 2 ml. of pancreas extract + 1 ml. of duodenal extract + 4 ml. of water.
- (5) 2 ml. of pancreas extract + 1 ml. duodenal extract (boiled) + 4 ml. of water.

⁴ For these experiments as well as for those on the other pancreatic ensymes commercial preparations of trypsin and pancreatin may be employed.

⁶ Congo red fibrin (see Appendix) may be used in this and the following tests on tryptic digestion. If Congo red fibrin is used the experiments should be carried out at room temperature. Also in Exp. (b) and (c) phenolphthalein should not be added but the proper amount of alkali as determined in a separate test. Buffer solutions of suitable pH may also be used in these tests instead of the acids and alkalies suggested.

Boil contents of tube (4) for 5 minutes and cool to 40° C. Keep all tubes at 40° for 20 minutes for activation. Add 1 ml. of 0.5 per cent sodium carbonate to each tube and the same quantity (about the size of a pea) of fresh fibrin. Shake the tubes and place at 40° C. Observe frequently during the course of an hour. Tube (2) should show the most rapid digestion. Why?

- 4. Quantitative Determination of Tryptic Activity: See Spencer's Method, p. 349. See also Eleventh Edition of this book.
- 5. Separation of Tryptic Enzymes (Proteinase and Carboxypeptidase) from Other Enzymes and from Each Other: The separation is made by adsorption methods. For the preparation of adsorbent, see p. 286. For the preparation of crystalline tryptic enzymes, see p. 287.

To 5 g, of pancreas dried with acetone and ether (see p. 360), add 50 ml. of glycerol and let stand over night. Add 50 ml. of water and centrifuge. Treat the supernatant fluid with 5 ml. of N acetate buffer pH 3.8 and 5 ml. of alumina Cγ containing about 125 mg. of Al₂O₃. Centrifuge. Repeat the treatment with alumina four times in all. Dipeptidase, etc., is thus removed. Treat 11 times at pH 7 with 6-ml. portions of the alumina mixture. The residual solution contains proteinase but no carboxypeptidase. Wash the combined residue with 40 ml. of 20 per cent glycerol. Then treat with 50 ml. of 0.04 N NH₃ containing 20 per cent glycerol. Treat the elution three times with 4-ml. portions of the alumina at pH 7. Wash the combined adsorbates with 20 per cent glycerol and then with 50 ml. of the 0.04 N NH₂ (in 20 per cent glycerol). This solution should contain carboxypeptidase but no proteinase. The action of the proteinase may be studied on casein by Spencer's method (p. 349) and of the peptidase on chloracetyl-l-tyrosine or other synthetic peptides. For activation enterokinase is necessary (see Exp. 3). The optimum pH for the peptidase is 7.4.

EXPERIMENTS ON PANCREATIC AMYLASE

- 1. Demonstration of Presence of Amylase in the Pancreas: Into a test tube introduce 5 ml. of starch paste and 2 ml. of pancreatic extract. Shake and put in a water bath at 40° C. for 30 minutes. Divide into two parts. Test one with iodine for undigested starch and the other by Benedict's test for reducing sugar. The reducing sugar formed by pancreatic amylase is maltose as is the case with salivary amylase.
- 2. Quantitative Determination of Amylolytic Activity:
 Method of Willstätter, Waldschmidt-Leitz, and Hesse: In this method the

Method of Willstütter, Waldschmidt-Leitz, and Hesse: In this method the reducing sugar formed is determined by hypoiodite titration.

Into a 50-ml. cylinder (with a ground-in stopper) introduce 25 ml. of a freshly prepared 1 per cent solution of soluble starch (see the Appendix), 10 ml. of buffer solution pH 6.8 (5.1 ml. of 0.2 M KH₂PO₄ + 4.9 ml. of 0.2 M Na₂HPO₄), and 1 ml. of 0.2 N NaCl. Mix and bring to a temperature of 37° C. Add the enzyme solution to be tested. Mix and return at once to the bath. Keep at 37° C, for exactly ten minutes. Then add 2 ml. of N HCl to stop the action. Wash the contents of the cylinder with a little water into an Erlenmeyer flask. Add 0.6 ml. of 0.1 N lodine solution for each mg. of maltose expected. Then add drop by drop with shaking 0.1 N NaOH sufficient to neutralize the added HCl and to change the primary phosphate of the buffer to secondary form (for both of which 30 ml. is required) and a further amount 1.5 times the volume of the iodine solution used. Let stand 15 minutes, acidify with dilute H2SO1, and titrate the excess iodine with 0.1 N thiosulfate. The iodine taken up by the starch and the enzyme solution is found in a control determination. One ml. of 0.1 N l is equivalent to 17.15 mg. of C12H22O11 or maltose.

Calculation: The equation for a monomolecular reaction is

$$k = \frac{1}{t} \log \frac{a}{a - a}$$

Applying to above determination a is the amount of substrate (not the full 0.25 g. of starch but 75 per cent of this or 0.1875 as representing the practical limits of saccharification of the starch); t is the time (10 minutes). Assume the iodine required to be 2.29 ml. and the blank determination 0.53 ml., iodine taken up by maltose will be 2.29 - 0.53 = 1.76 ml. of 0.1 N I, equivalent to 0.0302 g. of maltose.

Then:
$$k = \frac{1}{10} \log \frac{0.1875}{0.1875 - 0.0302} = 0.0076$$

This reaction constant expresses also the number of units of amylase in the amount of amylase preparation used. The unit of amylase is 100 times the amount required under the given conditions to give a constant of 0.01. This is approximately the amount in 2 cg. of dried pancreas. The amylolytic strength of a preparation may be expressed in units per cg. For plant amylase a buffer of pH 5 should be used. For accurate work the amount of enzyme used should be such as to give a constant of 0.01 - 0.03 or hydrolysis of not over 40 per cent of the substrate.

EXPERIMENTS ON PANCREATIC LIPASE⁷

- 1. Influence of Bile on Action of Lipase: Prepare five test tubes as follows:
 - a. 0.5 ml. of olive oil + 5 ml. of neutral pancreatic extract + 4.5 ml. of water.
 - b. 0.5 ml. of olive oil + 9.5 ml. of water.
 - c. 0.5 ml. of olive oil +8.5 ml. of water +1 ml. of bile.
 - d. 0.5 ml. of olive oil + 5 ml. of neutral pancreatic extract + 3.5 ml. of water + 1 ml. of bile.
 - e. 5 ml. of neutral pancreatic extract + 4 ml. of water + 1 ml. of bile.

Shake the tubes thoroughly, add a drop of toluene to each, and place them in an incubator or water bath at 40° for 24 hours. At the end of this period add a drop of phenolphthalein to each tube and titrate with 0.05 N NaOH to a permanent pink color. Shake the tube during the titration. Record the amount of 0.05 N alkali necessary to neutralize the contents of each tube. Which tube required the most? Why?

- of each tube. Which tube required the most? Why?

 2. "Litmus-milk" Test: Into each of two test tubes introduce 10 ml. of milk and a small amount of litmus solution. To the contents of one tube add 3 ml. of neutral pancreatic extract? and to the contents of the other tube add 3 ml. of water or of boiled neutral pancreatic extract. Keep the tubes at 40° C. and note any changes which may occur. What is the result and how do you explain it?
- 3. Copper Soap Test for Lipase: Prepare a 2:100 agar-agar solution, mix with an equal volume of 5:100 starch paste, incorporate in this mass about 1/40 of its volume of the neutral fat desired (butter, lard, etc.), heat with constant agitation until a homogeneous emulsion is produced, pour into a Petri dish, and cool rapidly. With a fine pipet distribute on the surface of the solidified mass small drops of the liquid to be tested, keep 1 hour at 38°, pour a saturated aqueous CuSO₄ solution over the surface, allow to stand 10 minutes, and rinse with H₂O. The presence of lipase is shown by the appearance of beautiful bluish-green spots. These are copper soap. The addition of the starch, which is not indispensable, produces a rather white opaque background against which the spots appear very distinct.
- 4. Ethyl Butyrate Test: Into each of two test tubes introduce 4 ml. of water, 2 ml. of ethyl butyrate, C₄H₇COO·C₂H₃, and a small amount of litmus powder. To the contents of one tube add 4 ml. of neutral pancreatic extract and to the contents of the other tube add 4 ml. of water or of boiled

⁷ A vegetable lipase preparation may be made as described on p. 288.

Litmus-milk powder may be used if desired. To prepare it add 1 part of powdered litmus to 50 parts of dried milk powder. For use in testing, 1 part of powdered litmus-milk may be added to 9 parts of water.

² Commercial pancreatin may be used in this test if desired.

neutral pancreatic extract. Keep the tubes at 40° C. and observe any change which may occur. What is the result and how do you explain it? Write the equation for the reaction which has taken place.

5. Quantitative Estimation of Lipase: Method of Willstätter, Waldschmidt-Leitz, and Memmen: A constant degree of activation is obtained by the addition of albumin and calcium salts. An adsorption compound fat-Ca oleate-albumin-lipase very favorable to lipase action is believed to be formed.

Into a wide-mouth 30-ml. flask with a ground glass stopper, introduce the enzyme preparation made up to 10 ml. of water, then 2.5 g. of olive oil and 2 ml. of buffer (0.66 ml. of N NH₄OH + 1.34 ml. of N NH₄Cl) and 0.5 ml. of 2 per cent CaCl₂. Shake a little and add 0.5 ml. of 3 per cent albumin solution. Shake by hand uniformly and strongly for 3 minutes to get a stable characteristic emulsion. Put in a thermostat at 30° C. for 57 minutes (total time of lipase action 60 minutes). Wash into an Erlenmeyer flask with 96 per cent alcohol to make a volume of about 125 ml. Add 20 ml. of ether and mix. This stops lipase action. Add 12 drops of 1 per cent solution of thymolphthalein and titrate with 0.1 N alcoholic KOH to a distinct blue color. From the reading subtract the titration value of the buffer (13.4 ml. of 0.1 N KOH) and of the enzyme solution. A lipase unit is the amount required under the specified conditions to split 24 per cent of 2.5 g. of olive oil of a saponification value of 185 (meaning that 1 g. of the olive oil completely hydrolyzed requires for neutralization 185 mg. of KOH).

Calculation: One ml. of 0.1 N KOH = 5.61 mg, of KOH, If 12.5 ml, of 0.1 N KOH (corrected for control) were required $12.5 \times 5.61 = 70.6$ mg, of KOH. Then 70.6×100

 $\frac{70.6 \times 100}{185 \times 2.5}$ = 15.1 per cent split. If the splitting is more than 24 or less than 10

per cent, repeat. Ten per cent decomposition by pancreatic lipase corresponds to a lipase value of 0.028 and 24 per cent to 1.0. Add to 0.28 an amount of 0.044 for each per cent of decomposition above 10 and up to 24. If using other than pancreatic lipase or if other conditions are altered a special curve of variations of percentage hydrolysis with different amounts of enzyme must be plotted from experimental data obtained using the enzyme in question. Concentration of lipase may be expressed as units per cg. of substance.

Intestinal Digestion

Strictly speaking, all digestive processes which take place in the intestine may be classed under Intestinal Digestion. However, we will consider here only those digestive processes which are brought about by enzymes which have their origin in the intestine. The activities of those enzymes which originate in the pancreas have been discussed in Chapter 16, Pancreatic Digestion.

It has been shown that the reaction of the small intestine may vary from acid to alkaline and is influenced by the state of digestion.

The enzymes of the intestine are of great importance to the animal organism. These include (1) various peptidases (aminopeptidase, dipeptidase, etc.); (2) carbohydrases such as sucrase, maltase, and lactase; (3) phosphatases, and others. The intestinal juice has been found to contain these enzymes only in small amounts and therefore appears to be of minor importance in digestion. The intestinal mucosa is, however, rich in these enzymes, which exert their chief action at the surfaces of the mucosa, or intracellularly, and prevent the absorption of unsplit products such as lactose or peptone.

Peptidases. The peptidases of the intestinal mucosa include a number of different enzymes of which relatively few have been well characterized. The activity of this group of enzymes was at one time attributed to a single enzyme called erepsin. This name is now used only as descriptive of the general properties of this group of enzymes. The ereptic enzymes have the common property of splitting only those peptide linkages which are adjacent to the end of a peptide or polypeptide chain. They are thus exopeptidases; they may be further characterized according to whether the action on a peptide linkage involves the presence on the amino acids attached to the linkage of a free amino group or its equivalent (aminopeptidases), a free carboxyl group (carboxypeptidases), or both (dipeptidases). Other characteristic criteria have been and doubtless will continue to be found. None of these enzymes of the intestinal mucosa has as yet been crystallized.

Aminopeptidases. The aminopeptidases of the intestinal mucosa acting on the products of peptic and tryptic digestion catalyze the splitting of the peptide linkage adjacent to the end of the polypeptide chain carrying a free amino group, to produce a free amino acid and a polypeptide of lower molecular weight. This process can apparently continue down to the stage of complete hydrolysis into amino acids, since aminopeptidase preparations will act on synthetic dipeptides, although less rapidly than on polypeptides. Some structural specificity is undoubtedly involved in aminopeptidase action; thus leucylpeptidase, an aminopeptidase which may be differentiated from others in the intestinal mucosa, is character-

ized by its high rate of action on synthetic peptides containing leucine, and this enzyme is presumably a prototype of other as yet unrecognized enzymes. The optimum pH for intestinal aminopeptidase activity is approximately 8.

DIPEPTIDASES. The dipeptidases of intestinal mucosa have relatively little action on polypeptides but split dipeptides rapidly. They have not been very well characterized. They presumably supplement the action of the other peptide-splitting enzymes present. Ereptic enzymes similar to those just described are found not only in intestinal mucosa but in many other plant and animal tissues as well. Some proteinases are likewise found in the intestinal mucosa. Through the combined action of all of these enzymes protein is finally split to the stage of individual amino acids. The ereptic enzymes have little or no action on native proteins.

Carbohydrases: Suchase. The three carbohydrases suchase, maltase, and lactase are also important enzymes of the intestinal mucosa. The suchase acts upon suchose and inverts it with the formation of glucose and fructose. Suchases may also be obtained from several vegetable sources. For investigational purposes suchase is ordinarily obtained from yeast (see p. 288). Intestinal suchase has an optimum pH of 5 to 7; yeast invertase acts best at pH 4.5.

Lactase. This enzyme splits lactose with the consequent formation of glucose and galactose. Freshly prepared suspensions of intestinal mucosal tissue are much more active than water extracts, or the intestinal juice, indicating that the activity is intimately associated with the mucosal cells. The optimum pH for intestinal lactase is about 5.4 to 6.0.

MALTASE. This enzyme possesses the power of splitting maltose, the end-product of the digestion of starch by amylase, into glucose. Maltase is best prepared from yeast. Its optimum pH is 6.7–7.2.

Enterokinase. This substance is discussed in Chapter 16. It is not a digestive enzyme but activates the tryptic enzymes.

Phosphatase. The phosphatase of the intestinal mucosa acts upon nucleotides, glycerophosphates, and hexosephosphates liberating inorganic phosphate and the organic component (nucleosides, glycerol, or hexose). Apparently but a single phosphatase is involved in these reactions. A similar phosphatase is also found in many other tissues of the body. The decomposition of nucleic acids which are not affected by gastric or pancreatic digestion apparently requires the presence in the intestinal juice of a polynucleotidase which breaks the nucleic acids up into simple nucleotides which are then acted upon by phosphatase. A nucleosidase which decomposes purine nucleosides into a carbohydrate group and purine bases is found in the intestinal juice. Pyrimidine nucleosides appear to be absorbed unchanged but are decomposed by enzymes found in various tissues. Phosphatase of the intestinal mucosa has an optimum pH of about 8.6.

GENERAL EXPERIMENTS ON INTESTINAL DIGESTION

Preparation of Intestinal Extract: Wash a piece of hog intestine about 18 inches long. Run through a meat chopper, or, better, scrape off the mucosa

with a knife or piece of glass. Rub in a mortar with sand. Add 5 volumes of water and a little chloroform and let stand at room temperature for 24 hours. If necessary to expedite laboratory work the extract may be used after two hours. Strain through cloth or loose cotton. This extract may be used for the general experiments on phosphatase, ereptic enzymes, and sucrase. The presence of some mucosal cells in suspension increases the enzyme activity.

EXPERIMENT ON INTESTINAL PHOSPHATASE

1. Demonstration of Action of Intestinal Phosphatase on Nucleic Acid and on Sodium Glycerophosphate: Prepare a 2 per cent solution of yeast nucleic acid with the aid of just sufficient dilute NaOH to make the resulting solution pink to phenolphthalein (pH 8.6). Then prepare a 2 per cent solution of sodium glycerophosphate and make just pink to phenolphthalein. To each of four test tubes add 10 ml. of the intestinal extract prepared as above. Boil two—(b) and (d)—for one to two minutes. To tubes (a) and (b) then add 10 ml. of the 2 per cent nucleic acid solution and to tubes (c) and (d) 5 ml. of the glycerophosphate solution. Add 2 to 3 ml. each of toluene and chloroform to each mixture. Keep at 38° C. for 24 hours.

Heat the tubes to boiling in a water bath to coagulate protein. Add 5 ml. of 5 per cent HCl and allow to stand for one hour. This precipitates any unchanged nucleic acid. Filter and take aliquots of the filtrate (about 10 ml.). Precipitate the phosphate from each mixture by adding 5 ml. of magnesia mixture and 5 ml. of ammonia. Allow to stand over night. A heavy precipitate of magnesium ammonium phosphate should be found in the tubes (a) and (c), indicating that the phosphoric acid of the nucleic acid and of the glycerophosphate had been liberated by the phosphatase of the intestinal extract. The control should show only a slight precipitate.

EXPERIMENTS ON PEPTIDASES

- 1. Demonstration of Peptidase Activity: To about 5 ml. of a 1 per cent solution of peptone in a test tube add about 10 ml. of the intestinal extract prepared as described above. Prepare a second tube containing a like amount of pentone solution but boil the intestinal extract before introducing it. Place the two tubes at 38° C. for two to three days. At the end of that period heat the contents of each tube to boiling, filter, and try the biuret test on each filtrate. In making these tests care should be taken to use like amounts of filtrate, sodium hydroxide, and copper sulfate in each test in order that the drawing of correct conclusions may be facilitated. The contents of the tube which contained the boiled extract should show a deep pink color with the biuret test, due to the peptone still present. On the other hand, the biuret test upon the contents of the tube containing the unboiled extract should be negative or exhibit, at the most, a faint pink or blue color, signifying that the peptone, through the influence of the intestinal extract, has been transformed, in great part at least, into simple peptides and amino acids which do not respond to the biuret test. To other portions of the filtrates add a few drops of bromine water. A violet color indicates free tryptophane and hence that amino acids have been liberated. Proteinase in the extract changes the peptone to polypeptides. The latter are broken down by aminopeptidase to simple peptides which under the action of dipeptidase yield amino acids. The action of several enzymes is thus involved.
- 2. Demonstration of Dipeptidase Using Glycyltryptophane: Introduce 5 ml. of glycyltryptophane solution into each of two tubes. To one add 5 ml. of intestinal extract, to the other 5 ml. of boiled extract. Let stand over night. Add a few drops of bromine water to each. A violet color indicates free tryptophane and hence the presence of dipeptidase.

- 3. Quantitative Determination of Dipeptidase: To 25 ml. of 0.05 N glycylglycine add NaOH to pH 8. Warm to 37° C. Add enzyme solution. Carry out a formol titration on an aliquot at once (control) and repeat at intervals. Choose a determination representing less than 30 per cent digestion. Calculate k in: $k = 1/t \cdot \log a/(a x)$. Activity equals k/g, enzyme preparation.
- 4. Separation of Peptidases (Dipeptidase and Aminopeptidase) by Adsorption Methods: The procedure involves removal of tryptic enzymes and subsequent separation of peptidases using ferric hydroxide. For general discussion see p. 285.
 - a. Preparation of Original Extract: Wash thoroughly some hog intestine and scrape off the mucosa. Rub up 100 g. of mucosa in a mortar with 500 ml. of glycerol (87 per cent). This extract keeps for months. Take 50 ml. of this extract which has stood at room temperature for one day, add 150 ml. of water, pour at once into centrifuge tubes and whirl for 5 minutes at 4000 revolutions per minute.
 - b. Concentration by Acetic Acid Precipitation: To each 100 ml. of supernatant fluid from above add 10 ml. of 0.1 N acetic acid and centrifuge.
 - c. Separation of Trypsin by Alumina Adsorption: To each 100 ml. of supernatant fluid from second centrifugation add 1 ml. of N potassium acetate (to give pH 4.7-5.0) and 20 ml. of alumina suspension Cγ containing 150 to 170 mg. Al₂O₃. Centrifuge and wash the precipitate twice with 100-ml. portions of 20 per cent glycerol. Then digest with 50 ml. of 0.1 M Na₂HPO₄ containing 20 per cent glycerol (about pH 8.2) and centrifuge. The supernatant fluid contains the peptidases but no trypsin.
 - d. Separation of Peptidases (Aminopeptidase and Dipeptidase): To 80 ml. of supernatant fluid from either (b) or (c) above add 3 ml. of N acetate buffer pH 3.8 (pH of solution 4.0) and 10 ml. of ferric hydroxide suspension (320 mg. Fe₂O₃). Centrifuge. To 75 ml. of supernatant fluid add 5 ml. more of ferric hydroxide suspension. Centrifuge. Treat 65 ml. of supernatant fluid again with 4 ml. of ferric hydroxide. Keep the mixtures cool with ice during the above treatments. The supernatant fluid contains aminopeptidase.
- 5. Separation of Dipeptidase from Iron-adsorbate: To the first precipitate from d (using 10 ml. of ferric hydroxide suspension), add 25 ml. of 1 per cent Na,HPO, solution containing 20 per cent glycerol. Stir well, let stand, and centrifuge. The fluid is neutralized and filtered. It contains dipeptidase with a trace of aminopeptidase. The dipeptidase activity may be tested as above or on dl-leucylglycine and aminopeptidase on dl-leucyl-diglycine.

EXPERIMENTS ON CARBOHYDRASES

1. Demonstration of Sucrase: To about 5 ml. of a 1 per cent solution of sucrose, in a test tube, add about 1 ml. of intestinal extract, prepared as described above, and a few drops of chloroform. Prepare a control tube in which the intestinal extract is boiled before being added to the sugar solution. Let stand for 24 hours. Heat the mixture to boiling to coagulate the protein material, filter, and test the filtrate by Benedict's test (see p. 57). The tube containing the boiled extract should give no response to Benedict's test, whereas the tube containing the unboiled extract should reduce the Benedict's solution. This reduction is due to the formation of glucose and fructose from the sucrose through the action of the enzyme sucrase which is present in the intestinal epithelium.

For the preparation of Vegetable Sucrase see p. 288.

2. Demonstration of Lactase and Maltase: Repeat the above experiment but use 1 per cent solutions of lactose and maltose. Is there any evidence of lactase and maltase activity?

¹See p. 286.

Bile

Secretion of Bile. The bile is secreted continuously by the liver and passes into the intestine through the common bile duct which opens near the pylorus. This process is continuous even during prolonged fasting, provided there is no obstruction. The ingestion of food, however, increases the secretion. Meat is effective in this respect, fat less so, while starch and sugar appear to be without effect.

Introduction of acid into the duodenum stimulates bile formation, suggesting that secretin is responsible. However, injection of secretin preparations, while leading to a copious secretion of pancreatic juice in one to three minutes, produces a much slighter secretion of bile and then only after seven to nine minutes. Ligation of the pancreatic vein prevents this action on the liver, hence it is suggested that some metabolic product of the pancreas is responsible.

Bile salts absorbed from the intestine have a marked power to stimulate bile formation. The passage of bile directly from the liver or through the emptying of the gallbladder serves to induce a further secretion. Dehydrocholic acid is an especially effective cholagogue.

Mechanism of Emptying of the Gallbladder. There appear to be at least two mechanisms active in gallbladder emptying. One of these involves the contraction of the gallbladder and the other the tone of the sphincter of Oddi at the entrance of the common bile duet into the intestine. Cream or egg yolk cause an emptying of the gallbladder apparently by inducing an active contraction of this organ, probably accompanied by a relaxation of the sphincter at the same time. The active agent is the free fatty acid liberated on digestion of these foods. The organic acids of fruits and the gastric acid have the same effect. In cases of acute cholecystitis, fats, acid fruits, and meats which stimulate acid secretion in the stomach should therefore be reduced in the diet in favor of cereal foods. The contraction is apparently brought about through liberation from the intestinal mucosa of a hormone, cholecystokinin, whose chemical nature is not yet determined. Magnesium sulfate promotes evacuation by causing a dilation of the sphineter.

Functions of the Bile. We may look upon the bile as an excretion as well as a secretion. In the fulfillment of its excretory function it passes such substances as lecithin, metallic compounds, cholesterol, and the decomposition products of hemoglobin into the intestine and in this way aids in removing them from the organism. As a secretion, the bile assists materially in the digestion and absorption of fats from the intestine by its emulsifying action on the fats of the diet and by facilitating the absorption of the fatty acids formed by the action of the pancreatic juice.

A decreased appetite for fats has been shown in rats after the ligation of the common bile duct. A further important function of the bile is to aid in the absorption of vitamin K. Symptoms of vitamin K deficiency frequently accompany the absence of an active secretion of bile into the intestine.

Composition of Bile. The bile is a ropy, viscid fluid which is usually alkaline in reaction (pH 7.8), and ordinarily possesses a decidedly bitter taste. It varies in color in the different animals, the principal variations being yellow, brown, and green. Fresh human bile from the living organism ordinarily has a vellow-brown or golden-yellow color. Postmortem bile is variable in color. It is very difficult to determine accurately the amount of normal bile secreted during any given period. For an adult man it has been variously estimated at from 500 ml. to 1100 ml. for 24 hours. The specific gravity of the bile varies between 1.010 and 1.040 and the freezing point is about -0.56° C. As secreted by the liver, the bile is a clear, limpid fluid which contains a relatively low content of solid matter. This secretion has a specific gravity of approximately 1.010. After it reaches the gallbladder, however, it becomes mixed with mucous material from the walls of the gallbladder, and this process coupled with the continuous absorption of water and certain other components from the bile has a tendency to concentrate the secretion. Therefore the bile as we find it in the gallbladder ordinarily possesses a higher specific gravity than that of the freshly secreted fluid. The specific gravity under these conditions may run as high as 1,040. There is a decrease in inorganic salts due to absorption, while the concentration increases the content of organic substances. Even though it is concentrated in the gallbladder, the bile remains practically isotonic with the blood because the increased content of high molecular weight bile salt ions is accompanied by a decrease in chloride and bicarbonate ions. The pH of bladder bile may fall as low as 6, as compared to the definitely alkaline reaction of fistula bile.

The principal organic constituents of the bile are the salts of the bile

QUANTITATIVE COMPOSITION OF HUMAN BILE (PARTS PER 1,000)

Constituent	Fistula Bile	Bladder Bile
**************************************		-1
Water	976.0	860.0
Solids	24.0	140.0
Bile acids.	5.7	53.7

Total lipids	2.9	18.8
Fatty acids		8.5
Neutral fat	0.8	1.5
Cholesterol	0.8	5.7
Phosphatides	0.5	2.2
Inorganic matter	7.4	8.5

acids, bile pigments, neutral fats, lecithin, phosphatides, nucleoprotein,

BILE 371

mucin, and cholesterol. Inorganic constituents include chiefly sodium, chloride, and bicarbonate, with some phosphate, sulfate, potassium, calcium and magnesium. The metals iron, copper and zinc are also frequently present in detectable amounts. The bicarbonate content of hepatic bile is higher than that of serum; the chloride content of bile is lower than in serum, the chloride ion being replaced largely by the organic bile salt ions.

The quantitative composition of bile varies according to the source of the bile, i.e., whether the bile for analysis is obtained from the gallbladder or by means of a fistula before it reaches the gallbladder. The variation in the composition of these two types of bile is shown in the table of selected analyses on page 370.

Bile Acids. The bile acids are elaborated exclusively as far as known by the hepatic cells of vertebrates. They may be divided into two groups: (1) the glycocholic acid group and (2) the taurocholic acid group. In human bile glycocholic acids predominate while taurocholic acids are more abundant in the bile of earnivora. The glycocholic acids are combinations through peptide linkage of cholic acids and glycine NH₂·CH₂·COOH. The taurocholic acids are similar combinations of cholic acids with taurine NH₂·CH₂·CH₂·SO₃H. Taurine is evidently derived in the body from cysteine.

There are several varieties of cholic acids and therefore there are several forms of glycocholic and of taurocholic acids depending upon the nature of the cholic acid entering into the combination. The principal cholic acids are (1) cholic acid C₂₄H₄₀O₅ with three hydroxyl groups; (2) desoxycholic acid C₂₄H₄₀O₄ with two hydroxyl groups; (3) anthropodesoxycholic acid and (4) hyodesoxycholic acid which are isomeric with desoxycholic acid, differing only in the position of one hydroxyl group; and (5) lithocholic acid C₂₄H₄₀O₃ which has a single hydroxyl group. Human bile contains the first three of these in the proportion of about three parts of cholic acid to one part each of desoxycholic and anthropodesoxycholic acids. Ox bile contains about 6 parts per 100 of cholic acid and about one-eighth as much desoxycholic acid. Hyodesoxycholic acid is found in hog bile and chenodesoxycholic acid (identical with anthropodesoxycholic acid) in the bile of the goose and chicken. The cholic acids are closely related in structure to cholesterol and are probably formed in the body from cholesterol. See the structural formulas for cholic and desoxycholic acids.

Cholic acid (3, 7, 12-Trihydroxycholanic acid)

Desoxycholic acid (3, 12-Dihydroxycholanic acid)

The bile acids are present in the bile largely as sodium salts. The sodium glycocholate and taurocholate may be isolated in crystalline form, either as balls or rosettes of fine needles or in the form of prisms having ordinarily four or six sides (Fig. 110). The bile salts are readily soluble

Fig. 110. Bile salts.

in water. The free acids are slightly soluble in water but readily soluble in alcohol.

The bile acids have the property of combining with fatty acids to form compounds which have been called choleic acids. Fatty acids containing 16 or more carbon atoms combine with 8 molecules of bile acid, the lower fatty acids with from 6 to 1 molecules. These compounds are soluble and diffusible in alkaline or slightly acid solution. For this reason, and because they markedly lower the surface tension in solution and thus promote emulsification, the

bile acids greatly assist in the digestion and absorption of fat in the intestines. Through similar combinations they likewise assist in the absorption of cholesterol, fat-soluble vitamins, carotene, and other substances. They are also responsible for holding the cholesterol of the bile in solution. In these compounds secondary valences are apparently involved.

There is considerable evidence that the bile acids are used over and over again by the body. After secretion into the intestine, that fraction of the bile salts which is reabsorbed as choleic acid complexes is liberated in the intestinal mucosa. The bile salts set free, as well as any which have been absorbed as such, are carried to the liver in the portal circulation, where they become available for re-secretion in the bile. This has been called the enterohepatic circulation of the bile salts. It is presumably responsible in part for the marked stimulatory (choleretic) power of the bile salts themselves on bile flow from the liver, since when the bile salts reach the liver they provide that organ with a readily available supply of a major constituent of the bile itself.

BILE 373

Bile Pigments. The pigments of normal bile are bilirubin and biliverdin (dehydrobilirubin). The green color predominating in certain biles as ox bile is due to biliverdin. Other types of bile like human bile commonly show the yellow color of bilirubin. Modifications of these pigments may be found in gallstones or in altered bile.

The bile pigments result mainly from the breakdown of the hemoglobin of the red cells; a consideration of the structures of the bile pigments (p. 374) indicates that they are derived specifically from the heme

portion of hemoglobin (see Chapter 22). Other heme derivatives in the body- such as catalase, the cytochromes, etc.—may contribute to a certain extent to bile pigment formation. The formation of bile pigments occurs chiefly in the liver, but to some extent also in the spleen and other tissues. Wherever extravasation of blood occurs, as following bruises, a conversion of blood hemoglobin to bile pigment slowly takes place. This conversion is apparently going on even

Fig. 111. Bilirubin. (Ogden.)

in normal red cells, since small amounts of bile pigment have been isolated from this source.

The first step in the formation of bile pigments appears to involve an oxidative seission of the porphyrin ring, to produce carbon dioxide and an open-ring compound. In this process the iron is not necessarily lost from the molecule, nor does the open-ring compound lose its affinity for globin. One such compound of globin and an open-ring iron porphyrin derivative is called choleglobin, by analogy to hemoglobin, and other compounds analogous to those found in the field of heme chemistry are known. In general, these pigments are green in color, hence the names verdohemin, verdohemoglobin, verdohemochromogen, etc., and the opening of the porphyrin ring has apparently rendered the iron labile, so that it is easily split off by such means as treatment with dilute acid Further steps in bile pigment formation are obscure; apparently the iron and the globin become detached in some way to produce biliverdin, which may then be reduced to form bilirubin.

Further stages in the transformation of bile pigments involve the action of intestinal bacteria. In the intestinal lumen, bilirubin undergoes reduction by bacterial action to form the substance mesobilirubinogen. This compound ordinarily is further reduced to form stercobilinogen, which on oxidation becomes converted into stercobilin, the principal pigment of normal feces. Stercobilin has been produced in the laboratory from mesobilirubinogen by incubation of the latter with normal feces, or with bile-free feces plus added bile. A portion of the stercobilinogen and stercobilin is apparently absorbed from the intestinal tract and reexcreted by the liver; thus some gets into the blood stream and ultimately is excreted by way of the kidneys into the urine. In the urine

these two pigments are known respectively as urobilinogen and urobilin. Considerable confusion has resulted from the nomenclature of these compounds; at the present time it appears to be largely a question of different names for the same substances. Normally the amounts of urobilinogen and urobilin in urine are rather small, and obviously depend upon such factors as the rate of pigment production and re-absorption, and upon the efficiency of the liver in excreting the re-absorbed material. Thus the urobilinogen content of the urine will be low in simple anemias, but high in diseases associated with extensive blood destruction and where liver function is impaired.

The chemical relationship between certain of the various bile pigments and their derivatives is illustrated by the following structures: (Me = CH_3 ; Et = C_2H_5 ; X = CH_2 ·COOH).

Bilirubin is insoluble in water but its alkali salts are soluble. It is soluble in chloroform and somewhat in alcohol, but very slightly in ether or benzene. Biliverdin is insoluble in water, ether, or chloroform, but soluble in alcohol. The calcium salts of the pigments are insoluble in water. Solutions of bilirubin exhibit specific light absorption only at the extreme blue end of the spectrum, where the band merges into the end of the

BILE 375

visible spectrum and is not ordinarily detectable as a discrete band in the spectroscope. If an ammoniacal solution of bilirubin-alkali in water is treated with a solution of zinc chloride, however, it shows bands similar to those of bilicyanin (Absorption Spectra Plate I), the two bands between C and D being rather well defined. When bilirubin is treated with diazotized sulfanilic acid, this reagent couples with bilirubin to form a deeply colored azo dye, known as azobilirubin or azorubin. This reaction is the basis for the Van den Bergh test for bile pigments and is also used in the quantitative determination of bilirubin in biological fluids (see Chapter 23).

Biliary Calculi (Biliary Concretions, Gallstones). Biliary calculi. otherwise designated as biliary concretions or gallstones, are frequently formed in the gallbladder. These deposits may be divided into five classes. (1) cholesterol calculi, (2) cholesterol-calcium calculi, (3) cholesterolcalcium-pigment calculi, (4) calcium-pigment calculi, and (5) calculi made up almost entirely of inorganic material. This last class of calculus is formed principally of the carbonate and phosphate of calcium and is rarely found in man although quite common to cattle. The calcium-pigment calculus is also found in cattle, but is more common to man than the inorganic calculus. This calcium-pigment calculus ordinarily consists principally of bilirubin in combination with calcium; biliverdin is sometimes present in small amount. The cholesterol calculus is the one found most frequently in man. These may be formed almost entirely of cholesterol, in which event the color of the calculi is very light, or they man contain more or less pigment and inorganic matter mixed with the cholesterol, which tend to give calculi of various colors.

Our knowledge of the origin of gallstones is imperfect. Among the factors concerned may be stagnation of bile, disturbances of metabolism, and infection. Cholesterol is held in solution in bile by means of bile acids. If cholesterol excretion is increased or bile salt excretion diminished, cholesterol stones may form. Prolonged stagnation of bile may work in the same direction if the bile salt concentration is reduced by their resorption from the bladder. The resorption of alkaline bile salts tends also to decrease the pH of the bile and thus to reduce the solvent action of the bile salts on cholesterol, which is greater in alkaline than in acid solutions. Infection, with or without stagnation, provides abundant nuclei for stone formation, and chemical alterations in the bile favor the formation of cholesterol-calcium-pigment stones. The impairment in the concentrating power of the mucosa due to inflammation, through failure to keep the bile salt concentration sufficiently high, may also be a factor.

Okey¹ reports the finding of gallstones in guinea pigs being used for the study of effects of high cholesterol diets. The stones occurred only when cholesterol and riboflavin were added to diets containing 25 per cent protein, and were not found when the riboflavin concentration was decreased.

For a discussion of cholesterol see Chapter 11, Nervous Tissue.

EXPERIMENTS ON BILE²

1. Reaction: Test the reaction of fresh ox bile, using suitable indicator paper.
What is the approximate pH of bile?

 Nucleoprotein and Bile Acids: Acidify 5 ml. of bile with acetic acid, drop by drop. Note the formation of a precipitate of nucleoprotein and bile acids.

- 3. Inorganic Constituents: Evaporate 10 ml. of bile to dryness in an evaporating dish. Fuse the residue with an excess of sodium carbonate-potassium nitrate "fusion mixture." Cool, extract with 10 ml. of water, and add sufficient concentrated nitric acid to make the extract slightly acid. Filter, and test the filtrate for chloride, sulfate, and phosphate (see Chapter 28).
- 4. Preparation of Bilirubin from Bile: 500 ml. of bile from surgical drainage patients or 50 ml. of postmortem gallbladder bile (diluted two to three times) are allowed to stand for a few hours in the refrigerator and the supernatant fluid decanted. This is diluted several times with water and 5 per cent barium chloride solution is added with stirring. If the precipitate of barium bilirubinate does not flocculate immediately, add a few drops of 10 per cent NaOH. When the precipitate settles the supernatant fluid is siphoned off. The precipitate is poured on a filter, washed with water on the paper, dried, and pulverized in a mortar. The powder is extracted with warm alcohol, followed by ether and chloroform and again air-dried. The precipitate is transferred to a 50-ml. centrifuge tube, moistened with 10 per cent sulfuric acid, and washed three times in a little absolute alcohol, centrifuging and pouring off the alcohol each time. The residue is twice treated in a flask with boiling chloroform, filtered, and the chloroform evaporated, avoiding overheating toward the end. The bilirubin so obtained is rubbed into glacial acetic acid, centrifuged, the acid drained off, and the procedure repeated; the residue is air-dried. It is redissolved in boiling chloroform, filtered and evaporated to dryness. The final product (40 to 100 mg.) is brick red in color, free from ash, and quite stable.
- 5. Tests for Bile Pigments. Practically all of these tests for bile pigments are based on the oxidation of the pigment, by a variety of reagents, with the formation of colored derivatives, e.g., mesobilirubin (yellow), mesobiliverdin (green to blue), and mesobilicyanin (blue to violet).
- a. Gmelin's Test: To about 5 ml. of concentrated nitric acid in a test tube carefully add 2 to 3 ml. of diluted bile so that the two fluids do not mix. At the point of contact note the various colored rings: green, blue, violet, red, and reddish-yellow. Repeat this test with different dilutions of bile and observe its delicacy.
- b. Rosenbach's Modification of Gmelin's Test: Filter 5 ml. of diluted bile through a small filter paper. Introduce a drop of concentrated nitric acid into the cone of the paper and note the succession of colors as given in Gmelin's test.
- c. Huppert's Test: To 10 ml. of bile solution add 5 ml. of milk of lime (a suspension of Ca(OH), in water). Mix well and filter. The pigment is carried down as a compound with the calcium hydroxide. Put a clean test tube under the funnel and to the residue on the filter carefully add about 10 drops of concentrated HCl so as to dissolve the calcium hydroxide as completely as possible and set free the pigment, which remains on the filter paper. Pour 10 ml. of alcohol on the filter and let drain into the tube. Warm the filtrate in the test tube in a water bath. A green color in the solution indicates bile pigment.

*See Appendix.

² For experiments on the function of bile salts which may be carried out in this connection see Chapter 19, Intestinal Absorption.

- d. Van den Bergh Test: To 5 ml. of diluted bile, add 2 ml. of freshly prepared Ehrlich's diazo reagent. Compare with a control on water alone. In this reaction, the compound azobilirubin (or azorubin) is formed by coupling of bilirubin with the diazotized sulfanilic acid of the Ehrlich reagent. This reaction is the basis for qualitative and quantitative procedures for estimation of bile pigments in blood serum. (See Chapter 23.)
- 6. Test for Bile Acids:
 - a. Furfural-H₂SO₄ Test: Mylius's Modification of Pettenkofer's Test: To approximately 5 ml. of diluted bile in a test tube add 3 drops of a very dilute (1:1000) aqueous solution of furfural:

Now run about 2 to 3 ml. of concentrated sulfuric acid carefully down the side of the tube and note the red ring at the point of contact. Upon shaking the tube the whole solution is colored red. Keep the temperature of the solution below 70 C. by cooling in running water during the mixing. b. Foam Test (v. Udránsky): To 5 ml. of diluted bile in a test tube add 3 to

Fig. 112. Cholesterol. (Courtesy, Dr. C. A. Bachhuber.)

4 drops of a very dilute (1:1000) aqueous solution of furfural. Place the thumb over the top of the tube and shake the tube until a thick foam is formed. By means of a small pipet add 2 to 3 drops of concentrated sulfuric acid to the foam and note the dark pink coloration produced.

- c. Gregory and Pascoe Test: To 1 ml. of dilute bile solution add 6 ml. of 45 per cent H₂SO₄ and 1 ml. of 0.3 per cent furfural solution. Stopper loosely and put in a water bath at 65° C. for 30 minutes. The presence of bile acid is indicated by a blue color in the solution. This test may be used as a quantitative method.
- d. Surface Tension Test (Hay): This test is based upon the principle that bile acids have the property of reducing the surface tension of fluids in which they are contained. The test is performed as follows: Cool about 10 ml. of diluted bile in a test tube to 17° C. or lower and sprinkle a little finely pulverized sulfur upon the surface of the fluid. The presence of bile acids is indicated if the sulfur sinks to the bottom of the liquid. Prove this point by repeating the test with water instead of bile.

7. Crystallization of Bile Salts: To 25 ml. of undiluted bile in an evaporating dish add enough animal charcoal to form a paste and evaporate to dryness on a water bath. Remove the residue, grind it in a mortar, and transfer it to a small flask. Add about 50 ml. of absolute alcohol and boil on a water bath for 20 minutes. Filter, and add ether to the filtrate until there is a slight permanent cloudiness. Cover the vessel and set it aside until crystallization is complete. Examine the crystals under the microscope and compare them with those shown in Fig. 110. Try one of the tests for bile acids upon some of the crystals.

8. Analysis of Biliary Calculi: Grind the calculus in a mortar with 10 ml. of

ether. Filter.

Filtrate I.

Add an equal volume of 95 per cent alcohol⁵ to the ether extract, allow the mixture to evaporate and examine for *cholesterol* crystals (Fig. 112). (For further tests see p. 261.)

Filtrate II.

Test for calcium, phosphates, and iron. Evaporate the remainder of the filtrate to dryness in a porcelain crucible and ignite. Dissolve the residue in dilute hydrochloric acid and make alkaline with ammonium hydroxide. A blue color indicates copper.

Residue I.
(On paper and in mortar.)

Treat with dilute hydrochloric acid and filter.

Residue II.
(On paper and in mortar.)
Wash with a little water.
Dry the filter paper.

Treat with 5 ml. of chloroform and filter.

Filtrate III. Residue III.

Bilirubin. (On paper and in mortar.)

color)

Treat with 5 ml. of hot alcohol.

Biliverdin. (Green color)

- 9. Preparation of Taurine: Add 50 ml. of concentrated hydrochloric acid to 150 ml. of bile in a casserole. Boil the mixture in the hood down to a volume of about 50 ml., filter into a small evaporating dish to remove insoluble material, and concentrate the filtrate by boiling or on the water bath to a volume of about 10 ml. Filter the hot solution through a small filter into a 50-ml. graduated cylinder. If the volume is over 12 ml., return the filtrate to the evaporating dish, continue the evaporation, and filter a second time through the same filter. To the filtrate add 3 volumes of 95 per cent alcohol, mix, and cool in ice water for about 30 minutes. Filter off the crystals on a small funnel, allow to drain thoroughly, then transfer the crystals to a test tube and dissolve by warming in about 3 ml. of water. Add 5 volumes of alcohol and allow to stand until maximal crystallization has occurred. Filter off the pure crystals, wash with 5 ml. of alcohol, and allow to dry. Make the following tests upon the taurine just prepared:
 - a. Examine under the microscope. Compare with Fig. 113, p. 379.

The alcohol is added because it is often found that orystallization from pure other does not yield typical cholesterol orystals.

- b. Solubility in water and alcohol.
- c. Dissolve a little taurine in water and test this solution for sulfate by adding dilute hydrochloric acid and a few drops of barium chloride solution. Is any sulfate present? Boil the solution for a few minutes. Does taurine contain any ethereal sulfate (sulfate hydrolyzable by acid)? To another portion of taurine solution add sodium hydroxide, a few drops of lead acetate, and boil. Is any "lead blackening" sulfur present?
- d. Fuse a little taurine in a porcelain crucible with sodium carbonatepotassium nitrate "fusion mixture." When the crucible contents are
 colorless, cool, dissolve carefully by the addition of dilute hydrochloric
 acid, filter into a test tube, and add barium chloride solution. What
 happens? Explain. What do these experiments indicate concerning the
 nature of the sulfur in taurine?

Fig. 113. Taurine.

Fig. 114. Glycine. (See also Fig. 41.)

10. Preparation of Glycine: Concentrate the first alcoholic filtrate from Exp. 9 until no more alcohol remains. The glycine is present here in the form of a hydrochloride and may be liberated from this combination by the addition of freshly precipitated lead hydroxide or by lead hydroxide solution. Remove the lead from the filtrate by treatment with hydrogen sulfide. Filter and decolorize the filtrate by animal charcoal. Filter again, concentrate the filtrate, and set aside for crystallization. Glycine separates as colorless crystals (Fig. 114). See also pp. 118 and 119.

Intestinal Absorption

Mechanism of Absorption. Absorption is primarily a function of the small intestine. Very little absorption takes place from the stomach and the process is nearly complete before the colon is reached. The small intestine is particularly adapted to carry on this process by virtue of its great length (about 9 meters in man) and by the structure of its mucous membrane. The surface of the latter is greatly increased (to a total area of about 10 square meters) by the presence of folds and of fingerlike processes called villi. The latter possess a rich blood supply, lymph spaces called lacteals, and muscle fibers whose contractions mechanically assist absorption. The mucous membrane through which substances must pass to enter the blood or lymph is extremely thin, but it must not be forgotten that it consists of living cells.

Substances in solution tend to distribute themselves uniformly throughout the solvent, and this tendency, which we measure as osmotic pressure, is a powerful force. Undoubtedly osmosis may play some role in the absorption of certain substances which may be present in the intestine in far higher concentrations than in the blood. There is much evidence, however, that the process is rarely one of simple diffusion.

The facts with regard to the absorption of ionic substances (salts, amino acids, etc.) have been made much more intelligible by the development of the Donnan theory of membrane equilibria. This explains how it is possible for ionic diffusion to be more or less selective and how certain ions may pass into the blood although present there in higher concentration than in the intestinal lumen.

Even with this extension, however, it is not yet possible to explain many phenomena of absorption on a purely physical basis. Not only do the regulatory powers of the cell and its changing structure influence the course of diffusion processes but it seems probable that certain substances in their passage enter into chemical combination with constituents of the protoplasm thus making possible different types of selective transportation. Furthermore white blood cells actually migrate back and forth between the lymph and the lumen of the intestine. There is evidence that certain of these may actually engulf particles of iron compounds and fat droplets. One of their functions may thus be to assist by phagocytosis in the absorption of difficultly soluble substances. Their number is hardly adequate to permit their playing a large role in the absorption of foodstuffs; however, their accumulation in the intestinal mucosa during digestion would indicate that their function is an important one.

The intestinal mucous membrane further possesses the power of excreting certain substances into the gut. Sucrose injected into the blood stream appears in part in the duodenum and calcium salts are eliminated by the

mucosa of the large intestine. The glands of the mucosa secrete a digestive fluid, the intestinal juice, and the cells themselves contain enzymes such as proteinases and peptidases, carbohydrases, and phosphatases which help to prevent the passage of incompletely decomposed proteins, carbohydrates, and organic phosphates into the blood.

Because of the many factors involved, the study of intestinal absorption offers certain difficulties. Investigation of the processes concerned helps, however, to throw light on permeability and other fundamental properties of protoplasm. It is further of the greatest practical importance to understand the factors governing the absorption of the many essential foodstuffs, and to determine the conditions under which there is a loss of the great protective power of the intestinal mucosa to detoxicate or prevent the absorption of toxic substances, which may be ingested or produced during digestion or putrefaction.

Absorption of Carbohydrates. Carbohydrates are absorbed almost entirely as the simple monosaccharides, glucose, fructose, and galactose, each having a characteristic absorption rate. Of the disaccharides, lactose is least readily hydrolyzed in the intestine and some of it occasionally reaches the blood as such. In these cases it is eliminated unchanged in the urine. Sucrose entering the blood is also excreted as such. When strong sugar solutions enter the bowel they are diluted by the intestinal secretion until the concentration is reduced to a point favorable for absorption; i.e., when the osmotic concentration equals that of the blood plasma. Lactose, because of its slow digestion and absorption, reaches a much lower portion of the bowel than other sugars and is thus more effective in promoting the growth of acidophilic rather than putrefactive bacteria.

The simple sugars entering the blood are quite rapidly removed therefrom by the liver and other tissues for oxidative and storage purposes. After the ingestion of 100 g, of glucose a maximum blood sugar value of about 0.15 per cent is reached in less than an hour, the normal figure of about 0.1 per cent being restored by the end of two hours. The height and duration of the blood sugar rise is relatively independent of the size of the administered dose, indicating that absorption of glucose is not primarily influenced by differences in concentration between the intestinal lumen and the blood.

If the intestinal mucous membrane is destroyed, or poisoned by such a substance as sodium iodoacetate, it acts like an ordinary permeable membrane and sugars pass through it according to ordinary laws of diffusion. Thus the pentoses pass through more rapidly than the hexoses. With the normal living membrane, however, the hexoses show more rapid absorption. Apparently the hexoses are combined with phosphate in passing through the cells of the mucous membrane. The formation of this compound greatly speeds up the absorption process and makes possible absorption even from a sugar solution of lower concentration than the blood. The intervention of chemical mechanisms of the living cell also makes possible a certain selectivity in absorption, and an adaptation of the mucous membrane in the direction of self-protection of the body against rapid absorption of toxic substances.

Absorption of Protein. Protein is absorbed in the form of individual amino acids. The amino acid content of both portal and systemic blood rises after a meal. The amino acids of the diet entering the body are carried by the blood to all the tissues of the body where they rapidly become incorporated into the metabolic processes of the cells and become indistinguishable from the amino acids already present unless they have been labeled in some way, as with isotopic nitrogen, which is the way these facts were discovered. Thus the dietary amino acids are not to be regarded as somewhat of a surplus, as they were at one time, to be drawn upon or oxidized as the need arose, but rather as a daily contribution to the general processes of nitrogen metabolism in the body (see Chapter 33).

A variable and sometimes significant proportion of the dietary amino acids escape absorption and are metabolized by the bacteria of the intestinal tract. The products of this action may be absorbed and appear in the blood or urine. The relatively high ammonia content of portal blood is attributed to these processes, as is the indican content of the urine. The significance of such intestinal putrefaction is discussed in Chapter 20.

That incompletely decomposed protein may sometimes be absorbed is indicated by the production in certain individuals of anaphylactic reactions (cutaneous eruptions, asthma, etc.) following the ingestion of particular types of protein. Such reactions are not produced by completely hydrolyzed proteins.

Absorption of Fat. Hydrolysis is essential for the absorption of fats. There is no good evidence that unhydrolyzed fat is absorbed in appreciable amounts. Mineral oil is nonhydrolyzable and is not absorbed to any significant degree although experiments have demonstrated that some absorption may occur when the oil is in an extremely fine state of emulsification.

The glycerol formed in fat hydrolysis is very soluble in water and is readily absorbed. On the other hand, the fatty acid products of hydrolysis are quite insoluble in water, and even in the form of their alkali salts, the soaps, a nondiffusible colloidal complex is formed. Yet it has been known for a long time that soaps are readily absorbed from the intestine; how, then, does this process occur? The answer to this question appears to lie in the concomitant presence of the bile, and especially the bile salts. In animals such as the rabbit, where the bile duct enters the intestine considerably below the entrance of the pancreatic duct, it can be seen by direct observation that the lymph vessels of the mesentery do not indicate by a milky appearance (chyle) the appreciable absorption of fat from the intestine until after the point where the bile enters the intestine. It is known that the presence of bile facilitates digestion of fats by pancreatic lipase; it appears undisputed that the bile likewise aids in the absorption of digested fats. This is indicated, among much other evidence, by the appearance of large amounts of fats and fatty acids in the feces when the bile duct is obstructed. According to Verzár, the bile salts form a loose and not too well characterized compound (the "choleic

acid" of Wieland) with the fatty acid products of digestion, the resulting substance being readily diffusible, even in vitro across artificial membranes, and this accounts for the absorbability of digested fat. The chief effect here seems to be on the state of aggregation and diffusibility of the colloidal soaps; the relation between intestinal pH and the ratio of insoluble fatty acid to the more soluble soap has been overstressed and erroneously interpreted.

The prompt appearance of neutral fat in the intestinal lymphatics during fat absorption indicates that the products of fat digestion are recombined in the intestinal mucosa, presumably by a reversal of the processes of fat hydrolysis. There is considerable evidence that the mucosal phospholipids are concerned in the resynthesis of fat. Feeding of fats containing suitably labeled fatty acids (e.g., elaidic acid, the isomer of oleic acid) results in the prompt appearance of the labeled fatty acid in the phospholipid fraction of the intestinal mucosa, without increase in the total phospholipid content. This indicates a rapid turnover of the fatty acid portion of the phospholipid molecule, and may be interpreted to signify that phospholipids act as intermediates in the resynthesis of fats in the mucosal cells (Sinclair). The absorption of fat is favored by the presence of unsaturated linkages and relatively short chain fatty acids. The character of the fat is also somewhat modified during the process of absorption so as to more nearly resemble the body fat of the animal.

After resynthesis, the greater part of the fat first enters the lacteals of the intestinal villi and then the lymphatics, forming an emulsion (the chyle) which is carried via the thoracic duct to the jugular vein. An increase in the fat content of the blood and lymph following a meal ("fat tide") is readily demonstrated, the fat appearing in the form of minute globules called chylomicrons. The fat of the diet is therefore unique among the other components of the diet in that in large part it "by-passes" the liver. The significance of this anatomical arrangement is not clear, but it may possibly be related to the recognized ability of liver tissue to oxidize fatty acids rapidly to the stage of acetoacetic acid and β -hydroxybutyric acid.

Absorption of Sterols. Cholesterol, like the fatty acids, forms compounds with the bile acids which facilitate its absorption. Unabsorbed cholesterol is reduced to coprosterol. It is uncertain whether this change to coprosterol is brought about solely through bacterial action. The plant sterol phytosterol is not absorbed and hence cannot become a source of cholesterol in the animal body. Ergosterol is said to be absorbed but slightly if at all, while the irradiated form (calciferol) is more readily absorbed. Apparently the absorption of sterols is very specific, so that even isomerism may alter absorbability, while saturation of unsaturated bonds may change a sterol from a readily absorbable substance to one completely unabsorbable. Of the many sterols found in plant or animal foods, the only one which is absorbed in the human intestine, aside from the D vitamins, is cholesterol. Certain forms of vitamin D are absorbed to different degrees in different species.

Absorption of Inorganic Salts. The selective nature of absorption applies even to inorganic salts. Thus sulfates are much less readily absorbed than chlorides and tend to withdraw water from the blood. For this and other reasons the sulfates have a cathartic effect. The absorption of calcium and phosphorus is of especial interest because of its relation to the development of rickets and because this absorption can be so profoundly affected by minute amounts of antirachitic vitamin and hence by ultraviolet radiation. The acidity of the intestinal contents is also of importance for the absorption of the relatively insoluble salts of calcium. Dietary iron appears to be absorbed only when it is in the ionized inorganic form, and clinical and experimental evidence indicates that ferrous iron is much more available for absorption than ferric iron; organic iron, such as in hemoglobin, is not absorbed at all. Calcium, magnesium, phosphorus, and iron are excreted to a considerable extent by the intestinal mucosa. Hence a study of their absorption at different levels of the intestinal tract is required for an understanding of the factors involved. The absorptive power of the colon for food substances is relatively low.

Methods of Studying Absorption. Much of our information on absorption has been obtained from the study of isolated intestinal loops which retain their nerve and blood supply. Solutions can be injected into such loops and the contents removed at any time for analysis. The relative rates of absorption of various substances can thus be determined under controlled conditions. Small animals such as the rat may be sacrificed after the ingestion of test substances, the intestinal tract removed, washed out, and the washings then analyzed to establish the extent of absorption.

Histological examination of the mucosa of animals killed after a meal has shown the presence of fat globules in the cells.

By establishing fistulas of the intestine the course of absorption in different parts of the tract has been studied.

Analysis of the blood and lymph gives information of great importance relative to the nature of the products entering the blood stream. Urine analyses show the rapidity with which soluble inorganic salts are absorbed. Transfusion experiments on the intestine are little used because a normal mucous membrane is difficult to maintain. Studies on absorption from the stomach may be made with a stomach tube and a similar procedure may give some information as to absorption from the colon. Fecal analyses show the completeness of digestion and absorption of various substances present in the food.

Animals may also be fed a diet containing a definite amount of a non-absorbable substance such as iron oxide, or a labelled component such as elaidic acid or compounds containing the isotopes of hydrogen, phosphorus, nitrogen, iron, or carbon. By suitable analyses of the intestinal contents and the other parts of the animal body the rate and extent of absorption may be evaluated. The use of isotopes in particular appears to offer great promise in elucidating the mechanism of absorption. For a discussion of isotopes, see Chapter 34.

EXPERIMENTS ON ABSORPTION

- 1. Experiment to Show the Action of Bile Salt Solutions on Fatty Acids and Cholesterol: Prepare five test tubes as follows:
 - a. Five ml. of buffer solution pH 7 + 2 ml. of a 10 per cent solution of bile salts + 1 ml. of a 1 per cent solution of oleic acid in alcohol.
 - b. Five ml. of buffer solution pH 7 + 2 ml. of water + 1 ml. of 1 per cent oleic acid solution.
 - c. Five ml. of buffer solution pH 9+2 ml. of water +1 ml. of 1 per cent oleic acid solution.
 - d. Five ml. of water + 2 ml. of 10 per cent bile salt solution + 1 ml. of a 0.05 per cent solution of cholesterol.
 - e. Five ml. of water + 2 ml. of water + 1 ml. of cholesterol solution.

Place all tubes in a water bath at 40° C. for a few minutes and observe the tubes for turbidity.

Fatty acids form a clear soap solution only at pH 9 or higher. With bile salts a clear and diffusible solution is formed even below pH 7. Bile salts also have a similar action on cholesterol. This is important also in connection with the excretion of cholesterol in the bile.

- 2. Determination of Rupidity of Absorption of Sugars from the Entire Gastrointestinal Tract: Method of Cori:
 - **Principle:** Animals are given sugar solutions by a stomach tube. After a suitable time has elapsed the animals are killed, the entire gastrointestinal tract removed, and the total sugar remaining unabsorbed determined.

Procedure: Rats two to three months old and weighing from 120 to 189 g. are weighed. They are then placed in small wire screen cages with screen bottoms so that there is no access to feces. For 48 hours they are given water but no food. The rats are again weighed and are then fed the solutions to be tested, usually 1.25 to 2.5 ml. of 25 to 89 per cent sugar solutions. These are introduced by means of stomach tubes consisting of Nos. 4 to 5 urethral catheters softened by plunging for a moment into boiling water. A small mouthpiece is used and the catheter marked to indicate the depth to which it should be introduced. A syringe of the Record type with a needle to connect with the catheter is used to inject the fluid. If diarrhea is caused the experiment is discarded.

An animal is killed at each hourly interval. The entire gastrointestinal tract is removed, slit open, and washed thoroughly with water making up to a volume of nearly 500 ml. A small amount of dialyzed iron is added and then a little sodium sulfate to precipitate it, along with interfering substances. The sugar is determined by the Benedict method or some other method. Blood sugar may also be determined by the Hagedorn-Jensen method or other micro method. Sugar may also be determined in the urine. (In another experiment it may be shown by analysis of the gastric contents that a dilution of the sugar solution takes place in the stomach.) The amount of sugar absorbed per 100 g, of body weight of the animals is calculated. An absorption curve may also be plotted from the results obtained with similar animals at 1, 2, 3, 4, etc., hours. Cori found that the rate of absorption of hexoses is independent of the concentration, and the rates of absorption of some monosaccharides are in the following order: galactose > glucose > fructose > mannose > xylose > arabinose. No glucose appeared in the urine but about 50 per cent of the galactose was excreted by this channel.

If a soluble ferric salt such as ferric ammonium citrate is added to the sugar solutions it is possible to determine in what parts of the tract digestion and absorption of carbohydrates, etc., more particularly occur (see the experiment below).

The tolerance of animals for sugars injected intravenously may also be determined and an idea obtained as to the rapidity with which sugars are

absorbed when injected intravenously as compared with absorption from the intestine. Cori found the tolerance for glucose given intravenously to be from 2.2 to 2.5 g. per kilo of body weight per hour.

3. Influence of Carbohydrates on the Utilization of Calcium and Phosphorus:
Method of Bergeim:1

Principle: To a standard diet is added a definite proportion of iron oxide and of the carbohydrate whose effect it is desired to study. The ratios of calcium and phosphorus to iron are determined for foods and feces and the percentage absorption calculated. The accurate separation of feces of the experimental period is not necessary.

Procedure: Feed two or more albino rats (about 60 g. in weight) on a phosphorus-low and calcium-high diet (whole yellow corn 76, wheat gluten 20, calcium carbonate 3, sodium chloride 1, and c.p. ferric oxide 0.2) for about three weeks. Put in separate cages with screen bottoms. Collect feces for a five-day period. Then modify the diet of the animals by substituting glucose for 30 parts of corn in one case, and an equal amount of lactose in the other. After a two-day interval, collect the feces for a period of four days. Then exchange diets so that the first animal gets lactose and the second glucose. After a two-day interval collect feces again over a four-day period. All feces need not be collected. Those contaminated with urine are discarded.

About 0.5 g. (not weighed) of feces from each collection is ashed preferably in a 35-ml. silica crucible at a moderate temperature. Add a few drops of nitric acid to the residue and heat again to destroy the last carbon. Add 10 ml. of 15 per cent hydrochloric acid and heat until the ash is dissolved. Wash into a flask with water to make about 35 ml. Ash 2 g. of food and dissolve the ash in the same way. Determine iron, calcium, and phosphorus in the ash solutions by standard methods (see Chapters 23 and 32) and record the number of mg. of each in 1 ml. of ash solution.

Calculate the ratios Ca/Fe and P/Fe for food and feces, and calculate percentage absorption or utilization of Ca and P. For example, if the ratio Ca/Fe for food is 10:1 and in feces 4:1, unabsorbed Ca is 4/10 or 40 per cent and utilization is 100-40=60 per cent.

Lactose promotes calcium absorption by creating an acid medium (lactic acid) in the intestines. Glucose has little effect. Vitamin D markedly improves absorption of Ca and P.

the gastrointestinal tract see Bergeim: J. Biol. Chem., 70, 47 (1926); Arch. Internal Med., 37, 110 (1926).

Putrefaction and Detoxication

PUTREFACTION

General. The food residue and the digestive and other secretions as they pass into the lower ileum and colon are acted upon by the bacterial flora which becomes permanently established in man during the first few days of life. The extent of bacterial activity is indicated by the fact that nearly one-third of the solid matter of normal feces is made up of bacteria.

The enzymes present in and produced by these microörganisms break down some of the undigested polysaccharides, proteins, and other complex compounds. The end-products from carbohydrate breakdown are usually innocuous, whereas many of the compounds resulting from the decomposition of proteins are toxic. The latter fact has given rise to the assumption that when the rate of production and absorption of these products is increased above normal as in constipation, a condition of autointoxication is produced which is characterized by malaise, headache, irritability, and other symptoms.

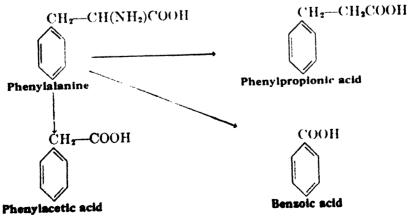

It is now believed that many of these disagreeable effects of constipation may be due to mechanical factors and that the psychic element may at times also play a dominant role. It is very probable too that allergic reactions may account for some of the symptoms ascribed to specific toxins. Nevertheless, it is an established fact that physiologically potent substances are produced by the intestinal bacteria, and that the organism is protected against these by a system of defenses known as the detoxication mechanisms.

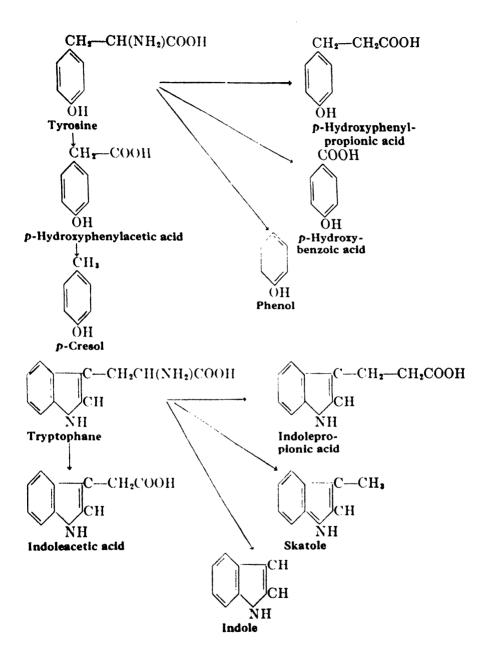

Deamination and Decarboxylation. It is most probable that the bacteria first decompose the protein into α -amino acids by a process much the same as that employed by the proteolytic enzymes of normal digestion. Some of the amino acids thus liberated are either directly decarboxylated—i.e., lose the CO_2 from the carboxyl group and become converted to primary amines—or are reductively deaminized and changed to fatty acids which, if they contain the aromatic nucleus, are ultimately exidized to benzoic or phenylacetic acids.

$$R-CH_{2}-COOH \stackrel{-NH_{2}}{\longleftarrow} R-CH(NH_{2})-COOH \stackrel{-CO_{2}}{\longrightarrow} R-CH_{2}-NH_{2}$$

By the action of the carboxylase bacteria on arginine, lysine, phenylalanine, tyrosine, tryptophane, and histidine, the following amines are formed:

The second type of putrefaction process, namely, the formation of acids, is much more common, but fortunately much less toxic. The aliphatic amino acids are of little importance in this connection, so that only the more important aromatic acids will be represented, showing the progressive steps in their disintegration:

Toxicity of Products of Putrefaction. Of the numerous compounds formed as the result of putrefactive processes, only a few are sufficiently toxic to exert any marked systemic effect. The ones that have the strongest physiological action are the amines, especially those derived from the amino acids containing the aromatic and other cyclic structures. Pentamethylenediamine (cadaverine) and tetramethylenediamine (putrescine), which are classed as ptomaines since they can be isolated from putrefying flesh, are, in spite of their offensive names, relatively harmless. The condition known as ptomaine poisoning is due to bacterial toxins and not to these amines.

Tyramine and histamine possess powerful physiological actions. Tyramine is closely related to adrenaline both in structure and in action. It is a vasoconstrictor and elevates blood pressure. Histamine causes powerful capillary dilatation and permeability. It constricts smooth muscle and stimulates various glandular secretions. Histamine is formed not only by bacterial action in the intestines, but is produced in the body and appears definitely to function as a hormone. It appears likely that it is one of the physiological agents that stimulate the secretion of hydrochloric acid in the stomach. In peptone and anaphylactic shock relatively large amounts are suddenly released into the circulation. The quantity absorbed from the intestinal tract is small compared to that which the body can and does produce in these types of shock.

Of the putrefactive products other than amines, indole and skatole, which are derived from tryptophane, have received much attention. Both possess a disagreeable odor and are mainly responsible for the characteristic odor of feces, and perhaps for the "bowel breath" sometimes observed in intestinal toxemia. The daily excretion of 10 to 20 mg. of indican (indoxyl potassium sulfate) under normal conditions indicates that considerable indole is absorbed. Not all of the urinary indican is necessarily of exogenous origin, since the excretion is markedly elevated in carcinoma of the liver. The content of indole and skatole in the feces is much higher than the quantity absorbed, and it is questionable whether the small amount that enters the body causes any harmful effects.

Phenol, p-cresol, and allied compounds are distinctly toxic, but since the quantities produced are relatively small and since the elimination occurs with much dispatch it seems quite likely that no definite harm to the body, either immediate or remote, can be ascribed to these compounds, provided the defense mechanism is not impaired. The aromatic acids, particularly benzoic and phenylacetic acids, are entirely innocuous. Only a small portion of the benzoic acid excreted in the urine (as hippuric acid) comes from putrefaction; most of it is derived from quinic acid which is present in many fruits, especially cranberries and prunes.

Some of the bacterial products formed in the intestines are distinctly useful to the body. It is probable that a considerable portion of the required amount of vitamin K comes from the action of E. coli and other intestinal bacteria; and evidence is accumulating that other vitamins may be similarly synthesized. Due to these findings the normal bacterial flora is no longer regarded as a menace to health, but rather as an important auxiliary factor to nutrition.

DETOXICATION

In its broadest sense, the detoxication mechanisms include all reactions that actively protect the body against lethal agents, but for practical purposes the immunological reactions against specific bacterial toxins must be considered separately, and this subject is beyond the scope of this text. Discussion will therefore be limited to the purely chemical reactions employed by the body against toxic substances.

Detoxication begins in the intestines. For example, much of the histamine is destroyed in the alimentary canal which contains a specific enzyme, histaminase, for this purpose. The intestinal wall serves as a barrier to many harmful products. Those absorbed are carried to the liver where much of the detoxifying work is done. Other organs such as the kidney also contain enzymatic mechanisms utilized for inactivating noxious compounds. The principal reactions in detoxication are oxidation and conjugation, but to a minor extent reduction and hydrolysis are also employed. There is no valid evidence that these reactions have been developed specifically for detoxication. It seems more reasonable to suppose that they are normal metabolic reactions which the body can apply to foreign substances—i.e., to compounds not utilized for normal physiological processes.

Detoxication consists largely either in the destruction of a toxic compound or in changing a chemical group which is highly active physiologically to one which is less so. Another factor which must be considered, however, is that the end-products of detoxication almost invariably possess a much higher acidity than the original compound. The ionization constant of hippuric acid (2.3×10^{-4}) is considerably greater than that of benzoic acid (6.5×10^{-5}) . Quick¹ has postulated that an important factor in detoxication is the conversion of a weakly acidic substance which the body excretes with difficulty to a relatively strong acid which readily can be eliminated by the kidney. A strong acid consequently requires no conjugation, and this probably accounts for the fact that mandelic acid (ionization constant 4.3×10^{-4}) is readily excreted unchanged.

¹ Quick: J. Biol. Chem., 97, 403 (1932).

Oxidation, Reduction, and Hydrolysis. The first attempt of the body to protect itself against a toxic compound is to destroy it by oxidation. Many substances such as ethyl alcohol are completely burned to carbon dioxide and water. Sometimes the intermediary oxidation products are more toxic than the original compound as illustrated by methyl alcohol which yields formaldehyde and formic acid.

The oxidation of aromatic compounds is of great physiological importance. Benzene itself, as well as many simple aromatic compounds such as benzoic acid and phenol, are fairly resistant to oxidation. Certain side chains, particularly the groups CH2CH(NH2)COOH which occurs in phenylalanine and CH₂CO·COOH render the aromatic nucleus completely oxidizable. This suggests that oxidative deamination is the initial step in the metabolism of amino acids.

$$\begin{array}{c} C_6H_5CH_2CH(NH_2)COOH \,+\,O \to C_6H_6CH_2COCOOH \,+\,NH_3 \\ \hline Phenylalanine & Phenylpyruvic acid \end{array}$$

Of particular interest is the oxidation of phenyl-substituted fatty acids. Oxidation takes place on the β -carbon atom, and the side chain is progressively reduced by two carbon atoms so that ultimately the aromatic acids having a side chain with an odd number of carbon atoms yield benzoic acid and those with an even number yield phenylacetic acid.

$$\begin{array}{cccc} C_6H_5CH_2CH_2CH_2COOH \to C_6H_5CH_2COOH \to C_6H_5COOH \\ \hline Phenylvaleric acid & Phenylpropionic & Benzolc acid \\ C_6H_5CH_2CH_2COOH \to C_6H_5CH_2COOH + CH_3COOH \\ \hline Phenylbutyric & Phenylacetic & Acetic acid \\ \hline acid & acid & acid & acid \\ \hline \end{array}$$

From these observations Knoop formulated the hypothesis that normal fatty acids are likewise catabolized by β -oxidation (see Chapter 33).

The introduction of a carboxyl group into the benzene ring is one of the most effective means of reducing toxicity. Thus, the addition of the COOH group to phenol produces salicylic acid, a nontoxic compound. Toluene which the body oxidizes to benzoic acid is less toxic than benzene which yields on oxidation phenol, polyphenols, and muconic acid.

Reduction is rarely employed as a direct means of detoxication since the reduced compounds are usually more toxic than the oxidized derivatives. One of the best known reduction reactions serving as a means for detoxification is the conversion of aldehydes to alcohols which can then be conjugated. In the body chloral hydrate is reduced to trichloroethyl alcohol which is combined with glucuronic acid.

Hydrolysis may function in the elimination of foreign or noxious compounds. For example, acetylsalicylic acid (aspirin) is broken down in the body to acetic acid which is oxidized and salicylic acid which is excreted. Many glucosides such as the digitalis compounds are hydrolyzed with the liberation of a sugar and the aglycone as the first step in their metabolism and elimination.

Combination or Conjugation. The coupling of a compound, which resists the oxidative processes of the body, with a normal metabolic compound constitutes a primary defense mechanism. The organism utilizes a variety of substances for conjugation: glycine, glucuronic acid, sulfuric acid, cysteine, glutamine, acetic acid, ornithine, and the methyl group. Of these, the first three are used most extensively by the mammals and especially by man.

GLYCINE (GLYCOCOLL). Glycine or glycocoll is readily synthesized by the animal from other amino acids in the body or diet. An adult human can produce approximately 0.5 to 0.65 g. per hour. The liver is the important site of this synthesis, and in various diseases of this organ the production of glycine is greatly inhibited thus causing a marked reduction in the output of hippuric acid. This finding has led to the utilization of the hippuric acid excretion as a test of liver function.² The site of the conjugation of benzoic acid with glycine is not sharply localized; in the dog the coupling mechanism is present only in the kidney, but in man and in the rabbit the liver appears to be the important site of conjugation. Exogenous glycine can readily be utilized for conjugation by man, rabbit, and rat.³ In the latter the evidence was obtained by the use of isotopic nitrogen.

³ Schoenheimer, et al.: J. Am. Chem. Soc., 59, 1768 (1937).

GLUCURONIC ACID. Glucuronic acid is utilized by the body for the conjugation both of aromatic acids and of phenols and tertiary aliphatic alcohols. The linkage between glucuronic acid and phenols or alcohols is of the glucoside type which can be split by acid hydrolysis. With benzoic acid, the union is through one of the hydroxyl groups of the lactone structure forming 1-benzoylglucuronic acid. This compound in weak alkaline solution shows a marked change in rotation without hydrolysis. thus simulating true mutarotation. By more vigorous treatment with alkali it is completely hydrolyzed. The main source of glucuronic acid is the carbohydrate store in the body, but it can also be derived from glucogenic amino acids. The completely diabetic dog can synthesize glucuronic acid from the glucose fraction which would otherwise be excreted. Insulin increases the production of glucuronic acid in the dog. Lactic acid and pyruvic acid stimulate the production of glucuronic acid by surviving liver slices which suggests that the compound is built from three carbon chains. Free glucuronic acid is metabolized with difficulty and cannot be utilized by the organism for conjugation.

SULFURIC ACID. Sulfuric acid is combined with phenols and the resulting products are known as ethereal sulfates. Indican, which is the common name for indoxylsulfuric acid (see Chapter 28), is one of the best known members of this class of compounds. It is still uncertain whether the organism can utilize inorganic sulfates for the conjugation. It appears, however, that the ethereal sulfates are formed largely at the expense of endogenous catabolism, hence are always limited in amount and not a satisfactory index of intestinal putrefaction.

⁷ Shiple, Muldoon, and Sherwin: J. Biol. Chem., 60, 59 (1924).

GLUTAMINE. Glutamine is used by the human⁸ and by the chimpanzee⁹ for the detoxication of phenylacetic acid. All other animals so far studied combine phenylacetic acid with glycine. Oddly, substituted phenylacetic acids in man are conjugated with glycine and not with glutamine.

Cysteine. 10 Cysteine is employed for the detoxication of hydrocarbons such as bromobenzene¹¹ and naphthalene.¹² There is subsequent acetylation of the amino group of the cysteine resulting in the formation of a mercapturic acid. The synthesis of mercapturic acids has also been observed in humans.

Ornithine is employed by the fowl for the detoxication of benzoic acid. 13 Ornithine can be synthesized in the organism from arginine and proline, and possibly other amino acids (see Chapter 33 for further discussion).

ACETIC ACID. Acetic acid is combined with the aromatic amino group and also with the amino group of cysteine in the formation of mercapturic acids. In the physiological compound acetylcholine, acetylation of a hydroxy group occurs; no analogous detoxication reaction in vivo has as yet been recorded. The acetylation of p-aminobenzoic acid and of sulfanilamide and its derivatives is of particular interest. While the conjugation destroys the therapeutic effectiveness, it does not greatly diminish their toxicity.

METHYLATION. With the recognition that transmethylation is playing an important role in metabolism, it may well be that methylation as a type of conjugation has been underestimated. The reaction appears to be limited to compounds containing the pyridine ring. Nicotinic acid is in part methylated to form trigonelline (the methyl betaine of nicotinic acid) and in part is conjugated with glycine to form nicotinuric acid.

The conjugation of nicotinic acid is difficult to interpret as a detoxication measure since the compound is the antipellagra vitamin. It must therefore be considered as a normal and essential food accessory and not as a toxic substance. The conjugated products, trigonelline and nicotinuric acid, lack antipellagra potency.

The detoxication mechanisms vary with different species. Thus man conjugates benzoic acid almost entirely with glycine while the dog combines it mainly with glucuronic acid. The acetylation of p-aminobenzoic acid and sulfonilamide occurs in man and rabbit, but does not take place in the dog. The conjugation processes are also affected by other factors, particularly chemical structure. Any group in ortho position to the carboxyl radical inhibits the coupling of the latter with glycine. Thus, little salicylic acid is combined with glycine and excreted as salicyluric acid. Substitution in the ortho position also influences the conjugation of the COOH group with glucuronic acid; an acidic radical such as a halogen or a nitro group inhibits, whereas the basic amino group stimulates the production of glucuronic acid in the dog. The relation of the detoxication mechanisms to normal metabolic processes has received scant

¹⁴ Quick: J. Biol. Chem., 67, 477 (1926).

¹⁸ Quick: J. Biol. Chem., 96, 83 (1932).

attention. No explanation has been offered for the inhibitory action of sodium benzoate and sodium phenylacetate on the excretion of uric acid.

The observations that estriol is combined and excreted as estriol-glucuronic acid¹⁶ and that progesterone is eliminated as pregnandiol glucuronide¹⁷ suggest the possibility that the conjugation mechanisms may function in the regulation of hormones.

EXPERIMENTS ON PUTREFACTION AND DETOXICATION

TESTS FOR PRODUCTS OF PUTREFACTION

INDOLE AND SKATOLE

- 1. Herter's β -Naphthoquinone Reaction: To 10 ml. of unknown solution add 2 drops of 2 per cent solution of β -naphthoquinone sodium monosulfonate and 2 ml. of 10 per cent NaOII. Let stand 15 minutes. Shake with 2 ml. of chloroform. A pinkish-red color in the chloroform indicates indole. This is a very delicate test.
- 2. Ehrlich's p-Dimethylaminobenzaldehyde Reaction: To 10 ml. of unknown solution add 1 ml. of 5 per cent alcoholic solution of p-dimethylaminobenzaldehyde and 1 ml. of concentrated HCl. Indole gives a red color and skatole a blue color.
- 3. Nitroso-indole Reaction: Acidify the mixture with nitric acid and add a few drops of KNO₂ solution. Indole gives a red color and skatole a white turbidity.

PHENOLS, HYDROXY AROMATIC ACIDS, AND IMIDAZOLES

1. Conjugation with Glucuronic Acid and Glycine:

Principle. When man ingests anisic acid (p-methoxybenzoic acid), approximately 50 per cent is conjugated with glucuronic acid (ester linkage) and the remainder with glycine.¹⁸

Procedure: 3 g. of anisic acid are neutralized exactly with 10 per cent sodium hydroxide using phenolphthalein as the indicator. The solution is dlluted to 30 ml. and ingested. 200 ml. of water are drunk. The subject voids immediately after taking the drug, and then collects complete hourly specimens for three hours. Each specimen is measured and its reducing action tested by mixing five drops with 5 ml. of Benedict's qualitative sugar reagent in a test tube and heating. The glucuronic acid can also readily be determined quantitatively by using Benedict's quantitative sugar method. The remainder of the sample is acidified with 1 ml. of concentrated hydrochloric acid and stirred to precipitate p-methoxyhippuric acid. Inoculation with a small crystal of the compound will hasten precipitation. The crystalline product is filtered by suction, washed with a small amount of cold water, and dried. From the weight of the product plus the amount calculated that remained in solution (100 ml. of urine dissolve 0.24 g. of p-methoxyhippuric acid), the quantity of anisic acid which is conjugated with glycine can be calculated. If glycine or gelatin is taken with anisic acid, the amount of p-methoxyhippuric acid is greatly increased.

2. Hanke and Koessler's p-Diazobenzenesulfonic Acid Reactions: These tests are used for the detection and quantitative determination of histidine, histamine, and other imidazoles (giving a pink color), phenol, o- and

¹⁴ Cohen and Marrian: Biochem. J. 36, 57 (1936).

¹⁷ Venning and Brown: Proc. Soc. Exptl. Biol. Med., 34, 792 (1936).

¹¹ Quick: J. Biol. Chem., 97, 408 (1982).

¹⁶ Hanke and Kossaler: J. Biol. Chem., 39, 497 (1919); 50, 285, 271 (1929); 59, 808 (1934); 64, 475 (1925).

m-cresol (yellow color), p-cresol, p-oxyphenylpropionic, p-oxyphenylacetic and p-oxyphenyllactic acids (red color), and tyrosine and tyramine (blu-

ish-red on adding hydroxylamine).

To 5 ml. of 1.1 per cent sodium carbonate solution add 2 ml. of p-diazo-benzenesulfonic acid reagent. (See Appendix.) After 1 minute add 1 ml. of solution to be tested, and mix. Note the color and rapidity with which it develops. For tyrosine and tyramine make strongly alkaline with NaOH and then add a small amount of hydroxylamine hydrochloride solution. For details of separation and determination, see original papers.

3. Millon's Test: Test the material with Millon's reagent. A red color is given by compounds containing the hydroxyphenyl group.

4. Bromine Test: Add a few drops of bromine water. Cresols, phenol, and hydroxy aromatic acids give white precipitates of bromine derivatives.

QUANTITATIVE BROMINATION

Method of Day and Taggard.20.21

Principle: Phenol, aniline, and many of their derivatives such as hydroxyand amino-aromatic acids are readily brominated. A quantitative replacement of one or more nuclear hydrogens by bromine occurs. From the amount of bromine consumed, the quantity of aromatic compound is calculated.

Procedure: 0.2 g. of p-methoxyhippuric acid obtained in the preceding experiment and purified by recrystallization from hot water is neutralized with sodium hydroxide and diluted to 75 ml. The solution is quantitatively transferred to a 500-ml. glass stoppered bottle, and 25 ml. of 0.2 N bromate solution (75 g. of KBr and 5.6 g. of KBrO; per liter) are added. The solution is acidified with 5 ml. of concentrated hydrochloric acid and shaken for one minute. After 30 minutes the reaction bottle is cooled in ice or under the tap. The stopper is sufficiently dislodged to permit adding 5 ml. of 40 per cent KI solution. Care must be taken to prevent bromine vapor from escaping. The liberated iodine is titrated with 0.1 N sodium thiosulfate using starch solution as indicator. The amount of bromine consumed is calculated from the difference between the number of ml. of thiosulfate required in the titration of the sample and the titration of the blank using 25 ml. of 0.2 N bromate solution.

Calculation: The bromine is supplied by the reaction:

$$KBrO_1 + 5KBr + 6HC1 = 3Br_2 + 3H_2O + 6KC1$$

One molecule of p-methoxyhippuric acid reacts with one molecule of bromine:

$$CH_1OC_0H_1COOH + Br_2 = CH_1OC_0H_1BrCOOH + HBr$$

Each ml. of 0.1 N thiosulfate is equivalent to 0.01045 g. of p-methoxy-hippuric acid.

For the bromine equivalent of other amino and phenolic compounds the original articles of Day and Taggard and of Quick should be consulted.

Feces

General. The feces include the residue remaining in the intestine after the digestion and absorption of food together with products of intestinal secretion, epithelial debris, and bacterial growth and decomposition.

They are composed of the following substances:

- 1. Food residues, i.e., those portions of the food which either escape or are incapable of digestion and absorption.
- 2. The remains of the intestinal and digestive secretions not destroyed or reabsorbed.
- 3. Substances excreted into the intestinal tract, notably salts of calcium, iron, and other metals.
- 4. The bacterial flora of the intestinal tract and their metabolic endproducts.
- 5. Cellular elements to which may be added, under pathological conditions, blood, pus, mucus, serum, and parasites.
 - 6. Abnormally: enteroliths, gallstones, and pancreatic calculi.

The amount of the fecal discharge varies with the individual and the diet. Upon an ordinary mixed diet various authorities claim that the daily excretion by an adult male will aggregate 110–170 g. with a solid content ranging between 25 and 45 g.; the fecal discharge of such an individual upon a vegetable diet will be much greater and may even be as great as 350 g. and possess a solid content of 75 g. In the authors' experience the average daily output of moist feces, calculated on the basis of data secured from the examination of over 1,000 stools, was about 100 g. The variation in the normal daily output is so great that this factor is of very little value for diagnostic purposes, except where the composition of

INFLUENCE OF DIET ON FECAL DRY MATTER

Diel	Dry Matter (Per Cent)
Nursing infant	15.0
Milk Nursing infant	. 28.0
Meat	29.0
Bread	25.0
Potatoes	15.0
Cabbage	
Mixed diet	26 .0

the diet is accurately known. Lesions of the digestive tract, defective absorptive function, or increased peristalsis, as well as an admixture of mucus, pus, blood, and pathological products of the intestinal wall, may cause the total amount of excrement to be markedly increased. An idea of the variation of the percentage of dry matter in the feces, evacuated

after the ingestion of different diets, may be gathered from a consideration of the preceding table.

Fecal Pigments. The principal pigment of the feces is stercobilin which is chemically identical with the urobilin of urine, and like it is formed by oxidation of a chromogen stercobilinogen (or urobilinogen). This explains the darkening of stools upon exposure to air. The primary precursor of these compounds is bilirubin, which is reduced by intestinal bacteria to mesobilirubinogen; in the presence of a factor from bile this intermediate is transformed to urobilinogen or stercobilinogen, according to the relations shown on p. 374. Neither bilirubin nor biliverdin occurs normally in the fecal discharge of adults, although the former may be detected in the excrement of nursing infants. If these pigments are found in the feces of adults, they indicate an abnormally rapid transit through the large bowel, thus preventing their transformation into stercobilingen. The color of the fecal discharge is greatly influenced by the diet. A mixed diet, for instance, produces stools which vary in color from light to dark brown, an exclusive meat diet gives rise to a brownishblack stool, whereas the stool resulting from a milk diet is invariably light colored. Drugs and certain pigmented foods, such as cocoa, beets,

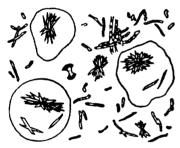

Fig. 115. Hematoidin crystals from acholic stools. (v. Jaksch.) Color of crystals same as the color of those in Fig. 111.

the chlorophyllic vegetables, and various varieties of berries, each afford stools having a characteristic color. This is well illustrated by the occurrence of yellow stools following the administration of rhubarb, senna, or santonin, and of red stools following prontosil treatment. The green color of the calomel stool is generally believed to be due to biliverdin. The black stools following the administration of bismuth or iron drugs result from the formation of metallic sulfides or suboxides. In cases of biliary obstruction the absence of pigment and the presence of excess

fat result in the formation of grayish-white acholic stools. Barium meals used in roentgenographic diagnosis impart a clay-white color to the feces.

Odor. Under normal conditions the odor of feces is due to skatole and indole, two substances formed in the course of putrefactive processes occurring within the intestine (see Chapter 20). Such compounds as methyl mercaptan, hydrogen sulfide, and similar substances resulting from bacterial putrefaction may also add to the disagreeable character of the odor. The intensity of the odor depends to a large degree upon the character of the diet, being very marked in stools from a meat diet, much less marked in stools from a vegetable diet, and frequently hardly detectable in stools from a milk diet. Thus the stool of the infant is ordinarily nearly odorless and tends to be rancid rather than putrefactive; it is believed that any decided odor may generally be readily traced to some pathological source.

FECES 401

Reaction. Experiments in which the actual hydrogen-ion concentration of the feces was determined indicate that the normal reaction of the excreta is slightly alkaline (pH 7.0 to 7.5). Pronounced dietary changes, (e.g., low protein diet, high protein diet, fasting, water drinking with meals) produce at most only minor changes in the reaction of the feces. The ingestion of large amounts of lactose may cause the production of an acid reaction.

Consistency. The form and consistency of the stool is dependent, in large measure, upon the nature of the diet. Under normal conditions the consistency may vary from a thin, pasty discharge to a firmly formed stool. Stools which are exceedingly thin and watery ordinarily have a pathological significance. In general the feces of the carnivorous animals are of a firmer consistency than those of the herbivora.

The continued ingestion of a diet which is very thoroughly digested and absorbed is frequently accompanied by the formation of dry, hard, fecal masses (scybala). Constipation generally results from the small bulk of the feces and its lack of moisture. At present the formation of scybala is considered pathological, as an expression of spastic constipation. To counteract this tendency toward constipation the ingestion of agar-agar, psyllium seed, or other vegetable gums is practiced. These are relatively indigestible and readily absorb water, thus forming a bulky fecal mass which is sufficiently soft to permit easy evacuation. Mineral oil, because of its lubricating and softening properties is much used as an aid in overcoming constipation. Though it is inert and practically nonabsorbable, excessive amounts of mineral oil may interfere with the absorption of fat-soluble vitamins.

Separation. It is frequently desirable for clinical or experimental purposes to make an examination of the fecal output which constitutes the residual mass from a certain definite diet. Under such conditions, it is customary to cause the person under observation to ingest at the beginning and end of the period in question some substance sufficiently different in color and consistency from the surrounding feces to render comparatively easy the differentiation of the feces of that period from the

feces of the immediately preceding and succeeding periods. One of the most satisfactory methods of making this "separation" is by means of the ingestion of a gelatin capsule containing about 0.2 g. of powdered charcoal at the beginning and end of the period under observation. This procedure causes the appearance of two black zones of charcoal in the fecal mass. A capsule containing carmine (0.3 g.) may be used in a similar manner and forms two dark red zones. Some similar method for the "separation of

Fig. 116. Charcot-Leyden crystals.

feces" is usually practiced in connection with accurate nutrition or metabolism experiments conducted for the collection of useful data regarding the income and output of nitrogen and other elements.

Macroscopical Examination. Among the macroscopical constituents of the feces may be mentioned the following: Intestinal parasites and

their ova, undigested food particles, gallstones, pathological products of the intestinal wall, enteroliths, intestinal sand, and objects which have been accidentally swallowed.

Microscopical Examination. The fecal constituents which at various times and under different conditions may be detected by the use of the microscope are as follows: (1) Constituents derived from the food, such as muscle fibers, connective-tissue shreds, starch granules, and fat; (2) formed elements derived from the intestinal tract, such as epithelium, erythrocytes, and leukocytes; (3) mucus; (4) pus corpuscles; (5) parasites, and (6) bacteria. In addition to the constituents named the following crystalline deposits occasionally may be detected: cholesterol, coprosterol, soaps, fatty acid, fat, hematoidin, "triple phosphate," Charcot-Leyden

Fig. 117. Microscopical constituents of feces: (A) Intact undigested meat fibers, (B) partially digested meat fibers, and (C) almost completely digested meat fibers.

Fig. 118. Microscopical constituents of feces: (A) Neutral fat, (B) fatty acid liberated by acetic acid, (C) soaps, and (D) fatty acid crystals.

crystals, and the oxalate, carbonate, phosphate, sulfate, and lactate of calcium. (See Figs. 115 to 122.)

The amount and composition of fat excreted by way of the feces is largely independent of food fat but tends to approximate the composition of blood lipids. Fecal fat is largely of endogenous origin, the secreted fat being partially reabsorbed; only to a minor degree does fecal fat come from epithelial debris and bacteria.

About one-third of the fat in normal feces is unsaponifiable. The coprosterol (also called coprostanol) of the feces is similar to cholesterol, and is formed by the reduction of the latter. It contains two more atoms of hydrogen than cholesterol and is thus a saturated alcohol C₂₇H₄₇OH. A small amount of cholestanol, an isomer of coprosterol, is also found in feces. It appears to be formed in the tissues and excreted in the bile. Except for the D vitamins, cholesterol is the only sterol absorbed from the intestine. The phytosterols of plants are not absorbed, being excreted

FECES 403

in the feces. Coprosterol responds to cholesterol color tests and has the same solubility, but possesses a lower melting point and crystallizes in fine needles instead of plates such as cholesterol forms.

Fig. 119. Microscopical constituents of feces: (A) Elastic tissue, (B) white fibrous tissue (macroscopical), and (C) white fibrous tissue (microscopical).

Fig. 120. Microscopical constituents of feces: (A) Cellulose remains of vegetables, (B) empty potato cells, (C) potato cells filled with starch, and stained with iodine, (D) hard cells found in pears, (E) spiral and woody fibers from pith of vegetables, and (F) vegetable hairs.

Fig. 121. Microscopical constituents of feces: (A) Calcium sulfate crystals, (B) cholesterol crystals, (C) charcoal detritus, (D) bismuth suboxide crystals, and (E) calcium oxalate crystals.

Fig. 122. Microscopical constituents of feces: (A) Schmidt test bag for study of pancreatic function, (B) nuclei of meat fibers digested, (C) nuclei of meat fibers undigested, and (D) undigested stained thymus cells.

The fat content of normal feces may vary from 5 to 25 per cent (on a dry basis). Excessive excretion of fat via feces is known as steatorrhea,

a condition due to failure to absorb fat as in enteritis, hepatic disorder, biliary obstruction, celiac disease, or sprue. Excreted fat is partly saponified and may entail loss of calcium, as soap, to the extent of producing pathological demineralization.

Blood in Feces. The detection of minute quantities of blood in the 'feces-so-called occult blood-is an aid to the correct diagnosis of certain disorders. In these instances the hemorrhage is ordinarily so slight that the identification by means of macroscopical characteristics as well as the microscopical identification through the detection of erythrocytes are both unsatisfactory in their results. Of the tests given for the detection of occult blood the benzidine reaction, Lyle-Curtman guaiac procedure and the ortho-tolidin tests are probably the most satisfactory. Since occult blood occurs with considerable regularity and frequency in gastrointestinal cancer and in gastric and duodenal ulcer, its detection in the feces is of especial value as an aid to a correct diagnosis of these disorders. Certain precautions are essential, such as the establishment of a meat-free diet over a period of time before the specimen is collected. (Feces from a meat diet will give an occult blood reaction with some of the most delicate tests.) Bleeding from the bowel such as is seen in hemorrhoids, as well as the admixture of menstrual blood, is to be considered in the interpretation of the result. After the ingestion of 50 ml. of human blood 85 to 95 per cent of the hemoglobin appears as protohemin in the feces.

Bacteria in Feces. It has been quite clearly shown that the intestine of the newly born is sterile. However, this condition is quickly altered and bacteria may be present in the feces before or after the first ingestion of food. There are three possible means of infecting the intestine; i.e., by way of the mouth or anus or through the blood. The infection by means of the blood seldom occurs except under pathological conditions, thus limiting the usual sources to the mouth and anus.

In infants with pronounced constipation two-thirds of the dry substance of the stools has been found to consist of bacteria. In the stools of normal adults probably about one-third of the dry substance is bacteria. The average excretion of dry bacteria in 24 hours for an adult is about 8 g. The output of fecal bacteria has been found to undergo a decrease under the influence of water drinking with meals. There is also a decrease in intestinal putrefaction, a fact which indicates that at least a part of the bacterial deficit is made up of putrefactive organisms. In some cases over 50 per cent of the total nitrogen of feces has been shown to be bacterial nitrogen.

Some of the more important organisms met with in the feces are the following: E. coli, B. lactis aerogenes, Cl. welchii, B. bifidus, and coccal forms. Of these the first three types mentioned are gas-forming organisms. The production of gas by the fecal flora in dextrose-bouillon is subject to great variations under pathological conditions; alterations in the diet of normal persons will also cause wide fluctuations. Data as to the production of gas are of considerable importance in a diagnostic way, although the exact cause of the variation is not yet established. It should be borne in mind in this connection that gas volumes are frequently variable with the

FECES 405

same individual. For this reason it is necessary in every instance to follow the gas production for a considerable period of time before drawing conclusions. While the question of the study of bacterial flora of the feces is somewhat beyond the range of this work, mention may be made here of the character of the organisms observed by Gram-staining of the stool after administration of different types of diet. It has been shown that when the diet is rich in protein, the protein type of flora becomes predominant in the stools. Smears show a fairly equal distribution of Gram-negative and Gram-positive organisms. Among the latter are largely the subtiloid organisms with some of the Cl. welchii, together with a moderate number of diplococci and coccoid forms. Most of the Gram-negative organisms resemble the E. coli. When the diet is carbohydrate the field is strongly Gram-positive and has a more homogeneous appearance. The bacteria seen consist chiefly of long slender Gram-positive rods belonging to the L. acidophilus and B. bifidus groups.

Enzymes in Feces. Various enzymes have been detected in the feces. The first one so demonstrated was pancreatic amylase. The amylase content of the feces has been considered to be an index of pancreatic activity. The excretion of this enzyme has been found to increase under the influence of water drinking with meals. Other enzymes which have been found in the feces under various conditions are trypsin, rennin, maltase, sucrase, lactase, nuclease, and lipase. In an abnormally rapid transit of food through the intestinal tract, such as is seen in certain diarrheas, nearly all of these enzymes may be detected.

Fecal Nitrogen. The nitrogen present in the feces exists principally in the form of (1) bacteria, (2) unabsorbed intestinal secretions and digestive juices, (3) epithelial cells, (4) mucous material, and (5) food residues. In the early days of nutrition study the fecal nitrogen was believed to consist principally of food residues. We now know that such residues ordinarily make up but a small part of the total nitrogen of the stools of normal individuals who exercise normal mastication. When meat has been "bolted," however, from 0.5 to 16 g. of macroscopical meat residues have been found in a single stool. The phrase "metabolic product nitrogen" has been used as a designation for all fecal nitrogen except that present as food residues and bacteria. Bacteria cannot logically be classed under "metabolic" nitrogen since they doubtless develop at the expense of food nitrogen as well as at the expense of that in the intestinal secretions. In the accurate study of protein utilization a correction should be made for metabolic nitrogen. Data regarding the output of metabolic nitrogen may be secured by determining the fecal nitrogen excretion on a diet of proper energy value but containing no nitrogen. However, to prevent tissue catabolism from exceeding its normal level, it is customary in studies of basal nitrogen metabolism to include a minimal percentage of adequate protein in the maintenance diet.

Fasting Feces. Feces are still excreted from the intestine even when no food is ingested. Carefully conducted fasting experiments have demonstrated this. A dog nourished on an ordinary diet to which bone ash has

¹ See Protein Utilisation in Chapter 33.

been added will excrete gray feces. When fasted such an animal will, after a few days, excrete a small amount of a greenish-brown mass, containing no bone ash. These are fasting feces. They are of a pitchlike consistency and turn black on contact with the air. Adult fasting men have been found to excrete 7 to 8 g, of feces per day, the daily nitrogen value being about 0.1 g. No separating medium such as charcoal or carmine (p. 401) should be used in differentiating fasting feces.

Examination for Clinical Purposes. The examination of feces for evidences of parasitism (detection of parasites and their ova), such as hookworm, tapeworm, etc., is of considerable clinical importance. For diagnostic purposes the macroscopical and microscopical examinations of the feces ordinarily yield much more satisfactory data than are secured from its chemical examination. Possibly with the exception of certain examinations for occult blood, the most satisfactory data for diagnostic purposes are secured by microscopical examination. This presupposes a knowledge of microscopical technic and the use of certain microchemical tests, by which much information can be obtained. The principal underlying this examination consists in the study of the actual changes which the various foodstuffs have undergone during digestion. A knowledge of the changes which occur in normal digestion and which are seen in normal feces enables one readily to detect pathological variations. One diet widely used for this purpose is the Schmidt diet. The modification² described below is better adapted to American conditions.

Modified Schmidt Diet

4 o'clock: Breakfast: 250 ml. of milk 100 g. of cream of wheat or oatmeal 60 g, of toast Dinner: 20 g of butter 250 ml. of milk Luncheon: Rice soup (chicken broth with rice) 100 g. of green vegetable (asparagus) 60 g, of toast 100 g, of mashed potato 60 g. of toast 20 g. of butter

250 ml. of milk

150 g. of chopped meat, grilled on the outside and rare in the center 100 g. of green vegetable (spinach) 100 g, of mashed potato

20 g. of butter 250 ml. of milk Stewed fruit

EXPERIMENTS ON FECES

1. Collection and Preservation of Feces (see also Chapter 33): Friction top tin cans may be prepared for the collection of stools by adding a few drops of formalin or alcoholic solution of thymol (from which the alcohol may be evaporated by warming). Stools may be dried directly in these cans. Where glass containers are preferred, pyrex pots with glass lids may be used. To prevent loss of nitrogen sufficient sulfuric acid should be added to render the fecal mixture strongly acid. The contents may be dried on a steam bath in a hood and the residue weighed and powdered for sampling. If nitrogen or mineral analyses are to be conducted, the fresh stools may be mixed with 100 to 200 ml. of water and an equal volume of concentrated H₂SO₄ gradually added while stirring. The homogenized suspension thus collected and preserved throughout the 24 hours may be diluted to volume and an aliquot taken for analysis.

^{*} Used by Dr. Martin E. Rehfuss of Philadelphia.

FECES 407

2. Macroscopical Examination: If the stool is watery pour it into a shallow dish and examine directly. If it is firm or pasty it should be treated with water and carefully stirred before the examination for macroscopical constituents is attempted. The macroscopical constituents may be collected very satisfactorily by means of a double layer of cheesecloth.

A Boas sieve may also be used to collect the macroscopical constituents of feces. This sieve is constructed of two easily detachable hemispheres

which are held together by means of a bayonet catch. In using the apparatus the feces are spread out upon a very fine sieve contained in the lower hemisphere and a stream of water is allowed to play upon it through the opening in the upper hemisphere. The apparatus is provided with an orifice in the upper hemisphere through which the feces may be stirred by means of a glass rod during the washing process. After 15 to 30 minutes of washing nothing but the coarse fecal constituents remain upon the sieve.

3. Microscopical Examination: After the ingestion of the test diet (see Schmidt diet, above) for several days, a specimen of the movement is collected. Any gross abnormalities in the form, consistency, and character of the stool as well as the admixture of certain pathological elements such as pus, blood, mucus, and parasites are recorded. The movement is then rubbed out on plates and examined for undigested food residues. Normally the test diet is almost completely digested and no gross undigested material is found. Therefore the presence of these macroscopical rests is in itself evidence of disturbed diges-

Fig. 123. Boas sieve.

tion. Clean slides and cover glasses are then prepared and a small representative portion of the movement is placed on each of three slides. The routine clinical method of examination follows: To the first slide is added a drop of distilled water and it is then examined with low and high powers.

Meat fibers are readily recognized by their yellowish hyaline appearance possibly with a few striae still visible in the fibers. Should meat fibers be found bound together by connective tissue or should raw connective tissue, either white fibrous or yellow elastic, be noted, it indicates a disturbance of gastric function inasmuch as one of the specific functions of the gastric juice is to dissolve the intercellular tissue binding together the fibers. If large numbers of meat fibers are found after a test diet, particularly if the nuclei are still intact in the fibers, the inference of poor or low pancreatic function is justifiable. This is true if it can be demonstrated that the food has been sufficiently long in its transit through the intestinal tract to permit the pancreatic enzymes to carry on their work. A dilute solution of methylene blue will readily show the nuclei if present.

The second slide is examined for fats and then treated with acetic acid and heated to split any soaps which may be present and form fatty acid.

Fats are met with in three forms: (a) Neutral fats readily demonstrated by Sudan III, Scharlach R, or osmic acid; (b) fatty acids which are usually found in the form of needlelike crystals soluble in ether, alcohol, and solutions of sodium hydroxide (these crystals do not stain with Sudan III but form drops on being warmed); (c) soaps are usually found in the feces either as amorphous flakes or scallop shell-like formations, but may occasionally occur in crystalline form. The calcium soaps which compose the bulk of the soaps in the feces can be distinguished from the potassium and sodium compounds because of their insolubility in hot water, alcohol, and ether. On heating with 30 per cent acetic acid, fatty acids are set free in drops which crystallize out on cooling.

The estimation of fats is a rather important matter and the trained observer can usually detect disturbances in fat digestion. Normally there are fats present

in the movement, but abnormally their quantity is relatively increased either in total fat or in one of its components. While it is true that bacterial activity plays a considerable role in the digestion of fats, a marked increase in fat usually indicates pancreatic disease, or a disturbance in pancreatic function. This is, of course, the case only when the amount of fat ingested is not in excess of that which can be readily handled under normal conditions. In cases of pure biliary obstruction without pancreatic involvement, fat-splitting takes place in a normal way, but the fatty acids and soaps formed are not absorbed owing to the absence of bile. Such a movement is full of soaps and fatty acid crystals and on treatment with acetic acid shows a marked increase in total fat over normal. Failure of absorption owing to extensive disease of the intestinal mucosa can produce a similar picture but will usually give some cytological evidence of intestinal disease. Pure pancreatic disease gives a marked increase in total and neutral fat with the presence of bile.

Undigested starches are readily recognized by their blue reaction with iodine. This can be studied on the third slide.

This phenomenon is the least frequent among the different forms of pathological digestion and usually indicates food bolting, an excessive ingestion of or poor preparation of carbohydrate food, or an infection of the bowel with so-called "garungsdyspepsia" rather than an actual disturbance of pancreatic function inasmuch as the amylolytic function of the pancreas is the most persistent and the last to disappear.

Disturbance in cellulose digestion, the presence of blood, leukocytes, mucus, etc., can all be demonstrated by appropriate technique and represent a chapter in the study of the feces of great diagnostic importance, but one which is beyond the province of this volume. (For further discussion, see p. 402. For illustrations of fecal constituents found microscopically, see Figs. 116 to 122.)

- 4. Reaction: Thoroughly mix the feces and apply moist indicator papers to the surface. If the stool is hard it should be mixed with water before the reaction is taken. Examine the stool as soon after defecation as is convenient, since the reaction may change very rapidly. The reaction of the normal stools of adult man is ordinarily neutral or faintly alkaline to litmus, but seldom acid. Infant's stools are generally acid in reaction. The glass electrode is useful in determining fecal pH since it is not affected by reducing substances commonly present, nor by the presence of solids.
- 5. Starch: If any imperfectly cooked starch-containing food has been ingested it will be possible to detect starch granules by a microscopical examination of the feces. If the granules are not detected by a microscopical examination, the feces should be placed in an evaporating dish or casserole and boiled with water for a few minutes. Filter and test the filtrate by the iodine test in the usual way (see p. 76).
- 6. Blood. Undecomposed blood may be detected macroscopically. If uncertain, look for erythrocytes under the microscope, and spectroscopically for the spectrum of oxyhemoglobin (see Absorption Spectra, Plate I).

In case the blood has been altered or is present in minute amount (occult blood), and cannot be detected by the means just mentioned, the following tests may be tried:

Benzidine Reaction: (a) Make a thin fecal suspension using about 5 ml. of distilled water. Shake with 5 ml. of ether to remove the fat and discard this ether extract. Acidify the residue with acetic acid and extract again with 5 ml. of ether. Pour the acid ether extract into a small evaporating dish. Evaporate to dryness on a hot water bath (with flame turned out). Add a few drops of water, a drop of saturated solution of benzidine in glacial acetic acid and a drop of 3 per cent hydrogen peroxide. A blue or green color indicates the presence of blood.

FECES 409

(b) Slide Modification: Take up a little of the solid stool on a match, smear it on an object glass, and pour the reagent over it. If there is blood present the smear turns blue and there is no misleading green tint from fluid. Make the solution as follows: Add a knife-tip of benzidine to 2 ml. of glacial acetic acid, and add 20 drops of a 3 per cent solution of hydrogen peroxide.

By this dry technique there is no danger of soiling the fingers, and the test is more sensitive than the usual "wet" benzidine test. The smear of stool is either blue or it is not blue. The rapidity of the color change gives some idea as to the proportion of blood in the stool; with much blood present the change to blue is instantaneous.

- 7. Quantitative Determination of Fecal Amylase: Hawk's Modification of Wohlgemuth's Method. See Ninth Edition of this book (p. 325).
- 8. Quantitative Determination of Fecal Bacteria. See Ninth Edition of this book (p. 327).
- Quantitative Determination of Indol in Feces: Bergeim's Modification of the Herter-Foster Method. See Tenth Edition of this book (p. 371).
- 10. Quantitative Determination of Fat in Feces:

Principle: The determination of fat in dried feces is a more or less tedious process, and one which is somewhat inaccurate if applied to pathological feces. Most of the methods for the determination of fat in the moist feces are accurate, but require a long time. Saxon has proposed a method for the determination of fat in moist feces, which is speedy, convenient, and accurate. The soaps of the feces are converted into free fatty acids by means of hydrochloric acid, and the material is then extracted by shaking with ether. The ether removes the neutral fat, the fatty acids which were present as such, the fatty acids derived from the soaps, and the cholesterol. The ether is removed by distillation, the crude fat purified by means of petroleum ether, and the weight of the total fat obtained. The fat is then dissolved in benzene and titrated with tenth-normal sodium alcoholate solution, using phenolphthalein as an indicator. The fatty acid is calculated, from the titration, as stearic acid.

Procedure: Place about 5 g. (accurately weighed) of the thoroughly mixed feces in a 100-ml. glass-stoppered graduated cylinder.

Add 20 ml. of distilled water, 1 to 2.5 ml. of concentrated hydrochloric acid (depending upon the amount of the sample), and, again, sufficient distilled water to make a total volume of 30 ml. Add exactly 20 ml. of ether, stopper, and shake vigorously for five minutes. Allow to stand for a few seconds, remove the stopper, add exactly 20 ml. of 95 per cent alcohol, and again shake for five minutes.

Stand the cylinder aside. The ether, containing practically all of the fat, will come to the top as a colored transparent layer. Draw the ether layer off into a tall 150- to 200-mi. beaker. The thin layer of ether which remains is diluted with 5 mi. of ether, the tube slightly agitated, and the ether drawn off. This is done in all five times, care being taken each time to wash down the sides of the cylinder. The stopper should also be washed. 20 mi. of ether are again added, and the cylinder shaken for five minutes and set

² Hawk: Arch. Internal Med., 8, 552 (1911).

⁴ Herter and Foster: J. Biol. Chem., 1, 257 (1906); Bergeim: J. Biol. Chem., 32, 17 (1917).

⁷ Care must be taken not to smear the neck of the cylinder. This may be avoided by removing the feces from the weighing bottle by means of a glass rod, the end of which is flattened, and bent in the shape of a hoe, and transferring small bits of the feces from the hoe to the cylinder, using short pieces of glass rod, which are dropped into the cylinder together with the feces. Tests made in the senior author's laboratory have shown that the fat of feces decreases on standing even in the frosen condition. Analyses should be made on fresh feces.

aside. When the ether has nearly stratified, draw it off and wash as before. During the second washing stratification will complete itself. Evaporate the ether⁶ until no trace of the alcohol, which has been carried over with it, remains. To the residue add 30 ml. of low-boiling petroleum ether (should boil below 60° C.), and allow to stand over night. Petroleum ether for this work should be frequently tested for a residue on evaporation. If a residue is left, the ether should be redistilled. Filter the petroleum ether solution of the fat, catch the filtrate and washings in a tall, weighed, 190-ml. beaker, evaporate off the solvent, dry at 90° C., desiccate, and weigh. After weighing, dissolve the contents of the beaker in 50 ml. of benzol, heat almost to the boiling point, add 2 drops of a 0.5 per cent solution of phenolphthalein, and titrate with a decinormal solution of sodium alcoholate.

Calculations: The weight of total fat is obtained by subtracting the weight of the empty beaker from the weight of the beaker plus the dried fat. The weight of fatty acids (in terms of mg. of stearic acid) is obtained by multiplying the number of ml. of decinormal sodium alcoholate solution by the factor 28.4. The difference between the weight of total fat and the weight of fatty acids is the weight of neutral fat in the sample extracted.

A separate determination without the addition of hydrochloric acid may be run upon the sample, for the purpose of determining the weight of neutral fat and free fatty acids. The difference between this weight and the weight of total fat is the weight of fatty acid present in the original sample in the form of soaps.

⁹ See Appendix.

⁸ Erlenmeyer flasks of about 200 ml. capacity may be used, instead of beakers, for the collection of the ether drawn from the cylinders. The ether may then be distilled and recovered. The same procedure may be followed in removing the petroleum ether.

22

Blood and Lymph

General. The blood circulates through the blood vessels of the body under the influence of the pumping action of the heart. In the larger vessels the blood is relatively out of contact with the tissues of the body; in the blood capillaries with their thin walls on the other hand there is close association between the blood and the tissue fluids and cells, whereby the functions of the blood are subserved.

The major functions of the blood are: (1) To carry the products of food digestion from the intestines and oxygen from the lungs to the tissue cells. (2) To carry waste products from the tissue cells to the excretory organs: kidneys, lungs, intestines, and skin. (3) To carry hormones and in other ways to coördinate the activities of the various tissues. (4) To aid in the defense of the body against disease. (5) To aid in the maintenance of hydrogen-ion, water, temperature, and other equilibria in the tissues.

The blood makes up about 5 to 7 per cent of the body weight in man, or approximately 2 to 3 liters per sq. m. of body surface, being more nearly proportional to the latter than to weight. Lower relative volumes of blood are observed in obese than in thin individuals. The volume of the circulating blood in a normal individual is maintained within rather narrow limits; any marked change in blood volume, as by sudden severe hemorrhage, etc., has serious consequences and may even result in death. Blood volume may be measured by the addition to the blood of a known amount of a readily detectable and nondiffusible substance, such as certain dyes, hemoglobin derivatives, and radioactive compounds; the extent to which the substance is diluted by the blood is a measure of the total blood volume.

Composition of Blood. Blood consists of a fluid portion, the plasma, and of formed elements. The latter include (1) the crythrocytes or red blood cells, (2) the leukocytes or white blood cells, and (3) the platelets. The formed elements make up about 45 per cent by volume and over 50 per cent by weight of whole blood. The specific gravity of whole blood averages 1.060; of plasma, about 1.026. The pH of blood is approximately 7.35, the freezing point about -0.56° C. These properties may vary with age, sex, nutritive condition, and in disease.

When freshly drawn blood is allowed to stand, it clots. As the clot retracts, a light yellow fluid exudes. This is blood serum. Serum is similar to plasma in many ways, the two terms often being equivalent, but there are certain differences which will be evident subsequently. The yellow color of normal serum or plasma is ordinarily due to the presence of small amounts of bilirubin, a bile pigment.

Blood Plasma. The plasma contains about 91 to 92 per cent of water and about 8 to 9 per cent of solid matter, of which about 7 per cent, or over 85 per cent of the total solids, is protein. The lipid constituents of plasma include fats, fatty acids, lecithin, and cholesterol. The inorganic ions are chiefly sodium, chloride, and bicarbonate, the latter being of particular importance, in conjunction with carbonic acid, in the maintenance of a constant blood pH. Smaller but physiologically very important amounts of potassium, calcium, magnesium, and phosphate are likewise present in the plasma.

Since the plasma is a carrier of nutrition, we find it to contain glucose (about 0.08 per cent), lactate, amino acids, fats and fatty acids, etc. As a carrier of excretory products it contains urea, uric acid, creatinine, carbon dioxide, and many other substances in small amounts. Some of these substances are altered in amount in disease (see Chapter 23, Blood and Tissue Analysis).

Plasma Proteins. The plasma proteins represent a complex mixture containing a number of components which differ in properties and function. The major component proteins of plasma include (1) fibrinogen, (2) the various globulins, and (3) the albumins; (4) nucleoprotein and (5) seromucoid are also present in limited amounts.

FIBRINGEN. The fibringen of normal human plasma is present in a concentration of about 0.3 to 0.4 g. per 100 ml. of plasma. Fibringen is likewise found in lymph and chyle as well as in certain exudates and transudates. Human blood fibringen has a molecular weight of approximately 500,000; the molecule appears to be quite elongated, the estimated dimensions being about 33 x 900 angstrom units. The amino acid composition is given in Chapter 4. Fibringen is insoluble in salt-free water but is soluble in dilute salt solutions. It is the most readily precipitable of all the common blood proteins by concentrated salt solutions, being precipitated upon half-saturation with sodium chloride or 20 per cent saturation with ammonium sulfate. The coagulation temperature of fibringen is about 55° C. in neutral solutions.

Fibrinogen is unique among the blood proteins in that it is readily converted into insoluble fibrin by the action of the enzyme thrombin. This process is the basis of blood clotting, the clot consisting of a fibrin mesh enclosing the formed elements of the blood. The resulting scrum has a protein content which is slightly lower than that of the original plasma, because of the loss of fibrinogen. The nature of the processes involved in the transformation of fibrinogen to fibrin is not clear, although gross changes in amino acid composition are known not to occur.

ALBUMINS AND GLOBULINS. The bulk of the plasma proteins consists of the albumin and globulin fractions. The albumin fraction ordinarily preponderates, comprising well over one-half of the total protein of normal human plasma, but this relation may be altered or even reversed in disease. As a class the plasma albumins differ from the globulins in having a greater solubility, a lower molecular weight, and a more acid isoelectric point. Human serum albumin, for example, has a molecular weight of 69,000 and an isoelectric point at pH 5.4 while the γ -glob-

ulin of serum (see p. 416) has a molecular weight of 156,000 and an isoelectric point at pH 6.5. Marked differences in amino acid composition between albumins and globulins have been established, as is evident from the data of the table on p. 109 in Chapter 4, but these differences, while significant from an analytical point of view, as yet have not been related to differences in either structure or function.

The albumin fraction of the plasma is relatively homogeneous and well characterized; a number of serum albumins from various sources have been obtained in crystalline form. Some of these crystalline proteins appear to contain carbohydrate as an integral portion of the molecule.

The globulin fraction on the other hand appears to consist of a variety of proteins of somewhat similar general characteristics, but which by suitable means may be further fractionated into a number of components. Although relatively homogeneous fractions of the plasma globulins have been obtained, none of these proteins has as yet been crystallized. From the point of view of solubility, two general types of globulin are recognized, cuglobulin and pseudoglobulin.

Euglobulin is a true globulin in that it is insoluble in salt-free water: pseudoglobulin, while possessing the general properties of the globulins, is soluble in salt-free water. This distinction between two types of globulins, while useful, is by no means well defined. The extensive studies of Sørensen on this subject, already referred to in Chapter 5, have led this investigator to postulate that the globulin fraction of serum represents a loose combination of euglobulin and pseudoglobulin of the type E_pP_q, in which E and P represent euglobulin and pseudoglobulin complexes respectively, combined in the relative proportions of p and q. Fractionation by various means results in a shift in the proportions of E and P with the resultant formation of more soluble and less soluble complexes. Sørensen was unable to prepare a sample of either euglobulin or pseudoglobulin which was entirely free of the other protein. Cohn, McMeekin, et al., have likewise shown that the "euglobulin" fraction of serum protein (i.e., globulin precipitated by dialysis) is considerably increased in amount over that first obtained by ammonium sulfate fractionation if the precipitated protein is freed from the last traces of salt by electrodialysis and if the solubility is not influenced by the presence of other proteins.

Fractionation of the Plasma Proteins. The separation and characterization of the individual protein components of the plasma is of considerable importance. It facilitates study of the chemical nature and physiological function of each protein and of the significance of variation in the protein composition of the plasma in health and disease. It likewise leads to the possibility of the commercial preparation, from human or animal plasma, of purified preparations of the individual proteins for laboratory, clinical, and industrial use.

Methods for separating the plasma proteins from one another are based almost entirely upon (1) differences in physical properties, such as solubility in water, concentrated salt solutions, and other solvents;

¹ Cohn, McMeekin, Oncley, Newell, and Hughes: J. Am. Chem. Soc., 42, 3386 (1940).

(2) rate of sedimentation in the ultracentrifuge; and (3) rate of electrophoretic migration. The various plasma proteins do not differ sufficiently in chemical composition or behavior to permit their separation at the present time on a purely chemical basis. Immunological means of separation—i.e., the use of precipitins (cf. Chapter 5)—specific for the individual protein, have certain disadvantages and have been little used.

DIFFERENCES IN PHYSICAL PROPERTIES. The type of fractionation obtained by differences in solubility in water and in concentrated salt solutions is illustrated in the following table which has been adapted from the work of various investigators.² The salts listed in the table,

FRACTIONATION OF THE PLASMA PROTEINS BY CONCENTRATED SALT SOLUTIONS

	Solubility in Dist. H ₂ ()	Precipitated by		A pproxi-	
Protein		Per Cent Saturation with Amm. Sulfate	G. So- dium Sul- fate per 100 ml., at 37° C.	Normal Conc. in g. per 100 ml. Plasma	Per Cent of Total Protein
Fibrinogen Euglobulin Pseudoglobulin I Pseudoglobulin II Albumin	- - + +	20 33 40 46 >50	13 5 17.5 21.5	0.3 0.2 1.3 0.5 5.2	4 3 17 7 69

ammonium sulfate and sodium sulfate, are those most commonly employed; sodium chloride, magnesium sulfate, and sodium or potassium phosphate may also be used under suitable conditions. It will be seen that as the concentration of salt is progressively increased, the various fractions become insoluble and will precipitate from solution. Fibrinogen, which is sometimes classified as a globulin because of its solubility characteristics, is the least soluble protein, followed by euglobulin, the pseudoglobulins, and albumin. It is usually considered that all the globulins of plasma are precipitated upon half-saturation with ammonium sulfate, or by a 22 per cent concentration of sodium sulfate at 37° C., and that the protein remaining in solution is albumin. This is the common analytical basis for separation of the albumin and globulin fractions of plasma prior to their analytical estimation.

The fractionation represented in the table above must be regarded as being quite arbitrary. The precipitation limits are not sharply defined, as might be inferred from the table, but rather represent arbitrarily established limits which in reality correspond to zones, between which there is no well-defined transition. The quantitative values given in the table are therefore characteristic of this particular type of fractionation

² Howe: J. Biol. Chem., 49, 109 (1921); Gutman, Moore, Gutman, McClellan, and Kabat: J. Clin. Insect., 26, 765 (1941); and others.

only, and should not be expected to agree with values obtained by fractionation by other methods. Despite this limitation, the method has proved of value in many studies on the variation in plasma protein fractions in health and disease.

Fractionation of the plasma proteins by various concentrations of aqueous alcohol is described by Cohn, Luetscher, et al.³ While alcohol denatures proteins readily at room temperature, denaturation does not occur at temperature ranges of 0° to -5° C., and satisfactory fractionation of the general nature of that obtained by the use of concentrated salt solutions is obtained. The advantage of alcohol fractionation appears to lie chiefly in the ease with which the fractionating agent may be removed from the protein, along with water, in the process of preparing stable dried preparations of the various fractions ("lyophilization"), thus rendering the method applicable to the large-scale preparation of such dry protein fractions for clinical and industrial use.

Use of the Ultracentrifuge. Separation of the plasma proteins in the ultracentrifuge of Svedberg has had somewhat limited applicability because of the superiority of other available methods, but has yielded valuable theoretical information. Svedberg found that bovine serum contained an albumin with a molecular weight of 67,000 as estimated from the sedimentation data, together with several globulins. The two most abundant globulins had molecular weights of 147,000,

and there was a third globulin with a much larger molecular weight which has been associated with the immunological functions of the plasma globulins.

Electrophoresis. The fractionation of the plasma proteins by the use of electrophoresis was initiated largely by the pioneer work of Tiselius. In the electrophoretic separation of the plasma proteins, advantage is taken of the differences in mobility of the various protein ions present under the influence of a potential gradient. The sample is placed in the lower portion of a U-shaped tube, the upper portion of which contains a protein-free solution, in such a way that a sharp boundary is formed between the two fluids. On the application of a potential gradient across the tube, the various protein ions present migrate into or away from the protein-free medium at a rate which may be made a function of the dimensions and net charge of the ion. Thus the lighter, more highly charged albumin ions will migrate at a faster rate than the globulin ions, and after a sufficient period of time

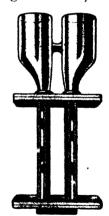

Fig. 124. Type of cell used for electrophoresis studies on plasma proteins. (Courtesy, Klett Manufacturing Co., New York.)

the various protein ions present will be distributed along the limb of the U-tube in proportion to their electrophoretic mobility. As the concentration of the individual proteins changes, the index of refraction of the medium likewise changes, and by suitable optical methods based upon

² Cohn, Luetscher, Oncley, Armstrong, and Davis: J. Am. Chem. Soc., 62, 3396 (1940).

this principle the migration of the various protein fractions may be followed (Longsworth, Svensson).

The type of "pattern" obtained during electrophoresis of a mixture of components is illustrated by Fig. 125, which represents the electrophoretic patterns of various animal plasmas. The distance along the x axis is a measure of the relative velocity of movement of the various ion species present, and the height of the peaks corresponds to the difference in refractive index between the moving boundary and the adjacent fluid, the area under each curve being proportional to the amount of material present moving with an average velocity represented by the position of the peak along the x axis. Thus by this method it is possible

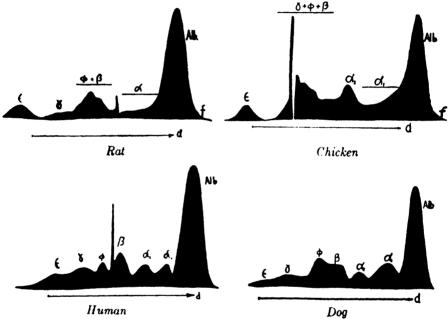

Fig. 125. Electrophoretic patterns of blood plasma from various animal species. (Courtesy, Deutsch and Goodloe, J. Biol. Chem., 161, 1 (1945).)

not only to distinguish between ion species of different mobilities but also to estimate the relative amounts of each type of ion present.

Tiselius demonstrated that normal plasma contained at least five electrophoretically distinguishable components, which were identifiable as albumin, fibrinogen, and three globulins, designated α , β -, and γ -globulin respectively, the α -globulin having the fastest velocity in the group and the γ -globulin having the slowest. From electrophoretic data, it is clear that while albumin and fibrinogen are reasonably homogeneous—the high sharp peak corresponding to a migration of protein ions the majority of which have the same net charge and weight—the globulin fraction consists of a number of types of ions which may be classed roughly into three groups but which obviously include ion species of quite varying mobilities within any one group. Indeed, later workers have been able

to show that the three globulin fractions of Tiselius may be resolved into further components which have been designated α_1 - and α_2 -globulin, etc. The fibrinogen peak is usually indicated by the symbol ϕ , and the slowest-moving component by ϵ . In some instances an f component, moving even faster than albumin, may be found. Separation of the different components to varying extent may be accomplished by changing the duration of electrophoresis, the pH of the solution, etc.

The type of quantitative fractionation of the plasma proteins that is obtained by electrophoresis is illustrated in the table below:

DISTRIBUTION OF PROTEINS IN CITRATED PLASMA AS DETERMINED BY ELECTROPHORETIC ANALYSIS*

	Grams per 100 ml. of Plasma	Per Cent of Total Protein
Total protein	6.03	100
Albumin	3.32	55
α -globulin	0.84	14
β-globulin	0 78	13
γ -globulin	0 66	11
Fibrinogen		7

^{*} Adapted from data of Cohn, Oncley, et al.: J. Clin. Invest., 23, 417 (1944).

It is to be noted that the three main globulin components are here present in approximately the same concentration, and furthermore that the ratio of albumin to globulin (the so-called "A/G ratio") is 1.45; in a similar study Gutman, Moore, et al. (loc. cit.) have reported an A/G ratio for normal human serum of 1.82. This value is to be contrasted with the value of approximately 2.0 or higher which is accepted as normal for fractionation by sodium sulfate precipitation.

There is no simple relation between the fractions of the plasma proteins obtained by salting out and those obtained by electrophoresis studies. Thus Cohn, McMeekin, et al. (loc. cit.) have reported that at 34 per cent saturation with ammonium sulfate, the protein fraction precipitating consisted largely of γ -globulin, one-third of which was euglobulin—i.e., precipitated on dialysis. At 40 per cent saturation with ammonium sulfate the fraction contained α - and β -globuling as well as some γ -globulin. This fraction likewise contained about one-third euglobulin. Increasing the saturation to 50 per cent yielded a precipitate which was free from γ -globulin but which contained both α - and β -globulins, with only a few per cent of the fraction insoluble in water. Thus the two methods of fractionation-salting out and electrophoresis-yield overlapping results and are not directly comparable. But it is to be noted that by suitable salting-out methods fractions can be prepared which are homogeneous electrophoretically and which correspond to the fractions obtained electrophoretically. Thus Pillemer and Hutchinson have reported

⁴ Pillemer and Hutchinson: J. Biol. Chem., 158, 299 (1945).

that at 0° C. and pH 6.7 to 6.9, fractionation of human serum proteins with 42.5 per cent methanol yields A/G ratios which compare favorably with those obtained by electrophoretic analysis.

At the present time it would appear that the electrophoretic method of analysis of the plasma proteins has its greatest value in studying the relative amounts of the various components present and the changes which these components undergo during disease, with a view to possible aid in diagnosis; while fractional precipitation is of value in the large-scale preparation of the individual components for industrial or clinical use, the purity of the fractions being controlled by electrophoretic analysis.

Origin of the Plasma Proteins. The liver is usually considered to be the site of formation of the plasma proteins, although other parts of the body may also have a function in this connection. Fibrinogen synthesis appears to be dependent entirely upon the liver. When the liver is damaged experimentally by poisons, the fibrinogen content of the blood falls, returning to normal with liver regeneration and repair. If the blood of a normal animal is removed as much as possible and replaced by defibrinated blood, the fibrinogen level is restored to normal in a few hours; in the hepatectomized animal this restoration does not occur.

Evidence relating the liver to the production of the other proteins of plasma is less definite. Liver atrophy is frequently found in experimental and clinical hypoproteinemia. Since the albumin fraction appears to suffer most under these conditions, it would appear that the liver is associated with albumin synthesis, and furthermore that the factors controlling the synthesis of albumin are different from those for globulin; indeed, there is considerable evidence that parts of the body other than the liver are concerned with plasma globulin formation.

The study of plasma protein production in experimental animals is facilitated by the use of the experimental technique known as plasmapheresis, in which whole blood is removed from an animal, the blood cells separated from the plasma and resuspended in a suitable isotonic protein-free medium, and returned to the animal's circulation. Thus a plasma protein deficit is produced which may be maintained at any desired point, and the extent to which the animal attempts to restore the plasma protein level to normal may be used as an index of plasma protein formation under various experimental conditions. Using this technique, for example, it has been found that plasma protein production in the dog may be maintained at normal levels for many weeks by the intravenous administration of a mixture of purified amino acids as the sole source of dietary nitrogen, and that those amino acids in particular which have been found by Rose to be essential in the diet of the young growing rat (see Chapter 33) are likewise significant in the production of plasma protein in the dog.

There is increasing evidence that the plasma proteins are in continuous metabolic equilibrium with other proteins and amino acids of the body. This view, first postulated by Whipple and collaborators as the result of studies on protein regeneration in animals by the plasmapheresis tech-

nique, is supported by the work of Schoenheimer, et al.,⁵ using the nitrogen isotope N¹⁵. When amino acids containing this isotope were fed to rats in nitrogen equilibrium, both the tissue proteins and the plasma proteins were found to incorporate the isotopic nitrogen rapidly and at about the same rate. On discontinuing isotope administration, the isotope gradually disappeared from the plasma proteins, the estimated "half life" of the plasma protein molecule being about two weeks. These and other experiments indicate that the plasma proteins in an animal are not static but are subject to continuous influence by dietary and metabolic factors.

Functions of the Plasma Proteins. In addition to the specific physiological function of certain of the plasma proteins, such as the role of fibrinogen and prothrombin in blood clotting and the role of the plasma globulins in immunological reactions, certain general functions of the plasma proteins are recognized. These may be classified as nutritive and physicochemical.

NUTRITIVE FUNCTION. The nutritive function of the plasma proteins has only recently been established, largely through the work of Whipple and his associates. They have shown that the nitrogen (and protein) requirements of the fasting animal can be adequately supplied by the intravenous injection of plasma protein. Since this injected protein disappears from the circulation in a short time, it is presumably metabolized. Analyses of urinary nitrogen excretion after plasma protein injection indicate an increased catabolism of protein. Whether this means that the plasma proteins are directly utilized metabolically or are first converted into tissue protein is not known; such a distinction would appear to be relatively unimportant in view of the existence of such a dynamic equilibrium between tissue proteins and plasma proteins as has already been postulated.

Physicochemical Functions. The physicochemical functions of the plasma proteins are equally important. Chief of these appear to be to aid in the maintenance of a normal blood volume and in the maintenance of a normal water content in the tissue fluids. By virtue of their colloidal dimensions the plasma proteins cannot normally diffuse through the blood capillary membranes into the relatively protein-free tissue fluids. They thus exert an osmotic pressure which acts as a force tending to hold a certain volume of water within the blood. This colloidal osmotic pressure—or "oncotic pressure," as it is sometimes called—has a magnitude of about 25 mm. Hg. Although this is much less than 1 per cent of the total osmotic pressure of the plasma, nevertheless it becomes the dominant osmotic force in the blood capillaries since the other plasma constituents are freely diffusible across the capillary membranes.

Of the various plasma proteins, albumin is by far the most significant in connection with osmotic pressure, being estimated to account for about 80 per cent of the total osmotic pressure of the plasma proteins. Gram for gram, albumin is at least twice as effective osmotically as

^{*}Schoenheimer, Ratner, Rittenberg, and Heidelberger: J. Biol. Chem., 144, 541, 545 (1942).

globulin, largely because of its relatively lower molecular weight. It has been shown that 1 g. of plasma albumin is responsible for the retention of roughly 20 ml. of water in the blood. A loss of plasma protein, and particularly of plasma albumin, therefore leads to a diminished blood volume, and this is presumably a major cause of the symptoms of hemorrhagic shock. The administration of plasma protein, especially plasma albumin concentrates, has been shown to be of considerable value in both experimental and clinical shock.

The colloidal osmotic pressure of the plasma proteins is opposed by the filtering force of the blood pressure, which tends to drive water and dissolved substances across the capillary membranes into the tissue fluids. At the arterial end of a blood capillary the blood pressure exceeds the colloidal osmotic pressure and fluid is forced from the blood into the tissues; at the venous end the reverse action takes place, fluid entering the blood from the tissues. Normally there is a balance between these two opposing forces and fluid distribution between the blood and tissues is normal. If this balance is upset by such conditions as a low plasma protein content or an increased permeability of the capillary walls to protein, excessive amounts of water will accumulate in the tissues (edema). A plasma protein deficit is therefore an important (although by no means the only) cause of edema. Edema due to plasma protein deficit has been successfully treated by measures which restore the plasma protein level to normal.

A second physicochemical function of the plasma proteins is in connection with acid-base balance. Because the plasma proteins in solution at pH 7.4 are on the alkaline side of their isoelectric points, they exist to a certain extent as alkali salts. They thus act similarly to the alkali bicarbonate of the blood in furnishing base for the neutralization of acid, and indeed it has been shown that in the plasma the proteins are second to bicarbonate in importance in this respect.

Other functions of the plasma proteins are also recognized. They aid in promoting the mobility of the corpuscles, since red cells settle more rapidly in plasma than in protein-free isotonic solutions. The globulin fraction appears to be the carrier of the immune substances of the blood, and indeed the isolation and concentration of immune substances from human plasma is an important phase of fractionating the plasma proteins. The plasma proteins also combine with certain drugs and have thus been ascribed a "vehicular" function, although the precise significance of this property is not yet known.

The Erythrocytes. The erythrocytes or "red cells" make up about 45 per cent by volume of the blood. Variations from this value are frequently encountered; they are associated with changes in either the number of cells per unit volume of blood, or the size of the individual cells, or both. The relative cell volume of blood is determined with the hematocrit, a graduated tube which may be filled with whole blood and centrifuged. The volume of packed cells relative to the initial volume of blood is a measure of the cell volume. The top layer of packed cells is frequently almost colorless, because of the predominance of leukocytes which are

not so heavy as the erythrocytes. The same phenomenon is noted when blood is allowed to clot without agitation; the lighter superficial portion of the clot is then known as the "buffy coat."

The erythrocytes are responsible for the opacity of blood. If blood is diluted with water this opacity disappears in a few moments, the fluid becomes translucent, and the blood is said to be hemolyzed or laked. On diluting blood with 0.9 per cent sodium chloride solution, however, no hemolysis occurs. The explanation for this lies in the osmotic behavior of the erythrocytes. Each cell may be considered as a miniature "osmometer," the water content of the cell depending upon both the osmotic pressure of the cell contents and of the surrounding medium. If, for example, the cell is in a medium such as 0.9 per cent sodium chloride solution, which has the same osmotic pressure as the cell contents, the water content of the cell will not change, nor will its size, and the medium is said to be isotonic with the cell. If the osmotic pressure of the medium is greater than that of the cell contents, water will be abstracted from the cell, it will decrease in size, and the solution is said to be hypertonic. A solution which has a lower osmotic pressure than the cell contents is hypotonic; in such a solution, the cell will absorb water and swell, the extent of swelling depending upon the degree of hypotonicity. In a sufficiently hypotonic solution the swollen erythrocyte loses its ability to retain hemoglobin, and hemolysis results. The osmotic pressure at which hemolysis occurs is known clinically as the fragility point, and its determination has a certain diagnostic value.

Other agencies besides osmotic pressure differences will bring about hemolysis of erythrocytes. These include alkali, ether, chloroform, soaps, bile salts, saponins, certain bacterial toxins, and snake venoms. In these instances hemolysis must be attributed to the actual modification or destruction of the cell stroma.

Human erythrocytes are nonnucleated biconcave disks, with an average diameter of about 8μ ($1\mu=0.001$ mm.). Mammalian erythrocytes vary in size from species to species, ranging from 2μ to about 9μ in diameter. In the blood of birds, fishes, amphibians, and reptiles the erythrocytes are ordinarily more or less elliptical, biconvex, and nucleated.

The number of erythrocytes present in human blood depends upon many factors, such as age, sex, altitude, exercise, etc. It is usually considered that the blood of a normal adult male contains 5,000,000 erythrocytes per cmm.; for a normal adult female the "count" is 4,500,000. Increased red cell count is noted after blood transfusion, during residence at high altitudes, and after strenuous physical exercise; in the latter case a count of 7,040,000 has been observed. An increase is also noted in starvation, after partaking of food, after cold or hot baths, after massage, after partial asphyxia, and after fright, as well as after the administration of certain drugs and accompanying certain diseases, such as cholera, diarrhea, dysentery, and yellow atrophy of the liver. In polycythemia counts as high as 11,000,000 have been noted, and almost as high values have been observed in cyanosis. Experimentally, polycythemia may be produced in animals by the use of phenylhydrasine or the inclusion of

cobalt salts in the diet. A decrease in the number of erythrocytes occurs in the different forms of anemia, values as low as 500,000 per cmm. or lower having been noted in pernicious anemia.

Erythrocytes possess the property of grouping together in masses, or "clumping." This action occurs normally on a microscopical scale, and since the cell aggregates settle faster than the discrete cells, clumping is a major factor in determining the sedimentation rate of the blood cells. a characteristic of blood the measurement of which was shown by Fåhreus to have considerable clinical value. If the clumping power of the cells is so enhanced as to produce macroscopically visible clumps, the process is called agglutination. Cells other than erythrocytes (e.g., bacteria) possess this property; when spoken of in connection with the blood the term "hemagglutination" is frequently used. Observation of hemagglutination is the basis for the establishment of blood types, so essential in connection with blood transfusion; indeed, it is agglutination of erythrocytes which renders incompatible the bloods of donor and recipient. A substance which will bring about hemagglutination is said to contain hemagglutinins; if these are species specific they are known as isohemagglutinins. In human plasma the isohemagglutinins are associated largely with the β - and γ -globulin fractions. Hemagglutinins are abundant in the vegetable kingdom; for a demonstration of hemagglutination, see p. 436.

Composition of Red Cells. The red cells contain approximately 65 per cent water and 35 per cent solids. Of the solids, the red chromoprotein hemoglobin comprises about 32 of the 35 per cent; most of the remaining 3 per cent forms the stroma of the red cell, which consists largely of protein, phospholipid, and cholesterol. Inorganic ions in the red cell include potassium, chloride, bicarbonate, and phosphate; of these, potassium is present in largest amount, being comparable quantitatively. and in certain respects equivalent physiologically, to the sodium of the plasma. Organic constituents include various phosphate esters and certain enzymes, such as phosphatases and carbonic anhydrase; this latter is of particular significance in connection with the function of the red cells in the carriage of carbon dioxide by the blood (see Chapter 24). Certain diffusible substances such as glucose and urea are found equally distributed between cells and plasma when concentrations are expressed in terms of the water present; it is important to remember in such comparisons as this that on a percentage basis the amount of water in the cells is much less than that in the plasma.

Although erythrocytes contain oxidative enzymes (the "yellow enzyme" of Warburg was first isolated from horse red cells), the respiratory metabolism of these cells is very small. The major functions of the red cell appear explicable on a purely physicochemical basis in terms of the role of hemoglobin and other substances present in the transport of oxygen and carbon dioxide by the blood.

Hemoglobin. Hemoglobin, the red coloring matter of the blood, is the most abundant protein in blood, being usually found to the extent of about 14 to 16 g. per 100 ml. of whole blood. It is normally found entirely within the erythrocytes, from which it may be released by suitable hemolytic agents. It is a readily crystallizable conjugated protein, consisting of a colorless protein portion known as globin, which makes up about 96 per cent of the hemoglobin molecule, and a colored nonprotein portion or prosthetic group which has been shown to be an iron-containing compound belonging to the class of porphyrins. The chemical nature of globin has been discussed in Chapter 6.

The molecular weight of hemoglobin is approximately 67,000, concordant results being obtained by a variety of methods. The iron content of crystalline human hemoglobin is 0.340 per cent. Since this corresponds to a minimal molecular weight of 16,700 on the basis of one Fe atom per molecule, it has been concluded that the hemoglobin molecule contains four Fe atoms, and the physicochemical behavior of hemoglobin is in agreement with this conclusion.

Hemoglobin is readily separated into its protein and prosthetic group components by treatment with acid, the globin usually being denatured in the process, and the iron-containing portion being obtainable under the proper conditions in the form of an insoluble crystalline compound known as hemin. The formation of hemin crystals is frequently used as a test for blood because of their characteristic appearance and the ease with which they may be obtained. Hemin has been synthesized and its structure is represented by the following formula:

It can be seen that the hemin molecule contains iron in the trivalent form, and that the rest of the molecule consists essentially of four substituted methyl-pyrrole rings linked together by —CH— bridges. Such a molecule is known as a metalloporphyrin, the metal in this case being iron. Various isomers of the porphyrin molecule are known, differing in the relative position of the substituting side chains, the isomer found in hemin being called protoporphyrin. To indicate the valence of the iron, which is of importance, it has been suggested that the terms ferroprotoporphyrin and ferriprotoporphyrin be used. Thus hemin is the chloride of ferriprotoporphyrin. The term "heme" is also frequently used as equivalent to ferriprotoporphyrin, hemin then being the chloride of heme. The older term "hematin" has been largely abandoned because of its indefinite connotation; it is roughly equivalent to heme.

When hemin is treated with a suitable reducing agent the ferric iron is reduced to the ferrous state. The resulting ferroprotoporphyrin or reduced heme readily combines with undenatured globin to form a compound which is closely similar to, if not identical with, natural hemoglobin. Thus hemoglobin is a combination of globin with reduced heme, the iron in the hemoglobin molecule being in the ferrous state. The nature of the combination between the protein and the prosthetic group is not known.

Heme and reduced heme have the ability to combine with other nitrogen-containing compounds besides globin and denatured globin; such substances include other proteins, ammonia, cyanide, nicotine, pyridine, etc. These combinations are known in general as hemochromogens. Spectroscopic and other studies of the various natural and synthetic hemochromogens have thrown much light on our knowledge of the chemical behavior of heme and hemoglobin, and hemochromogen formation has been utilized for the qualitative detection and quantitative determination of hemoglobin. The occurrence of heme in nature as the prosthetic group of the enzymes catalase and peroxidase, and in the cytochromes, has already been discussed (see Chapter 12).

Combination of Hemoglobin with Oxygen. A major physiological function of hemoglobin is based upon its ability to react reversibly with oxygen. This reaction may be written as follows:⁶

$$\begin{array}{ccc} \operatorname{Hb} & + \operatorname{O_2} \rightleftharpoons & \operatorname{HbO_2} \\ \operatorname{Hemoglobin} & \operatorname{Oxyhemoglobin} \end{array}$$

Under optimal conditions, 1 g. of hemoglobin will combine with 1.36 ml. of oxygen.⁷ The product of this reaction, oxyhemoglobin, is as well characterized a compound as hemoglobin, and is quite stable with respect to its oxygen content as long as there is sufficient oxygen present to prevent the reaction from going to the left. Oxyhemoglobin may be crystallized, and a specific form of crystal is obtained from the blood of each individual animal species (see Figs. 126 to 129). Reichert and Brown studied oxyhemoglobin crystals prepared from the blood of over 100 species of animals from the point of view of their crystallographic characteristics. Species differences are not confined to crystal form only; Barcroft and others have shown that oxyhemoglobin from various sources may differ in spectroscopic characteristics and in affinity for oxygen. Since hemin crystals are identical no matter from what species the blood is obtained, the species differences in oxyhemoglobins must presumably be related to differences in the globin portion of the molecule.

Bernhart and Skeggs, J. Biol. Chem., 147, 19 (1943).

⁶ The reaction is written in the form given for purposes of simplicity. It has already been pointed out that there are four Fe atoms per molecule of hemoglobin, and it is known that hemoglobin combines with oxygen in the proportion of one O_2 molecule per atom of Fe. Thus the reaction should really be written: $Hb_4 + 4O_2 \approx Hb_6O_6$. Furthermore, this latter reaction provides for the possibility of intermediate compounds such as Hb_4O_4 , Hb_4O_4 , and Hb_4O_6 , the formation of which would depend on the amount of oxygen available, and Pauling and others have shown that the sigmoid curve relating oxyhemoglobin formation to oxygen tension is explicable on the basis of equilibria involving the formation of such intermediate stages in oxygenation.

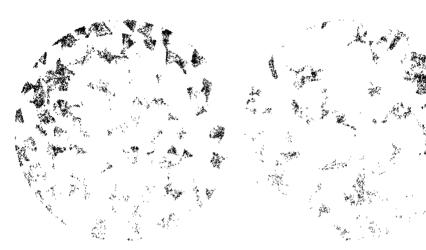

Fig. 126. Oxyhemoglobin crystals from blood of the guinea pig.*

Fig. 127. Oxyhemoglobin crystals from blood of the rat.*

Fig. 128. Oxyhemoglobin crystals from blood of the horse.*

Fig. 129. Oxyhemoglobin crystals from blood of the dog.*

The crystals in Figs. 126-129 were reproduced from photomicrographs furnished by the late Prof. E. T. Reichert, of the University of Pennsylvania.

The reversibility of the reaction between hemoglobin and oxygen to form oxyhemoglobin implies that the relative amounts of hemoglobin and oxyhemoglobin present in blood will depend upon the concentration of oxygen present, which in turn is proportional to the oxygen tension (Henry's Law). The oxygen tension within the red cells is determined largely by the oxygen tension of the plasma, since oxygen is freely diffusible across the red cell membrane.

The relation between the degree of oxygenation of hemoglobin and the oxygen tension is usually expressed graphically in the form of a curve, the "oxygen dissociation curve," which is illustrated by Fig. 130. The effect of such variables as pH and temperature on the ability of hemoglobin to combine with oxygen may be studied by noting their

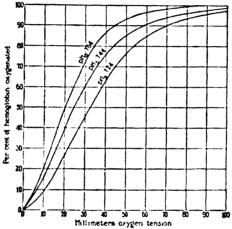

Fig. 130. Oxygen dissociation curve for hemoglobin in blood at various values of serum pH(pH₂). (Courtesy, Van Slyke and Peters: "Quantitative Clinical Chemistry.")

influence on the shape of the oxygen dissociation curve. From the curve it can be seen that when blood is in equilibrium with ordinary room air (oxygen tension = ca. 150 mm. Hg) or with the alveolar air of the lungs (oxygen tension = ca. 90 to 100 mm. Hg), practically all of the hemoglobin is oxygenated, i.e., the "per cent saturation" of the blood with oxygen is from 95 to 100 per cent. As the blood courses through the tissue capillaries, however, where there is a constant demand for oxygen, oxygen diffuses out of the plasma into the tissue fluids and the plasma oxygen tension falls to about 40 mm. Hg. At this tension the oxyhemoglobin has yielded up about one-quarter of its combined oxygen by dissociation; thus normal venous blood contains about 75 per cent oxyhemoglobin and 25 per cent hemoglobin, or is 75 per cent saturated with oxygen. Further lowering of the oxygen tension leads to increased dissociation of oxyhemoglobin; in the extreme condition of cyanosis only a minor portion of the pigment may be oxygenated. The sigmoid shape of the

curve is considered to have some physiological significance. As the oxygen tension is lowered (i.e., as the demand for oxygen becomes greater), a given decrease in tension produces a greater dissociation of oxyhemoglobin than is produced for the same decrease in tension at high tensions.

The physiological function of hemoglobin is not confined to oxygen transport; it is of equal significance in the carriage of carbon dioxide by the blood. This function is discussed in detail in Chapter 24.

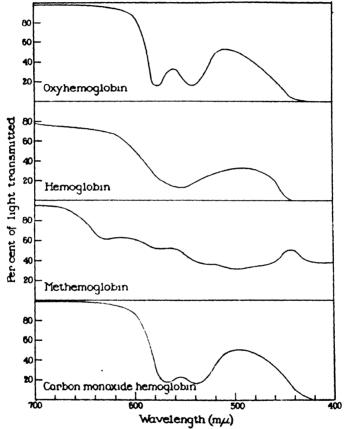

Fig. 131. Relation between wavelength and light absorption for hemoglobin and other blood pigments, all at a concentration of 1 g. per liter and at a solution depth of 1 cm.

Other Reactions of Hemoglobin. In addition to its ability to react with oxygen, hemoglobin will react with a variety of other compounds, such as carbon monoxide, nitric oxide, hydrogen sulfide, ferricyanide, etc., the product in most cases being a colored compound which, like hemoglobin and oxyhemoglobin, may usually be identified by its characteristic absorption spectrum. The absorption spectra of hemoglobin and some hemoglobin derivatives are shown in Plate I as they appear in the spectroscope, and in Fig. 131 as they are obtained quantitatively with the spectrophotometer. The dark bands in Plate I represent regions

of the spectrum where light is specifically absorbed by the colored molecule; the actual extent to which the light is absorbed in these regions

Fig. 132. Carbon monoxide hemoglobin crystals from hog blood. (Courtesy, Boor: J. Gen. Physiol., 13: 307 (1930).)

relative to elsewhere in the spectral range is indicated by the data of Fig. 131.

The combination between hemoglobin and carbon monoxide to form carbon monoxide hemoglobin is of interest because of the constant presence of small amounts of carbon monoxide in city air. Carbon monoxide hemoglobin is a bright red pigment which may be crystallized (see Figs. 132 and 133). Carbon monoxide has about 200 times the affinity for hemoglobin that oxygen has: furthermore the formation of carbon monoxide hemoglobin prevents hemoglobin from combining with oxygen. presumably because both gases

compete for the same spot in the hemoglobin molecule. Carbon monoxide will in fact displace oxygen from oxyhemoglobin, as this reaction indicates:

$$HbO_2 + CO \rightleftharpoons HbCO + O_2$$

This reaction ordinarily proceeds from left to right; it is however reversi-

ble if the concentration of oxygen is made high enough, and in this fact lies the therapy for carbon monoxide poisoning. Carbon monoxide hemoglobin is not toxic in itself; death from carbon monoxide poisoning is presumably due to failure of sufficient oxygen to reach the tissues because of the decreased oxygen-carrying capacity of the blood when a significant proportion (40 to 60 per cent or more) of the total hemoglobin is in the form of carbon monoxide hemoglobin. The anoxia of carbon-monoxide poisoning is not due entirely to passive blocking of oxygen transport by hemoglobin; the oxyhemoglobin present

Fig. 133. Carbon monoxide hemoglobin crystals from ox blood. (Courtesy, Boor: J. Gen. Physiol., 13: 307 (1930).)

in blood containing much carbon monoxide hemoglobin has been shown to be less efficient in releasing oxygen to the tissues under a given

PLATE IV

NORMAL ERYTHROCYTES AND LEUKOCYTES

gradient of oxygen tension. The blood of city dwellers regularly contains over 1 per cent of the total hemoglobin as carbon monoxide hemoglobin; tobacco-smoking may increase this to 5 per cent.

When hemoglobin is treated with certain oxidizing agents, either in vitro or in vivo, the substance methemoglobin is formed. This is a brown pigment which differs from hemoglobin and oxvhemoglobin in that the iron is in the ferric form, i.e., methemoglobin is a combination of heme, or ferriprotoporphyrin, and globin. Methemoglobin is usually detected by means of its characteristic absorption spectrum (see Plate I and Fig. 131). It does not combine with either oxygen or carbon monoxide. but does form a colored evanide derivative. There is little or no methemoglobin in normal blood; the appearance of a methemoglobinemia is noticed in certain diseases and after the administration of certain drugs, among them sulfanilamide. Methemoglobin is not toxic; its presence in blood simply means a proportional reduction in the oxygencarrying capacity of the blood. The clinical induction of a moderately severe methemoglobinemia has been proposed as an aid in the treatment of evanide poisoning, since methemoglobin combines with evanide and may thus prevent the latter from reacting with enzymes in the tissues.

Origin of Hemoglobin. Hemoglobin is synthesized in the body from the ingredients of the diet; iron, a source of the porphyrin nucleus. and amino acid precursors of the protein globin are of obvious importance in this connection. It is known that inorganic iron of the diet cannot be converted into hemoglobin without the presence of catalytic traces of copper; the way in which copper functions is not known. Studies on the origin of the porphyrin nucleus and on the significance of dietary amino acids in hemoglobin synthesis have vielded little definite information; work with isotopes indicates that glycine and acetic acid may be precursors of the porphyrin ring (see also Chapter 33). In the adult animal the erythrocytes are formed in the bone marrow; in the embryo the liver is an important source of red cell production, and the possibility that in the adult the liver retains a vital part in hemoglobin synthesis and erythrocyte formation cannot be overlooked. In the nutritional anemias there is usually a dietary deficiency leading to impaired hemoglobin formation; when the deficiency is corrected the anemia disappears. In pernicious anemia there appears to be lacking a factor which is necessary for the production of mature erythrocytes. This factor is apparently produced by the interaction of an ingredient of the diet with normal gastric juice, and is stored in the liver. It appears to be a polypeptide, but has not as yet been further characterized. Folic acid, a member of the B-vitamin complex (see Chapter 35) has been successfully used in the treatment of certain anemias, and promises to be of considerable value in this connection. The relation if any between folic acid and the "maturation factor" of liver is not as yet established.

The White Cells. The white corpuscles (or leukocytes) of human blood differ structurally from the red corpuscles (or erythrocytes) in many particulars (see Plate IV), such as being larger in size, in containing at least a single nucleus, and in possessing ameboid movement. They are

typical animal cells and therefore contain the following substances which are customarily present in such cells: Proteins, fats, glycogen, purines, enzymes, phosphatides, cholesterol, inorganic salts, and water. Compound proteins make up the chief part of the protein quota of leukocytes, the nucleoproteins predominating. Powerful proteolytic and glycolytic enzymes are also present. It is believed that there are two proteolytic enzymes in leukocytes, one active in alkaline solution and present in the polynuclear cells, and the other active in acid medium and present in mononuclear cells. It is claimed that the granular leukocytes originate in the bone marrow, whereas the nongranular leukocytes (lymphocytes) have a lymphatic origin (lymph glands or lymphoid tissue); this matter of origin is uncertain. The normal number of leukocytes in human blood varies between 5,000 and 10,000 per cmm. The ratio between the leukocytes and erythrocytes is about 1:350 to 500.

A leukocytosis is said to exist when the number of leukocytes is increased for any reason. Leucocytoses may be divided into two general classes: the physiological and the pathological. Under the physiological form would be classed those leukocytoses accompanying pregnancy, parturition, digestion, and excessive physical exercise, as well as those due to mechanical and thermal influences. Leukocytosis is also associated with such emotional states as fear, rage, or apprehension. The leukocytoses spoken of as pathological are the inflammatory, infectious, posthemorrhagic, toxic, and experimental forms, as well as the type which accompanies malignant disease.

Blood Platelets. The blood plates (platelets or plaques) are round or oval colorless disks which possess a diameter about one-third as great as that of the erythrocytes. Upon treatment with certain reagents—e.g., artificial gastric juice—they may be separated into a homogeneous non-refractive portion and a granular refractive portion. The blood plates are associated with the coagulation of the blood. This relation is discussed later.

Chylomicrons. Blood contains myriads of spherical particles, about 0.5 to 1.0 micron in diameter, which are highly refractive and show Brownian movement. These were first recognized by Boyle in 1665, but were later described more fully by Mueller who called them hemaconia or blood dust. However, Gage showed them to be minute fat globules, and curves of the chylomicron counts following the ingestion of fat have been studied in digestion experiments.

Blood Coagulation. The processes involved in the coagulation of the blood are not fully understood. Several theories have been advanced and each has its adherents. The literature on the subject is confused by the introduction of new terms for the same substances or processes. The theory which appears to be fully as firmly founded upon experimental evidence as any is substantially the following: When blood clots, it does so because of the action of a substance called thrombin on the fibrinogen of the plasma, converting it into insoluble fibrin. Thrombin is not normally present as such in the plasma, but in the form of a precursor, prothrombin. The activation of prothrombin to thrombin is

brought about by thromboplastin in the presence of calcium ions. According to Quick, prothrombin and calcium form the complex, prothrombin-Ca, which is acted on by thromboplastin. Thus the process of blood-clotting may be pictured as taking place in two steps:

- I. Prothrombin-Ca + Thromboplastin = Thrombin
- II. Thrombin + Fibrinogen = Fibrin (clot)

The mechanism of the activation of prothrombin by thromboplastin is not understood, but it is known that it is not a union of the two substances. Thrombin is typically enzymatic in its action, and does not require calcium for its activity.

Prothrombin is a protein containing about 4 per cent carbohydrate. It is found in the globulin fraction of the plasma proteins. It appears to be composed of two components (A and B) which are combined with calcium. Sodium oxalate or citrate removes the calcium from prothrombin, thus disrupting the complex. Component A gradually disappears from decalcified plasma on storage. Component B is stable, but is readily adsorbed with aluminum hydroxide. This component is diminished in vitamin-K deficiency, and in poisoning from dicoumarol. Dicoumarol has the following structure:

Dicoumarol

It was first isolated from spoiled sweet-clover hay (Link), and has a powerful anticoagulant activity, being used clinically for prolonging the clotting time of blood. For further discussion, see Chapter 36.

For the synthesis of prothrombin the body requires vitamin K, which is found in most green plants and is also synthesized by bacteria such as E.coli and others found in the intestinal tract. The synthetic compound 2-methyl-1,4-naphthoquinone (menadione) has as high a vitamin-K activity as the naturally-occurring vitamins K_1 (from plants) and K_2 (from bacteria). The utilization of vitamin K for the production of prothrombin is dependent upon the liver, and impairment of the function of this organ results in a fall of the prothrombin level of the blood.

Thromboplastin is believed to be a complex containing cephalin and a protein. It is widely distributed in the body. The brain, lungs, and other organs contain a high concentration, but the main source for the coagulation of the blood comes from the disintegration of platelets. It is believed by some that thromboplastin functions as an enzyme and is associated

⁸ Quick: Am. J. Physiol., 140, 212 (1943),

with tryptase; others hold that it reacts stoichiometrically with prothrombin. The fluidity of the blood is maintained by preventing active thromboplastin from gaining entrance. Presumably this is accomplished by keeping the platelets intact. In hemophilia the coagulation defect is believed to be due to a deficiency of thromboplastin. Tocantins attributes this to an abnormal increase of antithromboplastin in the blood.

Fibrinogen is the most unstable protein of the plasma. When acted upon by thrombin, it is converted to fibrin which separates out in the form of crystal-like needles or threads forming a reticulum which enmeshes the cellular constituents of the blood. The clot retracts due to the influence of the platelets, and when these are abnormally diminished in number as in hemorrhagic purpura, clot retraction is abnormally delayed or absent.

The blood contains several factors that antagonize the clotting process. The serum albumin fraction contains a factor that rapidly neutralizes thrombin, but it does not retard coagulation since the affinity of thrombin for fibrinogen is greater. Heparin, a mucoitin polysulfuric acid, is the natural anticoagulant. It is found in the mast cells of Ehrlich as polychromatic staining granules. Heparin inhibits coagulation in three ways: (1) In conjunction with a co-factor found in serum albumin, it is a powerful antithrombin. (2) It prevents the conversion of prothrombin to thrombin (a co-factor of the plasma again is required). (3) It inhibits the agglutination of platelets and prevents this disintegration. In peptone and anaphylactic shock a rapid outpouring of heparin into the blood occurs which brings about a marked increase in the coagulation time or even total incoagulability. Heparin is employed clinically for the prevention of postoperative intravascular clotting or thrombosis.

In the analysis of whole blood or plasma, it is necessary to prevent the blood from clotting upon withdrawal from the body. This may be done by the addition to the blood of substances such as oxalate or citrate salts which remove ionized calcium. Fluoride is also used as an anticoagulant. In this connection it is important to remember that unless special precautions are taken, the anticoagulant may significantly alter the distribution of diffusible substances between cells and plasma. Heparin is an excellent anticoagulant in this respect, since it does not have this drawback; it is, however, relatively expensive. If, immediately upon withdrawal from the body, the blood is rapidly stirred or thoroughly "whipped" with a bundle of coarse strings, twigs, or a specially constructed beater, the fibrin shreds will not form in a network throughout the blood mass but instead will cling to the device used in beating. In this way the fibrin may be removed and defibrinated blood obtained, which is useful for some purposes.

Medicolegal Tests for Blood. Among the medicolegal tests for blood are the following: (1) Microscopical identification of the erythrocytes, (2) spectroscopic identification of blood solutions, (3) the guaiac or benzidine reaction, (4) preparation of hemin crystals, (5) precipitin and other immu-

⁶ Tocantins: Am. J. Physiol., 139, 265 (1943).

nological tests. Tests (4) and (5) are the most satisfactory medicolegal tests for blood.

Up to within recent times it has been impossible to make an absolute differentiation of human blood. Immunological or biological blood tests make such a differentiation possible. The precipitin test is founded upon the fact that the blood serum of an animal into which has been injected the blood serum of another animal of different species develops the property of producing a precipitate with serum similar to that injected, but exerts this influence upon the blood serum from no other species. The antiserum used in this test is prepared by injecting rabbits with increasing amounts of human blood serum at intervals of about four days, until a total of between 25 and 35 ml. have been injected. After a lapse of four or five days the animal is bled, the serum collected, placed in sterile tubes, and preserved for use as needed. In examining any specific solution for human blood it is simply necessary to combine the antiserum with various dilutions of the solution under examination and keep the mixture at room temperature. If human blood is present in the solution a turbidity will be noted and this will change within one to three hours to a distinctly flocculent precipitate. This antiserum will react thus with no other known substance.

Of the other four blood tests mentioned the hemin test is the most satisfactory. It gives equally reliable results with fresh blood and with blood from clots or stains of long standing, provided the latter have not been exposed to a high temperature or to the rays of the sun for a long period. The technique of the tests is simple and the formation of the dark brown or chocolate-colored crystals of hemin is indisputable proof of the presence of blood in the fluid, clot, or stain examined. The weak point of the test, medicolegally, lies in the fact that it does not differentiate between human blood and that of certain other species of animals. See Exp. 14, p. 438.

The guaractest and the benzidine reaction are delicate tests if properly performed. One of the most common mistakes in the making of the guaiac test is the use of a guaiac solution which is too concentrated and which, when brought into contact with the aqueous blood solution, causes the separation of a voluminous precipitate of resinous material which may obscure the blue coloration; this is particularly true of the test when used for the examination of blood stains. A solution of guaiac made by dissolving 1 g. of the resin in 60 ml. of 95 per cent alcohol is very satisfactory for general use. The test is frequently objected to upon the ground that various other substances-e.g., milk, pus, saliya, etc.-respond to the test, and that it cannot therefore be considered a specific test for blood and is of value only in a negative sense. We have demonstrated to our own satisfaction, however, that many samples of milk give the blue color upon the addition of an alcoholic solution of guaiac resin without the addition of hydrogen peroxide or old turpentine. It has also been shown that those milks which respond positively fail to do so after boiling. In the case of blood the test is positive both before and after boiling the blood for 15 to 20 seconds. Pus does not respond after boiling. Old, partly

putrified pus gives the test even without the addition of hydrogen peroxide or old turpentine, whereas fresh pus responds upon the addition of hydrogen peroxide. Saliva gives a positive reaction only in case blood or pus is present. Certain plant extracts give the test before but not after boiling for 15 to 20 seconds. The use of an alcoholic solution of guaiaconic acid instead of an alcoholic solution of guaiac resin has been advocated. The blue color upon the addition of the guaiaconic acid to milk is said to result only when the sample of milk tested is contained in sterile bottles. In the application of the guaiac test to the detection of blood, it has been found possible to detect laked blood when present in the ratio 1:5,000,000 and unlaked blood when present in the ratio 1:1,000,000.

Lymph. Lymph may be considered as the "middle man" in the transactions between blood and tissues. It is the medium by which the nutritive material and oxygen transported by the blood for the tissues is brought into intimate contact with those tissues and thus utilized. In the further fulfillment of its function, the lymph bears from the tissues water, salts, and the products of the activity and catabolism of the tissues and passes these into the blood. Lymph, therefore, exercises the function of a "gobetween" for blood and tissues. It bathes every active tissue of the animal body, and is believed to have its origin partly in the blood and partly in the tissues.

In chemical characteristics, lymph resembles blood plasma. In fact, it has been termed "blood without its red corpuscles." Lymph from the thoracic duct of a fasting animal or from a large lymphatic vessel of a well-nourished animal is of a variable color (colorless, yellowish, or slightly reddish) and alkaline in reaction to litmus. It contains fibrinogen, prothrombin, and leukocytes, and coagulates slowly, the clot being less firm and bulky than the blood clot. Serum albumin and serum globulin are both present in lymph, the albumin predominating in a ratio of about 3 or 4:1. The principal inorganic salts are sodium salts (chloride and bicarbonate), whereas the phosphates of potassium, calcium, magnesium, and iron are present in smaller amount.

Substances which stimulate the flow of lymph are termed lymphagogues. Such substances as sugar, urea, certain salts (especially sodium chloride), peptone, egg albumin, extracts of dogs' liver and intestine, crab muscles, and blood leeches are included in this class.

In a fasting animal, the lymph coming from the intestine is a clear, transparent fluid possessing the characteristics already outlined. After a meal containing fat has been ingested, this intestinal lymph is white or "milky." This is termed chyle, and is essentially lymph possessing an abnormally high (5 to 15 per cent) content of emulsified fat. This chyle is absorbed by the lacteals of the intestine and transported to the lower portion of the thoracic duct. Apart from the fat content, the composition of lymph and chyle are similar.

EXPERIMENTS ON BLOOD

DEFIBRINATED OX BLOOD

 Reaction: Moisten red and blue litmus papers with 10 per cent sodium chloride solution and test the reaction of the defibrinated blood.

- 2. Microscopical Examination: Examine a drop of defibrinated blood under the microscope. Compare the objects you observe with Plate IV. Repeat the test with a drop of your own blood.
- 3. Specific Gravity: Determine the specific gravity of defibrinated blood by means of an ordinary specific gravity spindle. Compare this result with the specific gravity as determined in the next experiment.
- 4. Specific Gravity by Copper Sulfate Method:10 Fill a small test tube with a solution of copper sulfate of known specific gravity¹¹ approximating that of the blood under test, say 1.058. From a height of about 1 cm. above the surface of this solution, allow a drop of blood to fall into the solution from a pipet, medicine dropper, or the tip of the finger if fresh blood is being used. Observe the behavior of the drop after the momentum of the fall has been lost and during the next 10 seconds. During this period the drop will either rise, continue falling, or remain stationary. If it remains stationary, the blood has the same specific gravity as the copper sulfate solution. If the drop rises, the blood is lighter than the solution; if it falls, heavier. In either of these events, repeat the determination with a copper sulfate solution of lower or higher specific gravity as the case may be. Solutions with gravity intervals of 0.002 are convenient; intervals of 0.001 may be used, in which case by interpolation the results will be accurate to approximately 0.0005 unit.

When the blood drop enters the copper sulfate solution it becomes encased in a film of copper proteinate, which prevents changes in specific gravity by diffusion, etc., for only about 10 or 15 seconds. After this time the behavior of the drop has no significance. Instead of whole blood, plasma or serum may also be used, with appropriate changes in the range of specific gravity covered by the tubes. A single portion of solution may be used repeatedly until about one-fortieth of its volume of blood has been added. Changes in the color of the solution from blue to green do not impair its value.

The same principle may be employed using a mixture of nonaqueous solvents of known specific gravity, such as chloroform and benzene. This method has certain disadvantages over the copper sulfate method described here. For a description of the Hammerschlag procedure using nonaqueous solvents, see the Eleventh Edition of this book.

5. Tests for Various Constituents: To 50 ml. of water in a large casserole, add 2 drops of acetic acid and bring to a boil. At the point of vigorous boiling, add 10 ml. of defibrinated blood slowly from a pipet, with stirring. Continue boiling and stirring for one minute after all the blood has been added. Then pour the mixture immediately onto a large folded filter which has been prepared beforehand. If the filtrate is not practically clear and colorless it should be discarded and the process repeated with more blood. Reserve the coagulum for further use. Why is the coagulum colored dark brown? Evaporate the filtrate to about 25 ml., filtering off any precipitate which may form in the process. Make the following tests

upon the filtrate:

Va. Benedict's Test: To 5 ml. of the neutralized filtrate add 5 drops of Benedict's solution and boil one minute. Explain.

b. Chlorides: To a small amount of the filtrate in a test tube add a few drops of nitric acid and a little silver nitrate. In the presence of chloride, a white precipitate of silver chloride will form.

c. Phosphates: Test for phosphates by nitric acid and molybdate solution

according to directions given on p. 193.

d. Crystallization of Sodium Chloride: Place the remainder of the filtrate in a watch glass and evaporate it on a water bath. Examine the crystals under the microscope and compare them with those in Fig. 134.

¹⁶ Method of Phillips, Van Slyke, Dole, Emerson, Hamilton, and Archibald. See Chapter 23.

¹¹ See Appendix.

- 6. Test for Iron: Incinerate a small portion of the coagulum from Exp. 5, above, in a porcelain crucible. Cool, dissolve the residue in dilute hydrochloric acid, and test for iron by potassium ferrocyanide or ammonium thiocyanate. Which of the constituents of the blood contains the iron?
- 7. Hemolysis ("Laking Blood"): Note the opacity of ordinary defibrinated blood. Place a few ml. of this blood in a test tube and add water, a little at a time, until the blood is rendered transparent. Hemolysis has taken place. How does the water act in causing this transparency? Examine a drop of hemolyzed blood under the microscope. How does its microscopical appearance differ from that of unaltered blood? What other agents may be used to bring about hemolysis?
- 8. Osmotic Pressure: Place a few ml. of blood in each of three test tubes. Hemolyze the blood in the first tube according to directions given in Exp. 7, above: add an equal volume of isotonic (0.9 per cent) sodium chloride to the blood in the second tube, and an equal volume of 10 per cent sodium chloride to the blood in the third tube. Mix thoroughly by shaking, and after a few moments examine a drop from each of the three tubes under the microscope (see Figs. 135 and 256). What do you find and what is your explanation from the standpoint of osmotic pressure?

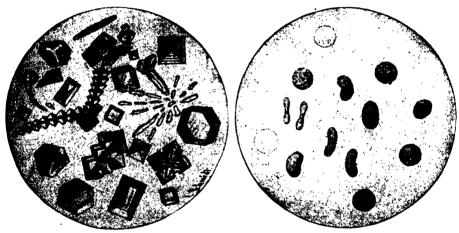

Fig. 134. Sodium chloride.

Fig. 135. Effect of water on erythrocytes.

9. Hemagglutination. The common garden bean, such as the Scarlet Runner, 12 contains a protein substance which exhibits the interesting property of causing clumping or agglutination of red blood corpuscles.

Dilute defibrinated blood¹³ ten times with physiological sodium chloride solution (0.9 per cent) and place 1 ml. in each of three small test tubes.

Grind three beans to a fine meal in a coffee mill or with mortar and pestle and extract for a few minutes with 0.9 per cent sodium chloride solution. Filter and add 0.05 ml. (about 2 to 3 drops) of the filtered extract to the first of the blood tubes, 0.01 ml. to the second, and 0.05 ml. of 0.9 per cent sodium chloride to the third.

Invert each tube to mix the contents thoroughly, and note the rapid agglutination and precipitation of the blood corpuscles in the first tube, a less rapid

12 The Scarlet Runner is a familiar variety purchasable in every seed store. It occurs in two varieties, the *white* and the *red*. Ricin, a protein constituent of the castor bean, also possesses pronounced agglutinating properties. Because of its poisonous nature it is, however, not suitable for use in class experiments.

13 Rabbit's blood is especially desirable and may be obtained for the purpose by bleeding from a small cut on the animal's ear and defibrinating.

agglutination in the second, while the third or control tube remains unaltered. In one-half hour the corpuscles in the first tube often are packed solid and one is able to pour off perfectly clear serum.

- If the remainder of the bean extract is boiled for a few minutes, the coagulum filtered out and 0.05 ml. of the filtrate added to the control tube, no agglutination occurs, indicating that the hemagglutinin has been destroyed or removed by the boiling.
- 10. Diffusion of Hemoglobin: Prepare some hemolyzed ("laked") blood, thus liberating the hemoglobin from the erythrocytes. Test the diffusion of the hemoglobin by preparing a cellulose dialyzer as described in Chapter 1. How does hemoglobin differ from other well-known crystallizable substances?
- 11. Guaiac Test: By means of a pipet drop a solution of guaiac in glacial acetic acid (strength about 1:60) into the solution under examination until a turbidity is observed, and add hydrogen peroxide, drop by drop, until a blue color is obtained.

In the detection of small amounts of blood the quantity of guaiac used should also be decreased. Do any other substances respond in a similar manner to this test? Is a positive guaiac test a sure indication of the presence of blood? (See the discussion on p. 433.)

12. Ortho-tolidin Test (Ruttan and Hardisty): To 1 ml. of a 4 per cent glacial acetic acid solution of o-tolidin in a test tube add 1 ml. of the solution under examination and 1 ml. of 3 per cent hydrogen peroxide. In the presence of blood a bluish color develops (sometimes rather slowly) and persists for some time (several hours in some instances).

This test is said to be as sensitive for the detection of occult blood in feces and stomach contents as is the benzidine reaction. It is also claimed to be more satisfactory for urine than any other blood test. The acetic acid solution may be kept for one month with no reduction in delicacy.

- 13. Benzidine Reaction. This is one of the most delicate of the reactions for the detection of blood. Different benzidine preparations vary greatly in their sensitiveness, however. Inasmuch as benzidine solutions change readily upon contact with light it is essential that they be kept in a dark place.
- The test is performed as follows: To 3 ml. of a saturated solution of benzidine in glacial acetic acid¹⁶ add 2 ml. of the solution to be tested and 1 ml. of 3 per cent hydrogen peroxide. A positive test is indicated by a blue or green color. The following modification is a much more delicate and reliable test.
- Confirmatory Test: Make 10 ml. of the solution acid with acetic acid and extract by shaking with 5 ml. of ether. The acid breaks up the hemoglobin to globin and heme and the latter is extracted by the ether. Pour off the ether into a small evaporating dish. Put on a hot water bath (with the flame turned out). Evaporate to dryness. To the residue add a few drops of water, a drop of saturated solution of benzidine in glacial acetic acid, and a drop of 3 per cent hydrogen peroxide. A blue or green color indicates blood.

¹⁴ Alkaline solutions should be made slightly acid with acetic acid, as the blue end-reaction is very sensitive to alkali. This is particularly necessary if an alcoholic solution of guaiac is used.

¹⁸ Glacial acetic acid is preferable, but if it is not available, alcohol acidified with acetic acid may be used.

The hemoglobin decomposes the hydrogen peroxide (catalysis) and the liberated oxygen oxidizes the benzidine. The sensitiveness of the benzidine reaction is greater when applied to aqueous solutions than when applied to the urine. The test is very delicate and more satisfactory than the guaiac test.

Lyle, Curtman, and Marshall suggest a different procedure in preparing the reagent and in conducting the test.

The test follows: Into a perfectly clean dry test tube introduce 1.4 ml. of benzidine solution, 16 add 0.2 ml. of water or glacial acetic acid, then 1 ml. of the fluid to be tested and finally 0.4 ml. of 3 per cent hydrogen peroxide. Note the appearance of a blue color, which reaches its maximum in five to six minutes.

The acetic acid keeps the benzidine in solution. An excess diminishes the delicacy of the reagent.

Hydrogen peroxide supplies oxygen for the reaction and also bleaches the blue color. An excess of peroxide interferes with the reaction by destroying the catalytic power of the blood and by reacting with the benzidine itself, with the formation of products which appear to have an inhibitory action. It is very essential that the peroxide be added *last*.

The benzidine solution should be dilute. Such solutions are exceedingly sensitive. Gregersen and Boas claim that the use of a too concentrated benzidine solution may lead to wrong diagnosis because of the excessive sensitiveness of the reagent. The feces of normal persons on a meat-free diet often yield a positive reaction. They suggest the use of a 0.5 per cent benzidine solution and the replacement of the hydrogen peroxide by barium peroxide which is much more stable. They, however, admit that slight hemorrhages may go undiscovered when this dilute benzidine solution is used.

14. Hemin Test:

a. Teichmann's Method: Place a very small drop of blood on a microscopical slide, add a small drop of water, and stir to lake the blood. Add a fraction of a drop of dilute (0.9 per cent) sodium chloride or potassium chloride solution and carefully evaporate to dryness over a low flame. Put a cover glass in place, run underneath it a drop of glacial acetic acid, and warm gently until the formation of gas bubbles is noted. Add another drop of glacial acetic acid, cool the preparation, examine under the microscope, and compare the crystals with those shown in Fig. 136.

The hemin crystals result from the decomposition of the hemoglobin of the blood. What are the steps involved in this process? The hemin crystals are also called Teichmann's crystals. Is this an absolute test for blood? Is it possible to differentiate between human blood and the blood of other species by means of the hemin test?

b. Nippe's Method: Spread a small drop of blood on a slide in the form of a film and evaporate to dryness over a low flame. Now add 2 drops of a solution containing 0.1 g. each of potassium chloride, iodide, and bromide

¹⁶ Bensidine solution may be prepared as follows: Place 4.33 ml. of glacial acetic acid in a small Erlenmeyer flask, warm to 50°, and add 0.5 g. of bensidine. Heat the flask for eight to ten minutes in water at 50°. To the resultant solution add 19 ml. of distilled water. This solution may be kept for several days without deterioration.

in 100 ml. of glacial acetic acid. Place a cover glass in position and heat gently over a low flame until gas bubbles form and the solution boils. Run 1 to 2 drops of the reagent underneath the cover glass and examine under a microscope. Compare the crystals with those shown in Fig. 136.

This method is more rapid than Teichmann's method and crystals of inorganic chlorides are not formed. In Teichmann's method crystals of sodium chloride (Fig. 134) often obscure the hemin crystals. For the preparation and purification of hemin on a large scale, see "Organic Syntheses," vol. 21, p. 53, 1941.

Fig. 136. Hemin crystals from sheep blood. (Reproduced from a photomicrograph furnished by the late Prof. E. T. Reichert, of the University of Pennsylvania.)

- 15. Immunological Determination of Blood Species. The serum proteins give immunological reactions, such as the precipitin reaction, which are specific not only for the individual proteins of the serum but also for the species of animal from which the serum is obtained. These immunological reactions are therefore used in medicolegal investigations to determine the species to which a particular blood sample or stain belongs. The species specificity of these reactions is demonstrated in the following experiments on the precipitin reactions of dog, beef, and human serums. Antiserums against human blood react with the serums of some of the higher apes, indicating a close relationship between the various species. Usually, however, even these reactions show quantitative differences which are sufficient to differentiate between human and other bloods.
- a. Preparation of Immune Serums (Antiserums): Prepare approximately 1 per cent solutions of dog, beef, and human serum proteins by diluting 15 ml. of the clear serums to 100 ml. with physiological (0.9 per cent) salt solution. Immunize rabbits against each of these solutions (antigens) by injection of the diluted serums into the marginal ear vein. Make the first injection with 1 ml. of antigen and follow with injections of 2, 4, 6, and

8 ml. portions at intervals of three or four days. On the fourth day after the last injection, collect 1 ml. of blood and test the serum for precipitin content by the method described below. If present in sufficiently high titer, bleed the rabbit from the heart, allowing the blood to coagulate. Transfer the clear serum to sterile vials closed with rubber stoppers. Add a few drops of chloroform to each vial as a preservative, and keep them in a refrigerator when not in use.

- b. Precipitin Reactions: The precipitin reactions are carried out in 25 mm. by 5 mm. tubes which are set into holes in a suitable board. 17 Set out three series of such tubes, each series consisting of three rows of four tubes each. Place a few drops of human antigen in the first row of tubes in each series, starting with the original 1:100 (1 per cent) solution in the first tube and using dilutions of 1:1,000, 1:10,000, and 1:100,000 in the other three tubes in the row.18 This may be done conveniently with the aid of a capillary pipet prepared by drawing out a piece of ordinary glass tubing. In a similar manner, partially fill the second row of tubes in each series with progressive dilutions of beef antigen and the third row with dog antigen. Then carefully stratify a few drops of undiluted human antiserum beneath the antigens in the 12 tubes of the first series, using clean pipets for each row to prevent contamination of the various antigens with each other. Treat the second series of antigens similarly with beef antiserum and the third series with dog antiserum. Positive precipitin reactions are indicated by the formation of visible precipitates at the surface of contact between the antigen and antiserum, in one hour at room temperature. Reactions are recorded by indicating the highest dilution of the antigen which forms a precipitate with the antiserum under the conditions of the experiment. If performed properly, with no contamination, precipitates will appear only in those tubes in which the antigen was treated with its own (homologous) antiserum. The stronger the antiserum, the higher the dilution of antigen with which it will react.
- c. Immunological Examination of Blood Stains: Extract the stain with 1 or 2 ml. of physiological salt solution. Filter and use the filtrate for making up dilutions of antigen and for precipitin reactions, as described above.
- 16. Catalytic Action: To about 10 drops of blood in a test tube add twice the volume of hydrogen peroxide, without shaking. The mixture foams. What is the cause of this phenomenon?
- 17. Crystallization of Oxyhemoglobin: Reichert's Method: Add to 5 ml. of the blood of the dog, horse, guinea pig, or rat, before or after laking, or defibrinating, from 1 to 5 per cent of ammonium oxalate in substance. Place a drop of this oxalated blood on a slide and examine under the microscope. The crystals of oxyhemoglobin will be seen to form at once near the margin of the drop, and in a few minutes the entire drop may be a

¹⁷ A convenient board for this purpose may be prepared by partially drilling holes, into which the tubes may slip easily, through a one-inch hardwood board. For ease in handling the various tests, these holes may be placed in rows about ½ inch apart with about ¾ inch between the holes in each individual row.

18 The various dilutions of the antigens may be made in small (10 cm. by 1 cm.) test tubes. Place 1 ml. of 1:100 antigen in the first tube, and 0.9 ml. of physiological salt solution in each of the other tubes. Withdraw 0.1 ml. of antigen from the first tube and add it to the salt solution in the second tube. Mix thoroughly by drawing the solution up into the pipet and blowing it back into the tube, repeating this process several times. Add 0.1 ml. of this solution, which contains 1 part of protein in 1,000 parts of solution, to the third tube, thus producing a 1:10,000 solution. Repeat this process for the higher dilutions. The same pipet may be used to introduce the various dilutions of an antigen into the precipitin tubes. In this case it is best to start with the highest dilutions of the antigen and work back to the more concentrated solutions, thereby preventing large changes in the concentration of the antigen. The same technique is used in adding antiserum to the various dilutions of the antigen.

solid mass of crystals. Compare the crystals with those shown in Figs. 126 to 129.

In some species (e.g., the rat) oxyhemoglobin tends to crystallize out of blood very rapidly. Merely pressing a small drop of blood between a cover slip and a microscope slide will result in a mass of oxyhemoglobin crystals.

18. Preparation of Hemoglobin: Method of Marshall and Welker: Draw blood into a flask and defibrinate by shaking with glass beads. Strain through cheesecloth. Centrifuge. Wash corpuscles three or four times with 0.9 per cent NaCl. Add ether a few drops at a time with thorough mixing until a clear solution is obtained. If the solution is viscid add a little water and then an equal volume of aluminum hydroxide cream (see Appendix). Mix thoroughly and filter. Cool to 0° C. and add absolute alcohol (also cooled to 0°) to make the alcohol percentage 20 to 30 per cent. Let stand at a few degrees below 0° C. Wash the crystals by decantation with 25 per cent alcohol at 0° C. Dry in a desiccator over sulfuric acid.

Fig. 137. Hemochromogen crystals. (Prepared and photographed by Dr. Arthur G. Cole, University of Illinois, College of Medicine.)

19. Hemochromogen Test: Add 2 or 3 drops of Takayama's solution¹9 to a small piece of suspected material on a slide. Cover with a cover glass. Examine under the microscope. Salmon pink crystals should appear in 1 to 6 minutes. At the same time the color changes through green-brown and dark red to pink, indicating the formation of a hemochromogen and confirming the test. The crystals have a shallow rhomboid form.

This method is simpler to use than the hemin test and may be used to confirm the latter in doubtful cases. It is not always given by old blood stains (over six months old) and hence does not replace the hemin test. The glucose may act as a reducing agent as well as by decreasing the solu-

¹⁶ A mixture of 3 ml. of 10 per cent NaOH, 3 ml. of pyridine, 3 ml. of a saturated solution of glucose, and 7 ml. of water. The solution works rapidly in the cold if at least 24 hours old. With a fresh solution warming or more time is necessary. It keeps for from one to two months.

bility of the hemochromogen. Schumm has cast some doubt on the

specificity of this test for blood.

20. Variation in Size of Erythrocytes: Prepare two small funnels with filter papers such as are used in quantitative analysis. Moisten each paper with physiological (isotonic) salt solution. Into one funnel introduce a small amount of defibrinated ox blood and into the other funnel allow blood to drop directly from a decapitated frog. Note that the filtrate from the ox blood is colored, whereas that from the frog blood is colorless. What deduction do you make regarding the relative size of the erythrocytes in ox and frog blood? Does either filtrate clot? Why?

BLOOD SERUM

- 1. Precipitation by Alcohol: To 5 ml. of serum in a test tube add twice the amount of 95 per cent alcohol and thoroughly mix by shaking. What is this precipitate? Make a confirmatory test. Test the alcoholic filtrate for protein. Explain the result.
- 2. Proteins of Blood Serum: Place about 10 ml. of serum in a small evaporating dish, dilute with 5 ml. of water, and heat to boiling. At the boiling point acidify slightly with dilute acetic acid. Of what does this coagulum consist? Filter off the coagulum (reserve the filtrate) and test it as follows:
 - a. Millon's Reaction: Make the test according to directions given on p. 154.
 - b. Hopkins-Cole Reaction: Make the test according to directions given on p. 173.
- 3. Sugar in Serum: To 5 ml. of the neutralized filtrate from Exp. 2 add 5 drops of Benedict's solution and boil one minute. What do you conclude?
- 4. Detection of Sodium Chloride: (a) Test a little of the filtrate from Exp. 2 for chlorides, by the use of nitric acid and silver nitrate. (b) Evaporate 5 ml. of the filtrate from Exp. 2 in a watch glass on a water bath. Examine the crystals and compare them with those reproduced in Fig. 134.
- 5. Separation of Serum Globulin and Serum Albumin: Place 10 ml. of blood serum in a small beaker and saturate with magnesium sulfate. What is this precipitate? Filter it off and acidify the filtrate slightly with acetic acid. What is this second precipitate? Filter this precipitate off and test the filtrate by the biuret test. What do you conclude? What other methods could be used here for separating these two protein fractions?

BLOOD PLASMA

1. Preparation of Oxalated Plasma: Allow venous blood to run into a centrifuge tube containing sufficient sodium oxalate to make a 0.2 per cent solution in the blood. Mix at once by rotation. Centrifuge at 3,000 r. p. m. for 15 minutes. Remove the clear plasma by means of a pipet.

2. Recalcification of Oxalated Plasma: Dilute 1 ml. of oxalated plasma to 30 ml. with 0.9 per cent sodium chloride solution, and add 1 ml. of 2.5 per cent calcium chloride solution. Mix and allow to stand at room temperature for 30 to 60 minutes. What happens? Explain. Insert a glass rod into the tube and carefully wrap the clot around the rod by rotating, pressing the clot against the side of the tube at the same time to squeeze the fluid out. If this is done carefully, the fibrin will be obtained in the form of a thin white sheath encasing the rod. Remove from the tube and strip off the fibrin. Test a portion with Millon's test. This method of converting fibrinogen into fibrin and isolating the fibrin is useful in the quantitative determination of fibrinogen in plasma.

3. Separation of Plasma Proteins: To 20 ml. of oxalated plasma in a small beaker add sufficient saturated ammonium sulfate solution to make the mixture 25 per cent saturated with ammonium sulfate. Filter off the

The addition of x ml. of saturated ammonium sulfate solution (100 per cent saturated) to 1 ml. of a solution which is y per cent saturated with respect to ammonium sulfate

precipitate of fibrinogen and reserve it for the following experiment. Raise the filtrate to 33 per cent saturation of ammonium sulfate by adding the calculated amount of saturated ammonium sulfate solution. Filter off the precipitate of euglobulin formed. To the filtrate from the euglobulin add sufficient saturated ammonium sulfate solution to bring the mixture to 46 per cent saturation of ammonium sulfate. Filter off the pseudoglobulin. Raise the filtrate from the pseudoglobulin precipitate to 64 per cent saturation of ammonium sulfate. Filter off the albumin. Precipitate the remainder of the albumin in solution by saturating the filtrate with solid ammonium sulfate. Test a small portion of each precipitate for protein. Estimate roughly the relative amounts of material obtained in each fractionation, by the bulk of the precipitate. How do your results compare with the data in the table on p. 414?

- 4. Experiments on Fibrinogen: Dissolve the fibrinogen from the preceding experiment in 10 ml. of 2 per cent NaCl solution. Add a few drops of dilute CaCl₂ solution to combine with any oxalate present and to give an excess of Ca ions. Add 2 to 3 drops of blood serum to furnish thrombin, or add a few drops of a thrombin solution prepared as described below. Note the coagulation of the fibrinogen.
- 5. Preparation of Thrombin (Eagle): Dilute 10 ml. of fresh citrated or oxalated plasma with 100 ml. of cold distilled water. Chill the mixture to about 5° C. in ice water and then bubble carbon dioxide gas through the solution for 5 to 10 minutes. Centrifuge off the precipitate and discard the supernatant fluid. Dissolve the residue in 10 ml. of 0.85 per cent sodium chloride solution and adjust the resulting solution to approximately pH 7.0 by the addition of sodium bicarbonate. Add to this final solution one-twentieth its volume of 0.1 M calcium chloride solution (1.1 per cent). Warm to 37° for a few minutes, insert a glass rod into the clot which forms and wrap the clot around the rod until all entrained fluid has been pressed out. Discard the clot, filter the remaining fluid, and store in the icebox. If kept cold, this thrombin solution is stable for about a week. Dried preparations of thrombin in sealed containers, which are stable indefinitely, may now be obtained from wholesale drug supply houses.

FIBRIN

- 1. Preparation of Fibrin: Allow blood to flow directly from the animal into a vessel and rapidly whip it by means of a bundle of twigs, a mass of strong cords, or a specially constructed beater. If a pure fibrin is desired it is not best to attempt to manipulate a large volume of blood at one time. After the fibrin has been collected it should be freed from any adhering blood clots and washed in water to remove further traces of blood. The pure product should be very light in color. It may be preserved under glycerol, dilute alcohol, or chloroform water.
- Solubility: Try the solubility of small shreds of freshly prepared fibrin in water, dilute acid, and alkali.
- 3. Protein Color Tests: Test a portion of fibrin by Millon's test; the Hopkins-Cole test; and the biuret reaction. What amino acids have you shown to be present in fibrin?

yields 1 + x ml. of a mixture which is z per cent saturated with respect to ammonium sulfate; i.e.

$$x \cdot 100 + 1 \cdot y = (x+1)z$$

By means of this relationship, the amount of saturated ammonium sulfate solution required to bring 1 ml. of plasma to any desired ammonium sulfate saturation, or to raise 1 ml. of plasma from one saturation to another, may be calculated. Thus, the amount of saturated ammonium sulfate solution required to bring 1 ml. of plasma to 33 per cent saturation of ammonium sulfate is given by: $x \cdot 100 = (x + 1)33$ (y in this case is 0). Thus the volume to add is ${}^{3}\text{M}_{7}$ or 0.493 ml. To raise 1 ml. of the solution at 33 per cent saturation of ammonium sulfate to 46 per cent saturation, the equation is $x \cdot 100 + 1 \cdot 33 = (x + 1)46$, from which $x = {}^{1}\text{M}_{4}$ or 0.241 ml.

SPECTROSCOPIC EXAMINATION OF BLOOD

As indicated in the text on p. 427, the spectroscope is a useful tool in the study of the blood pigments because of the differences in light absorption which these pigments show, and which are evident on spectroscopic examination. Plate I (Frontispiece) illustrates the appearance of the absorption spectra of hemoglobin and certain of its derivatives, the shaded portions of the spectrum in each case representing a region of specific light absorption. Since the ordinary hand spectroscope is not equipped with a wavelength scale, the absorption bands are usually located by reference to certain of the more prominent "Fraunhofer lines" of the sun's spectrum. These are dark lines, readily visible in the spectrum of sunlight, which correspond to the presence of certain elements in the vapors surrounding the sun. As shown in spectrum 1 of Plate I, the most prominent lines and their approximate wavelength in millimicrons are as follows: B, 687; C, 656; D, 589; E, 527; b, 517; F, 486.

Either the *direct*-vision spectroscope (Fig. 138) or the *angular*-vision spectroscope (Figs. 139 and 140) may be used in making the spectroscopic examination of the blood. For a complete description of these instruments the student is referred to any standard textbook of physics or to the catalogs of the manufacturers.

- 1. Oxyhemoglobin: Examine dilute (1:50) defibrinated blood spectroscopically. Note the broad absorption band between D and E. Continue the dilution until this single broad band gives place to two narrow bands, the one nearer the D line being the narrower. These are the typical absorption bands of oxyhemoglobin obtained from dilute solutions of blood. Now dilute the blood very freely and note that the bands gradually become more narrow and, if the dilution is sufficiently great, they finally disappear entirely.
- 2. Hemoglobin (So-called Reduced Hemoglobin): To blood which has been diluted sufficiently to show well-defined oxyhemoglobin absorption bands add a small amount of Stokes' reagent. The blood immediately changes in color from a bright red to violet-red. The oxyhemoglobin has been reduced through the action of Stokes' reagent and reduced hemoglobin has been formed, by the removal of the oxygen from the oxyhemoglobin. Examine this solution spectroscopically. Note that in place of the two absorption bands of oxyhemoglobin we now have a single broad band lying almost entirely between D and E. This is the typical spectrum of hemoglobin. If the solution showing this spectrum be shaken in the air for a few moments it will again assume the bright red color of oxyhemoglobin and show the characteristic spectrum of that pigment.
- 3. Carbon Monoxide Hemoglobin: The preparation of this pigment may be easily accomplished by passing ordinary illuminating gas¹² through defibrinated ox blood. Blood thus treated assumes a brighter tint (carmine) than that imparted by oxyhemoglobin. Examine the carbon monoxide hemoglobin solution spectroscopically. Observe that the spectrum of this substance resembles the spectrum of oxyhemoglobin in showing two absorption bands between D and E. The bands of carbon monoxide hemoglobin, however, are somewhat nearer the violet end of the spectrum. Add some Stokes' reagent to the solution and again examine spectroscopically.

²¹ See Appendix.

²² The so-called water gas with which ordinary illuminating gas is diluted contains usually as much as 20 per cent of carbon monoxide (CO).

Note that the position and intensity of the absorption bands remain unaltered.

The following are delicate chemical tests for the detection of carbon monoxide hemoglobin:

Alkali Test: Mix two drops of the suspected blood on a porcelain plate with an equal volume of 25 per cent NaOH. A reddish color remains in the presence of carbon monoxide hemoglobin. Treat two drops of normal blood in the same way. A brownish color is obtained.

Tannin Test: Divide the blood to be tested into two portions and dilute each with 4 volumes of distilled water. Place the diluted blood mixtures in two small flasks or large test tubes and add 20 drops of a 10 per cent

Fig. 138. Direct-vision spectroscope.

Fig. 139. Angular-vision spectrometer.

solution of potassium ferricyanide.²³ Allow both solutions to stand for a few minutes, then stopper the vessels and shake one vigorously for 10 to 15 minutes, occasionally removing the stopper to permit air to enter the vessel.²⁴ Add 5 to 10 drops of ammonium sulfide (yellow) and 10 ml. of a 10 per cent solution of tannin to each flask. The contents of the shaken flask will soon exhibit the formation of a dirty olive-green precipitate, whereas the flask which was not shaken and which, therefore, still contains carbon monoxide hemoglobin will exhibit a bright red precipitate, characteristic of carbon monoxide hemoglobin. This test is more delicate than the spectroscopic test and serves to detect the presence of as low a content as 5 per cent of carbon monoxide hemoglobin.

²³ This transforms the oxyhemoglobin into methemoglobin which does not combine with carbon monoxide.

¹⁴ This is done to dissipate any carbon monoxide present.

Dilution Test: In very dilute solution oxyhemoglobin appears yellowishred, while carbon monoxide hemoglobin under the same conditions
appears pinkish- or bluish-red. Dilute a drop of normal blood with water,
and dilute in parallel fashion a drop of blood containing carbon monoxide
hemoglobin with water, until by comparison a difference in tint is noted.
This is said to be as satisfactory a test as any for routine purposes.

Quantitative Determination of Carbon Monoxide: If possible collect blood from an arm vein in an oxalated tube. Otherwise wrap a finger of the subject with a rubber band. Prick deeply with a blood lancet. Draw 0.1 ml. of blood into a pipet and discharge into a test tube containing 0.9 ml. of

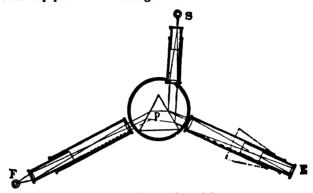

Fig. 140. Diagram of angular-vision spectroscope. (Long.) The white light, F, enters the collimator tube through a narrow slit and passes to the prism, P, which has the power of refracting and dispersing the light. The rays then pass to the double convex lens of the ocular tube and are deflected to the eyepiece, E. The dotted lines show the magnified virtual image which is formed. The third tube contains a scale whose image is reflected into the ocular and shown with the spectrum. Between the light, F, and the collimator slit is placed a cell to hold the solution undergoing examination.

distilled water, drawing back once or twice to insure removal of adhering blood. Mix immediately but not too vigorously. Add 1 ml. of freshly prepared pyrogallic-tannic acid solution and mix by inverting twice. After 15 minutes compare with standards prepared as follows: Lake one volume of oxalated human blood free from carbon monoxide with 9 volumes of distilled water. Saturate half of the laked blood with CO by rotating in a flask or separatory funnel filled with illuminating gas for 15 to 20 minutes, avoiding violent agitation. Mix proportional parts of the treated and untreated blood solutions to represent 0, 10, 20, 30, 40, . . . 100 per cent saturation. Transfer 1-ml. proportions of these solutions to test tubes of the same size as that used in the test. Add 1 ml. of freshly prepared pyrogallic-tannic acid solution to each and mix by inversion. Cover with a layer of melted paraffin and fill the remainder of the tubes with sealing wax. These standards are said to be permanent.

²⁵ Sayers and Yant: Bureau of Mines Technical Paper 373, (1925). These authors describe a compact field apparatus. For gasometric determination of carbon monoxide in blood see Chapter 24.

²⁶ Made by dissolving 2 g. pyrogallic acid and 2 g. of tannic acid in 100 ml, of distilled water.

- 4. Neutral Methemoglobin: Dilute a little defibrinated blood (1:10) and add a few drops of freshly prepared 10 per cent solution of potassium ferricyanide. Shake this mixture and observe that the bright red color of the blood is displaced by a brownish red. Now dilute a little of this solution and examine it spectroscopically. Note the single, very dark absorption band lying to the left of D, and, if the dilution is sufficiently great, also observe the two rather faint bands lying between D and E in somewhat similar positions to those occupied by the absorption bands of oxyhemoglobin. Add a few drops of Stokes' reagent to the methemoglobin solution while it is in position before the spectroscope and note the immediate appearance of the oxyhemoglobin spectrum which is quickly followed by that of hemoglobin.
- 5. Alkaline Methemoglobin: Render a neutral solution of methemoglobin, such as that used in Exp. 4, above, slightly alkaline with a few drops of ammonia. Due to the formation of alkaline methemoglobin the solution becomes redder in color and shows a spectrum different from that of the neutral solution. In this case we have a band on either side of D, the one nearer the red end of the spectrum being much the fainter. A third band, darker than either of those mentioned, lies between D and E somewhat nearer E.
- 6. "Alkali Hematin": This is probably a compound of heme and denatured globin. Mix one volume of a concentrated potassium or sodium hydroxide solution and two volumes of dilute (1:5) defibrinated blood. Heat the mixture gradually almost to boiling, then cool and shake in air a few minutes before using. Examine in the spectroscope. The typical spectrum shows a single absorption band lying across D and mainly toward the red end of the spectrum.
- 7. "Reduced Alkali Hematin" or Hemochromogen: Dilute the alkali hematin solution used in Exp. 6, above, to such an extent that it shows no absorption band. Now add a few drops of Stokes' reagent or ammonium sulfide and note that the greenish-brown color of the alkali hematin solution is displaced by a bright red color. This is due to the formation of hemochromogen or "reduced alkali hematin." Examine this solution spectroscopically and observe the narrow, dark absorption band lying midway between D and E. If the dilution is not too great a faint band may be observed in the green extending across E and b.
- 8. Acid Hematin: To some defibrinated blood add half its volume of glacial acetic acid and an equal volume of ether. Mix thoroughly. The acidified ethereal solution of hematin (heme) rises to the top and may be poured off and used for the spectroscopic examination. If desired it may be diluted with acidified ether prepared by mixing 1 part of glacial acetic acid with 2 parts of ether. A distinct absorption band will be noted in the red between C and D and lying somewhat nearer C than the band in the methemoglobin spectrum. Between D and F may be seen a rather indistinct broad band. Dilute the solution until this band resolves itself into two bands. Of these the more prominent is a broad, dark absorption band lying in the green between b and F. The second, a narrow band of faint outline, lies in the light green to the red side of E. A fourth very faint band may be observed lying on the violet side of D. The "acid hematin" that is obtained when blood is treated with dilute acid in aqueous solution, as in the colorimetric determination of hemoglobin, is a colloidal dispersion of hemin, and has no characteristic absorption bands.
- 9. Acid Hematoporphyrin: To 5 ml. of concentrated sulfuric acid in a test tube add 2 drops of blood, mixing thoroughly by agitation after the addition of each drop. A wine-red solution is produced. The strong acid splits the Fe from the porphyrin ring and hydrates the substituent vinyl groups, converting protoporphyrin into hematoporphyrin. A mixture of isomers is probably formed. Examine this solution spectroscopically. Acid

hematoporphyrin gives a spectrum with an absorption band on either side of D, the one nearer the red end of the spectrum being the narrower.

10. Alkaline Hematoporphyrin: Introduce the acid hematoporphyrin solution just examined into an excess of distilled water. Cool the solution and add potassium hydroxide slowly until the reaction is but slightly acid. A colored precipitate forms which includes the principal portion of the hematoporphyrin. The presence of sodium acetate facilitates the formation of this precipitate. Filter off the precipitate and dissolve it in a small amount of dilute potassium hydroxide. Alkaline hematoporphyrin prepared in this way forms a bright red solution and possesses four absorption bands. The first is a very faint, narrow band in the red, midway between C and D; the second is a broader, darker band lying across D, principally to the violet side. The third absorption band lies principally between D and E, extending for a short distance across E to the violet side, and the fourth band is broad and dark and lies between b and F. The first band mentioned is the faintest of the four and is the first to disappear when the solution is diluted.

DETECTION OF BLOOD IN STAINS ON CLOTH, ETC.

- Identification of Corpuscles: If the stain under examination is on cloth a
 portion should be extracted with a few drops of glycerol or physiological
 (0.9 per cent) sodium chloride solution. A drop of this solution should
 then be examined under the microscope to determine if corpuscles are
 present.
- 2. Tests on Aqueous Extract: A second portion of the stain should be extracted with a few drops of water and the following tests made upon the aqueous extract:
 - a. Hemochromogen: Make a small amount of the extract alkaline by potassium hydroxide or sodium hydroxide, and heat until a brownish-green color results. Cool and add a few drops of ammonium sulfide or Stokes' reagent (Appendix) and make a spectroscopic examination. Compare the spectrum with that of hemochromogen (see Absorption Spectra, Plate I). Hankin has suggested a test based upon the formation of cyanhemochromogen and the microspectroscopic demonstration of the spectrum of this compound.
 - b. Hemin Test: Make this test upon a small drop of aqueous extract according to the directions given on p. 438, or, better, make the test upon a little material scraped from the clot and put directly on a slide.
 - c. Guaiac Test: Make this test on the aqueous extract according to the directions given on p. 437. The guaiac solution may also be applied directly to the stain without previous extraction in the following manner: Moisten the stain with water, and after allowing it to stand several minutes, add an alcoholic solution of guaiac (strength about 1:60) and a little hydrogen peroxide or old turpentine. The customary blue color will be observed in the presence of blood.
 - d. Benzidine Reaction: Make this test according to directions given on p. 437 et seq.
 - e. Acid Hematin: If the stain fails to dissolve in water extract with acid alcohol and examine the spectrum for absorption bands of acid hematin.

Blood Analysis: Colorimetry and Photometry

The factors which influence the chemical composition of the blood in disease may be broadly classified as physical and metabolic. The former include those cases of retention due to alteration or destruction of permeable membranes in the excretory organs, such as the lungs, kidneys, and liver. The accumulation of nitrogenous waste products in certain forms of nephritis, and the hypercholesterolemia associated with obstruction of the biliary ducts by gallstones, are examples of retention brought about by such processes. In the so-called metabolic diseases alteration in the chemistry of the blood may be induced by increased or diminished formation or utilization of the various constituents. Thus the accumulation of glucose in the blood as a result of metabolic derangement is an outstanding feature of diabetes mellitus. In chronic nephritis with edema (nephrosis), the high cholesterol values are considered to be of metabolic origin. Without multiplying examples, suffice it to say that changes in the blood chemistry need not be anticipated unless some condition affecting formation, utilization, or elimination is suspected. It is noteworthy, however, that the line of demarcation between these factors cannot be drawn very sharply. For example, both metabolic and mechanical factors are probably at work in renal diseases. In this connection it is important to differentiate between cause and effect. For example, the evidence that gallstones are the result and not the cause of hypercholesterolemia is not complete.

The present status of clinical chemistry is largely the result of the development of methods for the satisfactory analysis of small amounts of blood. Prior to the advent of modern micromethods for blood analysis. quantitative knowledge of metabolic processes within the body was based primarily upon analysis of the diet and urine by the classical methods of analytical chemistry. This came about because the amounts of blood required for analysis by similar methods were so large as to preclude the routine use of blood analysis for clinical purposes, except for such isolated instances as the determination of hemoglobin. Shortly after the first decade of this century, the pioneer work of such outstanding biochemists as Folin, Benedict, Van Slyke, Myers, and their associates and pupils and many others, in developing methods for the analysis of small amounts of blood by volumetric, colorimetric, and gasometric methods, initiated the present phase of quantitative clinical chemistry in which blood analysis has become an indispensable adjunct to the study of the functions of the body in both health and disease.

called for and which are not described in detail here or elsewhere in this book. There is also a selected list of books and other treatises to which the reader is referred for a more comprehensive discussion than is possible in these pages of certain of the subjects considered here, particularly with reference to historical aspects and the clinical significance of laboratory data.

COLORIMETRY AND PHOTOMETRY

Introduction. Many methods for the quantitative analysis of blood, tissues, urine, and other biological material are based upon the production of colored solutions in such a way that the intensity or depth of color so obtained may be used as a measure of the concentration of substance being determined. Such use of color as an index of concentration has long been known to analytical chemists as the science of colorimetric analysis, or colorimetry, and the instrument used for color evaluation is called a colorimeter. These terms, while admittedly not precise, have the sanction of established usage, particularly when they refer to the very common type of color measurement in which the colored solution representing the substance in unknown concentration is brought by one means or another to exact color match with a suitable standard color. Until relatively recently this was the only practical method for colorimetric analysis, since the human eye is much more capable of establishing the presence or absence of exact color equivalence than it is of defining quantitative differences in color intensity in precise terms.

It is clear, however, from a knowledge of the physical nature of color. that color intensity may be established in terms of the degree of light absorption at specific regions or wavelengths in the visible spectrum. To take a simple example, a solution has a blue color because generally speaking it absorbs a lesser proportion of the blue components of the mixed white light passing through it than of any of the other colored components. Thus white light entering the solution will emerge in diminished intensity and have a preponderance of blue wavelengths. The darker the solution, i.e., the more intense the color, the greater must be the degree of light absorption at certain wavelengths, so that such light absorption may be used as a direct measure of color intensity. Analytical procedures based upon the direct measurement of color intensity in terms of light absorption at specific wavelengths are known as photometric procedures. and the instrument used is called a photometer. This usage is by no means universal, however, and there are many who continue to use the term "colorimetric" for methods based upon the production of colored solutions, regardless of the means by which the color intensity is established. To avoid confusion, it appears desirable to define a colorimetric procedure as one in which the colored solution representing the substance in unknown concentration is brought to exact color match with a standard color representing the substance in known concentration, while a photometric procedure is one based upon the direct measurement of color intensity in terms of the light-absorbing power of the solution at a specific region of the spectrum. Unlike colorimetric procedures, which are limited to the visible portion of the spectrum, the general principles of photometric procedures are as applicable to the absorption of energy in the ultraviolet and infrared portions of the spectrum as they are to absorption in the visible region, and increasing analytical use is being made of this fact. The use of turbidity and fluorescence for analytical purposes is discussed on pp. 485 to 487.

COLORIMETRY

As defined above, colorimetry is based upon the matching of a colored solution representing an unknown concentration of the substance undergoing analysis with a standard color representing the substance in known concentration. The substance must therefore be either colored by itself or capable of undergoing reactions leading to the production of a color. Furthermore, the color intensity must be dependent upon the concentration, otherwise the color reaction is valueless for colorimetric purposes. A colorimetric procedure therefore involves three operations: (1) The preparation of the colored solution to represent the unknown, (2) the obtaining of a suitable standard color, and (3) color matching.

If the substance being determined is itself colored—as, for example, hemoglobin, carotene, certain inorganic ions, dves, etc.—the preparation of the colored solution for analysis is usually relatively simple, and may involve merely appropriate dilution or concentration of the sample to produce a color of intensity suitable for comparison against a standard. Even under these conditions, however, it is usually better to separate the colored compound from possible interfering colored or noncolored material prior to estimation. If the substance must undergo a series of reactions leading ultimately to the production of a color, it is of the utmost importance to recognize that the final color intensity may be determined to a considerable extent not only by the concentration of unknown substance but also by the intermediate steps leading up to and including the development of the color. Such factors as the time of heating and cooling, order and rate of addition of reagents, whether the reagents are new or old, the time of standing and temperature of the solution during color development, the presence of nonchromogenic material such as neutral salts, and even the volume of solution in which the color reaction occurs, are all known to influence the final color intensity for a given amount of material in many if not all colorimetric procedures. For accurate and reproducible results, therefore, it is essential that all steps in a colorimetric procedure be carried out under as carefully controlled conditions as possible. In many cases the authors of colorimetric procedures have carefully specified the conditions for precise analysis, and these conditions should be followed without deviation.

The obtaining of a suitable standard color is obviously a most important phase of a colorimetric procedure. It may be stated without qualification that the most satisfactory standard color, and the one which should always be used for accurate results, is that obtained by treating a known concentration of the substance being determined by exactly the same procedure that is used for the unknown, at the same time, and under as

nearly identical conditions as possible. Thus the final colors in standard and unknown will be due to the same substance, differing if at all only in intensity, and the many nonspecific factors already mentioned which may influence color intensity will presumably affect the standard and unknown to exactly the same extent and will not influence analytical results based upon their comparison. All colorimetric procedures must be originally based upon the use of this type of primary standard, even though secondary standards may be later used, as discussed below. This results because there is no way to predict the relationship between color intensity and concentration except in terms of the color yielded by a known concentration of the substance.

It is assumed in the use of a standard color that if the standard and unknown exactly match in color intensity they represent equal concentrations of the substance being determined. In actual practice this may or may not be true. The standard usually contains the substance being determined in relatively pure solution; in the unknown, extraneous factors may be present which modify color intensity. Other substances than the one being determined may enter into the color reaction, and results will therefore be too high; the analytical problem under these conditions is to devise either a more specific color reaction or to find methods for eliminating nonspecific interfering substances, and much of the trend in colorimetric analysis has developed along these lines. Another type of interference which is less frequently recognized is the influence of nonchromogenic material present on the intensity of color produced by a given amount of chromogenic substance. This may be tested for by adding to the unknown a given amount of the pure substance, and measuring the resulting increment in color intensity. If this increment is greater or less than that known to represent the added amount of substance in pure solution, and there is no possibility of loss or destruction, then factors are present in the unknown which modify color intensity per unit concentration, and suitable correction must be made. This method of using an "internal standard," as it is sometimes called, does not prove that the total color yielded by the unknown is due to the substance being determined, but it does establish whether or not this substance is capable of giving a complete color reaction under the conditions of the analysis.

In some colorimetric procedures standard solutions are required containing substances which are expensive or difficult to obtain in the pure state (e.g., bilirubin, and at one time, creatinine), or which deteriorate rapidly on standing or may require unavailable technical skill and apparatus for standardization (e.g., hemoglobin). To provide for the routine use of colorimetric procedures based upon such standards, various "artificial" standards have been devised. In most instances these standards consist of stable colored solutions of dyes or inorganic salts, or of colored glass or gelatin. The color is selected by the investigator or manufacturer to correspond as closely as possible to that representing a known amount of the substance being determined. Examples of the use of artificial standards will be found in the Newcomer method for the determination of hemoglobin (p. 562), in the Benedict picrate method for the determination

of urine sugar (Chapter 32), and elsewhere. In using such standards, the color in the solution being analyzed is developed by the usual procedure and then compared against the artificial standard or standards representing known amounts of material.

There are many difficulties in the way of obtaining accurate results with artificial standards. Aside from the technical problem of an exact color match—and few individuals agree with one another on this point it has already been pointed out that color intensity depends not only upon concentration but also upon the technique of the analytical procedure. Therefore the intensity of color corresponding to a given amount of material being determined may vary from laboratory to laboratory. Furthermore, few colorimetric procedures result in the production of a color which does not show either an increase or a decrease in intensity on standing. Comparison against a simultaneously prepared standard which undergoes equivalent changes in color intensity will eliminate errors due to such changes; comparison against a stable standard will clearly give results which may depend largely upon the time of standing after color development, and careful control of this factor may therefore be necessarv. With few exceptions, artificial standards are satisfactory only where approximate results are sufficient; they should never be used simply to relieve the analyst of the responsibility for preparing and maintaining an exact standard solution. If artificial standards are used, they should always be checked in one's own laboratory and with one's own reagents. to eliminate errors from inexact calibration, and this checking should be repeated at frequent intervals or when new reagents are prepared.

Colorimeters. Colorimeters are instruments used to facilitate the exact matching of two colored solutions. This matching may be done in a variety of ways, summarized as follows:

1. By comparison against a series of standards. The unknown colored solution is compared by inspection with a series of color standards representing the substance being determined in known and varying concentration. The concentration of the unknown is given by the concentration of the standard which it exactly matches. The colorimeter is simply a device for holding the standards and unknown and for providing uniform conditions of illumination to facilitate exact color match. The method is simple and requires relatively inexpensive apparatus. Chief drawbacks include the labor of preparing and maintaining the standards, the possibility of error due to deterioration of standards already prepared, and the fact that the range and precision of the method is limited by the number of standards available. The method therefore finds greatest application where it is known that the scope of the analytical problem is limited to results within a certain range of concentration, and highest accuracy is not required. Examples of the use of this principle are found in the colorimetric determination of hydrogen-ion concentration (Chapter 1), in the Benedict picrate method for urine sugar (Chapter 32), and in an increasing number of "pocket," "bedside," and "field" analysis outfits available commercially for specific analytical purposes (see Fig. 141). In many instances these outfits are fitted with "artificial" permanent standards, usually of colored glass or gelatin, to eliminate the necessity of preparing a series of standards. The use of such artificial standards has already been discussed.

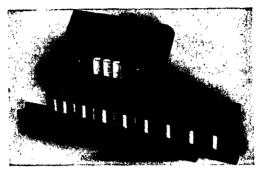

Fig. 141. Slide comparator, for colorimetric comparison against a series of standards. (Courtesy, W. A. Taylor Co., Baltimore.)

2. By dilution to color match. Either the unknown or the standard is diluted with water or other solvent until the two colors exactly match in intensity when compared under similar conditions of illumination and

depth of solution through which the light passes. Thus if the unknown must be diluted to twice its original volume to match a given standard, its original concentration is assumed to have been twice that of the standard, and in general if two colored solutions differing only in concentration are brought to color match by diluting one of them, the original concentration of the diluted solution is equal to the concentration of the undiluted solution multiplied by the ratio of final to initial volumes for the diluted solution. Only the simplest of apparatus is required for this procedure; the colorimeter may consist of two graduated test tubes (Fig. 142) or cylinders of equal bore. In the Sahli "hemoglobinometer" (see Fig. 177, p. 558), which exemplifies this type of color comparison, the blood sample is diluted in a graduated tube to match a permanent standard representing a known concentration of hemoglobin; from the dilution required the hemoglobin content of the sample is directly determinable. Dilution colorimetry is somewhat tedious, being comparable to a volumetric titration to an arbitrary end point, but results with an error not ex-

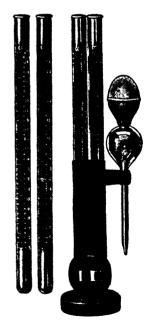

Fig. 142. Myers' testtube colorimeter.

ceeding 5 per cent may be obtained with practice. A major disadvantage of the dilution procedure is that many colored solutions are affected by dilution out of direct proportion to the change in total volume, due to the influence of such factors as neutral salt concentration, acidity, or even the relative amount of solvent itself on color intensity. Thus a blue solution of copper sulfate on being diluted to twice its original volume will have its color intensity affected not only by the change in volume alone but also by the change in copper-ion activity ("degree of dissociation") brought about by the dilution. It cannot be assumed that the dilution procedure is accurate, therefore, unless it has been shown to be so experimentally.

3. By varying the depth of solution through which the light passes. This procedure is the basis of the common laboratory visual colorimeter, and is the most exact and satisfactory method of color comparison. It is based upon what is commonly known as Beer's law, which for present purposes may be stated as follows: the intensity or density of color in a solution is determined for a particular substance solely by the number of colored particles (molecules or ions) in the light path. For example, a 1 per cent solution of a dye viewed through a solution depth of 20 mm. should have the same color as a 2 per cent solution viewed through 10 mm. of solution, since there are the same number of colored molecules or ions in the light path in each instance. In other words, color density is directly proportional to the concentration of colored substance and the depth of solution through which the light passes. Stated mathematically, for a particular colored substance,

$$D = k \times c \times l$$

where D is the color intensity or density, k is the proportionality constant characteristic of the substance, c is the concentration of colored substance, and l is the thickness or depth of solution traversed by the light beam.

For two solutions of the same substance at different concentrations c_1 and c_2 , and depths of solution l_1 and l_2 ,

and
$$D_1 = k \times c_1 \times l_1$$
$$D_2 = k \times c_2 \times l_2$$

If l_1 and l_2 are varied so that the two solutions have the same color intensity (i.e., $D_1 = D_2$), which is what is done in colorimeters based upon this principle, then

$$k \times c_1 \times l_1 = k \times c_2 \times l_2$$

or, by transposing and canceling out k,

$$\frac{c_1}{c_2}=\frac{l_2}{l_1}$$

Thus two different concentrations of the same colored substance are related inversely to the depths of solution required for color match. If one of these solutions is a standard of known concentration, C_s , adjusted to color match with the solution of unknown concentration, C_x , by varying the depth of solution (readings R_s and R_x respectively on the colorimeter), the equation becomes):

$$\frac{C_x}{C_s} = \frac{R_s}{R_x}$$

¹See pp. 468 to 470 for a more detailed discussion of Beer's law.

or

$$C_{\mathbf{x}} = \frac{R_{\mathbf{s}}}{R_{\mathbf{x}}} \times C_{\mathbf{s}}$$

i.e., the concentration of the unknown is given by the readings of standard and unknown and the concentration of the standard.

In using this equation, it must not be overlooked that the term concentration means amount per unit volume, hence a more exact form of the equation is as follows:

$$\frac{X}{V_x} = \frac{R_s}{R_x} \times \frac{S}{V_s}$$
 or
$$X = \frac{R_s}{R_x} \times S \times \frac{V_x}{V_s}$$

where X and S are the actual amounts of substance present in volumes V_x and V_8 of unknown and standard colored solutions respectively, and R_x and R_8 are the colorimeter readings as before. This form of the equation is the fundamental one upon which are based all colorimetric procedures of the type described here. In most procedures the final volumes of unknown and standard are the same, and the volume factor V_x/V_8 cancels out; results are then obtained primarily in terms of the actual amounts of substance present, and as a matter of fact the directions for most colorimetric procedures prescribe the taking of a definite amount rather than concentration of standard. In certain colorimetric procedures (e.g., the determination of creatinine in blood, p. 506) the volumes of standard and unknown differ, and in such cases these volumes must be substituted in the above equation.

The value of X as obtained by the above calculation represents the amount of material in the portion of sample actually taken for color development. To express results in terms of amount per 100 ml. of blood, for example, X must be multiplied by 100/v, where v is the volume of blood in ml. which contained the material on which the color was developed. Thus if color development in a blood sugar determination is carried out on a 2-ml. portion of filtrate from the blood diluted tenfold in the preparation of the protein-free filtrate used for the actual analysis, v in this case equals 0.2, since the 2 ml. of filtrate represent 0.2 ml. of original blood.

In applying the above equations to colorimetric calculations, certain limitations must be noted. For mechanical, optical, and analytical reasons the inverse relationship between concentration and depth of solution at color match is in general not applicable over the entire length of the colorimeter scale, which is usually about 40 to 50 mm. long and graduated in millimeters. The standard is ordinarily selected to be of such strength as to give a good intensity for color comparison at a depth of about 15 or 20 mm. It is a general rule that readings of an unknown which are less than half or more than double the reading of the standard are outside the range of application of Beer's law. The amount of sample taken for analysis is selected if possible so that the expected reading will

come within this range relative to the standard reading; readings outside this range are regarded as approximations only, to be used as a guide for repeating the analysis on a more satisfactory aliquot of sample. In general, it is better to change the amount of sample analyzed so as to come within the range of the standard than to alter the standard, since the standard is usually so selected as to provide the most satisfactory intensity for color match; lighter or darker standards may give less accurate results. If the amount of sample available is limited, however, and it is known that unusually high or low values may be encountered, the analysis may be saved by routinely providing several standards at different concentrations, the unknown being compared against the standard which it most closely matches on inspection.

In some colorimetric procedures the range of inverse proportionality between scale reading and concentration is much less than that represented by the "half or double" rule. The authors of such procedures usually specify the reliable range of readings. If the deviation from Beer's law is systematic, it is sometimes possible to establish a table of corrected values, showing the relation between the observed readings and the amount present, thus extending the range of permissible readings. From what has been said concerning the various factors which influence color intensity, however, it is clear that such a table is highly empirical and usually reflects the conditions prevailing in one laboratory only. It should be checked at intervals for accurate results; this checking is particularly important if a table developed elsewhere is to be used.

The use of light filters or of a monochromatic light source is ordinarily unnecessary in colorimetric comparisons, and mixed white light is commonly used, since if standard and unknown contain the same colored substance, at color match light transmission must be the same at all wavelengths. If extraneous colored material is present (i.e., if the reagents themselves are colored), or if unknown and standard differ in hue as well as in intensity, properly selected light filters may considerably improve the precision of readings or the range of applicability of Beer's law. When artificial standards are used, uniform and reproducible illumination is particularly important, since such a standard may for example represent one concentration by daylight and a different concentration by artificial light.

Colorimeters constructed to utilize the relationship between depth of solution and concentration expressed in Beer's law usually consist of (a) a source of light (mirror or built-in electric lamp); (b) a pair of adjustable cups and plungers, for varying the depth of solution through which the light passes; (c) an optical arrangement for looking down through the plungers and for bringing into juxtaposition the two fields of light from the solutions being compared, to facilitate exact color match. Many different commercial models are available. The constructional details of one type are shown in Fig. 143, and other types are illustrated in Figs. 144

^{1a} The instruments manufactured by the Klett Manufacturing Co., New York, the Bausch and Lomb Optical Co., Rochester, N. Y., and the American Optical Co., Buffalo, N. Y., are especially satisfactory in the authors' experience.

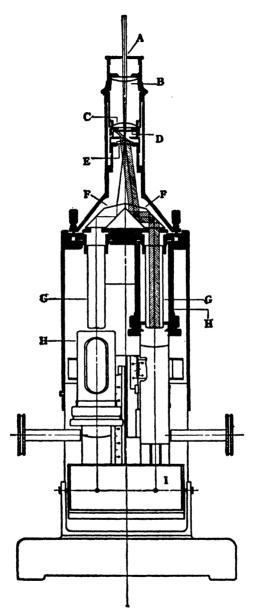

Fig. 143. Diagram showing construction of Duboseq colorimeter (Bausch and Lomb). (A) Eyepoint, (B) eye lens, (C) collective, (D) cover glass, (E) bi-prism, (F) rhomboid prism, (G) plungers, (II) cups, (I) mirror.

and 145. In the original colorimeter of this type, designed by Duboscq, the cups were fixed and the plungers were raised or lowered to vary depth

Fig. 144. Klett Biocolorimeter, with built-in lamp in base. (Courtesy, Klett Manufacturing Co., New York.)

of solution: in modern Duboscq-type colorimeters, the plungers are fixed and the cups are adjustable. The cups usually hold about 5 ml. of solution: micro-cups and plungers may be used for smaller volumes. Cups with flared tops, to provide for the use of smaller volumes of solution without overflow, are preferred over the straight-side type. Some types of cups leak when in contact with certain nonaqueous solvents such as chloroform, and are therefore unsuitable for such purposes unless sealed with a resistant cement. For illumination, the most satisfactory sources are North sky light or light from an electric lamp equipped with a "daylite" filter. In selecting a colorimeter, the choice should be determined largely by the size and definition of the optical field and the evenness of its illumination, the excellence of mechanical and optical construction, and the ease of operation and reading.

The general principles involved in the use of a Duboscq colorimeter are illustrated by the following experiments.

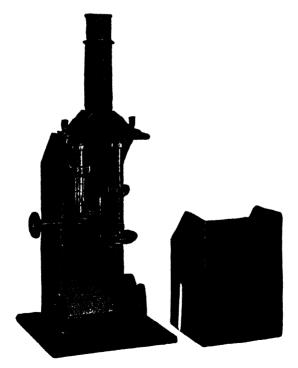

Fig. 145. Micro-colorimeter (Bausch and Lomb).

EXPERIMENTS ON COLORIMETRY

- 1. Preparation of Colorimeter for Use: (a) Light Source: Place the colorimeter on a firm table with the mirror facing the light source. A North window or "daylite" lamp is best. Some colorimeters have a built-in electric lamp in the base; this is equally satisfactory. Look through the eveniece of the colorimeter and note the appearance of the field, focusing if necessary to bring it into sharp definition. Adjust the mirror (or the lamp in the base) and note that the evenness and intensity of illumination can be varied at will by this adjustment. Adjust until the two halves of the field are approximately evenly illuminated, at maximum intensity. This is a preliminary adjustment only; final adjustment in an analysis must always be made with the standard, as described in Exp. 2.
 - (b) Checking the Zero: Place each cup, clean and dry, on its rack beneath a plunger and carefully rack up the cup until it comes in contact with the bottom of the plunger. Read the colorimeter scales; each should read 0.0. If they do not, locate the scale adjustment or its equivalent and adjust so that both scales read 0.0 when cup and plunger are in contact. Check by lowering the cups slightly, then raising to contact and again reading. Now lower the cups and interchange them on the plungers. Again bring to contact with the plungers and read. Are the scales still in adjustment? It is common practice to mark one cup, as by wrapping a rubber band around it, so that accidental exchange will not occur.
- 2. Use of Colorimeter for Comparing Two Solutions: Obtain two colored solutions, a "standard" and an "unknown," containing the same substance in slightly different concentrations. Half fill each cup with a portion of the "standard," place the cups on the racks, and rack up carefully to contact with each plunger. This serves to displace air bubbles which may be trapped under the plunger. Get into the habit of routinely checking the zero at this point at the same time. Lower the cups until both scales read exactly 15.0. Look through the eyepiece. Adjust the light source carefully until the two halves of the field are as evenly illuminated as possible. Theoretically, the reading on each side is now 15.0; actually, there is as much error in this adjustment as in the subsequent reading of an "unknown," therefore for precise results the solution on one side should now be read against the other side ("matching the standard against itself"). Leaving the left-hand cup set, lower the right-hand cup slightly to throw the two halves of the field out of balance, then raise the cup slowly while looking through the eyepiece until the field appears exactly even. Note the righthand scale reading. Repeat this process three or four more times, and average the readings. This is the actual reading of the standard that is used in the calculations.

When the reading of the standard in the right-hand cup has been established, remove this cup, discard its contents, and place a portion of "unknown" in the cup. Holding the cup in the hand, run it up and down briefly on the right-hand plunger, thus rinsing cup and plunger with the "unknown." Discard the cup contents and repeat the rinsing with a fresh portion. Finally half-fill the cup with fresh "unknown" and replace it on the cup rack. Run it up carefully to contact with the plunger, to displace air bubbles, then lower it until inspection through the eyepiece indicates color match. Make the reading, and repeat three or four times as described for the standard, averaging the readings. The average result is the reading of the "unknown."

From the readings of standard and unknown, and the known concentration of the standard, the amount of material in the "unknown" is calculated as follows:

Reading of Standard × Concentration of "Standard" = Concentration of "Unknown" of "Unknown" Note that in this calculation the readings of standard and unknown are both made on the same scale, i.e., the right-hand scale. The standard in the left-hand cup is set at 15.0 (or 20.0, or whatever value is specified) merely to establish a satisfactory color intensity for comparison purposes, and its reading does not enter into the calculations. As a matter of fact, some types of colorimeter do not have more than one scale. It is true that various other methods of reading a colorimeter have been proposed, but these are all subject to more error than the procedure described here.

In making colorimeter readings, it is good practice to rest the eyes frequently by looking up from the colorimeter, since the eyes tire easily and color discrimination becomes less acute. Make four or five independent readings and average them to minimize error; if one reading in the series is obviously quite different from the others it may be discarded in averaging. Best results are obtained if alternate readings are approached from above and below, with the hand removed from the instrument between readings, thus minimizing the tendency to return mechanically to the same reading.

- 3. Influence of "Personal Error" on Colorimetry: Repeat the above experiment, but after you have read the standard against itself, have another individual make independent readings, and compare results. How closely do you agree? Now read the unknown against the standard, and calculate the concentration of the unknown from your readings. Have the second person likewise read the unknown and calculate results from his readings. Is any difference in opinion concerning the readings reflected in the final results? In general, it is necessary for each analyst to make his own readings of both standard and unknown; in this way, differences of opinion as to precise color match do not influence results.
- 4. Beer's Law: Obtain a series of aqueous methylene blue solutions containing 0.004, 0.005, 0.010, 0.020 and 0.030 g. per liter respectively of the dye. Select the 0.010 g. per liter solution as a standard, and set at 15 mm. Match the standard against itself, making the readings as described in Exp. 2, and then read each of the other solutions against this standard. On a sheet of cross-section paper, plot the colorimeter readings on the y-axis against the concentration on the x-axis. Draw a smooth curve between the points. Now calculate by the use of Beer's law what the various readings should be for the determined reading of the standard. Plot these "theoretical" readings on the same graph, and connect the points by a smooth curve. Do the two curves overlap completely or do they diverge at any points? To what extent does this dye "follow Beer's law" under these conditions? How could you obtain accurate results in a colorimetric procedure which is known not to obey Beer's law?

Another way of plotting results is to plot the theoretical reading for a given concentration against the actual reading. A straight line indicates adherence to Beer's law. It is the general practice to obtain results by calculation based on Beer's law only if the unknown reading is not more than double or less than half the standard reading. Unknowns falling outside this range are repeated using more or less of the sample for analysis.

5. Influence of Analytical Procedure on Color Intensity: Into each of two small flasks place 20 ml. of standard ammonium sulfate solution contain-

ing 0.2 mg. of nitrogen (see p. 499). To one flask add 2 ml. of Nessler's reagent,² drop by drop, from a buret (because of its poisonous nature,² never use a pipet with Nessler's reagent). Set aside, and to the second flask add 2 ml. of the Nessler reagent, as rapidly as possible. Mix by lateral shaking and set aside. After 10 minutes' standing, read one of the two solutions against itself in the colorimeter, and then read the second solution against the first. Do the readings indicate that the two solutions have the same concentration of ammonia? What must be done to ensure uniform results?

PHOTOMETRY

General. Photometry, in the sense that the term is understood in analytical chemistry, consists in the measurement of the light-transmitting power of a solution in order to determine the concentration of light-absorbing material present. For purposes of simplicity the term light is used in place of the more inclusive term radiant energy. It must be understood that the principles upon which photometry is based are as applicable to the transmission of energy in the ultraviolet or infrared portions of the spectrum as they are to transmission in the more commonly employed visible or "colored" spectrum (see Fig. 308, Chapter 35, for a chart showing the spectral distribution of radiant energy).

The ability of a solution to transmit light is known as the transmittance, T, of the solution. Strictly speaking, transmittance is defined as the ratio of the intensity, I, of the light emerging from the solution to the entering or incident light intensity, I_0 , or

$$T=\frac{I}{I_0}$$

For photometric purposes, however, it is neither practical nor necessary to measure the incident light intensity and to define transmittance in this way. In a photometric procedure there is always a certain proportion of nonspecific light loss during passage through the solution due to reflection from glass surfaces, scattering, absorption by the solvent and reagents, and even possibly by contaminating traces of the substance which is being determined. Any of these will obviously influence a single measurement but should be constant from one measurement to another, and may therefore be balanced out by defining transmittance in relative terms. Thus it is more practical to define the transmittance T_c of a solution containing a concentration c of light-absorbing material as the ratio of the intensity I_c of light emerging from the solution to the intensity I_b of light emerging from a reference solution, usually the colorless solvent or reagent blank, both solutions being examined under equivalent conditions of wavelength, incident light intensity, and depth of solution; or

$$T_{\mathfrak{o}} = \frac{\mathbf{I}_{\mathfrak{o}}}{\mathbf{I}_{\mathfrak{b}}}$$

² See Appendix.

¹ See Chapter 32 for a discussion of the chemistry of Nessler's reagent and the reaction with ammonia.

In this way neither the intensity of the incident light nor the nonspecific light loss need be determined, and furthermore contaminating traces of the substance being determined, or reagents which are themselves colored, do not interfere in an analysis. The change in transmittance due to the presence of the substance is determined solely by the increase in light absorption above a level which is arbitrarily taken as zero. It is this possibility of ruling out error from blank light absorption which represents an outstanding advantage of photometric analysis over colorimetric analysis with the Duboscq colorimeter, where this cannot be done without the use of correction factors.

Transmittance is thus a relative measurement and is always less than 1.0 if light-absorbing material is present. It may be expressed numerically either as a decimal fraction or in terms of per cent, e.g., a transmittance of 0.6 or 60 per cent, depending upon whether I_b in the equation above is taken as 1.0 or as 100 per cent. A more satisfactory way of expressing the transmittance of a solution is in terms of its negative logarithm, or the value of $-\log T$, where T is the transmittance. The value of $-\log T$ is known as the optical density, D, or frequently as the extinction, E, of the solution. The utility of this basis for defining light absorption, particularly for photometric purposes, will be presented subsequently.

Determination of Transmittance. The light transmittance of a solution is determined by the use of an instrument known as a photometer. Many varieties and designs of photometers have been described and are available commercially; regardless of design, the basic principle upon which all analytical photometers operate is fundamentally the same, and may be described as follows: Light of suitable wavelength is allowed to pass through a reference solution, usually the colorless solvent or reagent blank, held in a container of fixed dimensions, known as a cuvette. The intensity of light emerging from the reference solution is established at an arbitrary value by any of the various methods described below, this value usually corresponding to a reading on the photometer scale of 0 optical density or 100 per cent transmittance. The reference solution is then replaced by the solution whose transmittance is to be determined, held in the same or a similar cuvette, and the emergent light intensity measured relative to that established for the reference solution: this relation gives the transmittance of the solution under examination.

The intensity of light emerging from a solution may be established by either visual, photographic, or photoelectric (or equivalent) means; of these, the last is most common, most accurate, and has largely displaced the others. In a visual photometer, the emergent light beam is compared in intensity with a parallel reference beam of similar properties which is of arbitrary and adjustable intensity. The adjustment required to bring the reference beam to the same intensity as that emerging from the solution

^{*}Some investigators, particularly in European laboratories, use the natural logarithm rather than the common logarithm, i.e., $-\ln T$ rather than $-\log T$. The choice is immaterial for photometric purposes but may lead to confusion in applying data obtained elsewhere. The relation between these two methods of expression is as follows:

under examination is the measure of the emergent light intensity. Measurements are therefore influenced by the acuity of visual color intensity discrimination, as in visual colorimetry. In the photographic plate method, the intensity of action of the emergent light on a photographic plate is compared with the action of light of relatively known and adjustable intensity under similar conditions. This procedure is tedious and has been used in the past largely for measurements in the ultraviolet and infrared portions of the spectrum, where the eye is insensitive. Much of the earlier data in the literature concerning light absorption in these regions of the spectrum is based on this method, but it has been superseded almost entirely by the use of light-sensitive devices such as the photoelectric cell or its equivalent.

Light intensity is determined photoelectrically by using photoelectric cells or similar light-sensitive devices which produce an electric current in proportion to the intensity of light striking their active surfaces. Two types in common use are (1) the photovoltaic cell ("plate type," "rectifier," or "barrier layer" cell) and (2) the photoemissive tube. A photovoltaic cell consists essentially of a metal plate coated with light-sensitive material (selenium, cuprous oxide) which is in turn coated with a thin transparent film of a metal such as gold or copper. Light passing through the transparent film sets up a flow of electrons in one direction ("rectified") which establishes a potential difference between the two poles of the cell, and causes a current to flow if the cell is in a suitable electric circuit. Because of the electrical characteristics of photovoltaic cells, the current is not suitable for amplification, but for ordinary light intensities it is sufficiently large to be registered on a microammeter or low sensitivity galvanometer, and many types of photometers employ such cells. Photoemissive tubes or phototubes are either evacuated or gas-filled tubes similar in appearance to radio tubes and containing a plate coated with some substance which emits electrons when light strikes it, the electrons traveling to a suitable anode under proper conditions. The intensity of incident light thus determines the flow of electrons through the tube, and hence the current in an external circuit. This current is very small but may be readily amplified, and photometers employing such tubes usually have an amplifier circuit. An advantage of phototubes is that they may be obtained with wide ultraviolet and infrared sensitivity, which is not the case with the photovoltaic cell.

With photosensitive devices, change in current output is used as a measure of change in light intensity. If the current output is adjusted to an arbitrary value with the reference or blank solution in place in the photometer, then the transmittance of an unknown solution is given by the ratio of current output for this selution as compared to that for the reference solution. It is assumed that the current output is strictly proportional to the light intensity; with well-designed photometers this is usually sufficiently true over the range of light intensity for which they are used. If it is not the case, there may be apparent deviation from the theoretical relation between transmittance and concentration as defined by Beer's law (see p. 468), and such photometers are usually worthless

for analytical purposes. Since the transmittance is measured in a photoelectric photometer in terms of current output rather than of actual light intensity, it has been proposed that in such instances the term photometric density be used for the value of $-\log T$, rather than optical density. From a practical point of view this distinction is unimportant and will not be used here, but it serves to emphasize the point that the numerical value of the optical density for a given substance may be considerably influenced by the characteristics of the photometer used for the measurement.

Light absorption at specific wavelengths is an intrinsic property of many substances, as for hemoglobin and other colored compounds in the visible region of the spectrum, and for many other compounds in the ultraviolet and infrared portions of the spectrum. It may therefore be used to characterize such substances, just as other physical constants are so used, in addition to its use in photometric analysis. The extinction at a specified wavelength for a known amount of a particular substance in solution is known as the specific extinction or extinction coefficient; the amount is frequently defined as that present in a 1-cm. layer of solution containing 1 per cent of the substance (symbolized by $E_{1,qqq}^{1,q}$). If the concentration is expressed on a molar basis, the term molar (or molecular) extinction is used. These constants are of more value for characterizing the substance in terms of its optical properties than for actual use in photometric analysis, but if they are sufficiently reproducible they may be used for the latter purpose, since they define the relationship between concentration and light absorption for the particular substance under specified conditions.

Beer's Law. The transmittance of a solution containing light-absorbing material depends upon (a) the nature of the substance, (b) the wavelength of the light, and (c) the amount of light-absorbing material in the light path; this latter depending in turn upon the concentration of substance and the depth of solution through which the light passes. The relation between these various factors was first clearly established for colored solutions by Beer, and hence is known as Beer's law. This relation may be expressed as follows: at a given wavelength,

$$T = 10^{-k \cdot l \cdot c}$$

where T is the transmittance, k is a constant characteristic for the substance, c is the concentration of light-absorbing material, and l is the depth of solution through which the light passes. The equation is exponential because of the particular characteristics of light absorption (see texts on physics for details); it may be converted to the more common logarithmic form by taking the logarithm of both sides, as follows:

or
$$log T = -k \times l \times c$$
$$-log T = k \times l \times c$$

These equations relating transmittance, concentration, and depth of solution, at a given wavelength, are the fundamental ones upon which photometric analysis is based.

Relation between Transmittance and Concentration. If the transmittances of a series of solutions of a particular substance in various known concentrations are determined, at a particular wavelength and constant depth of solution (the usual conditions in a photometric analysis), the resultant data relating transmittance to concentration may be

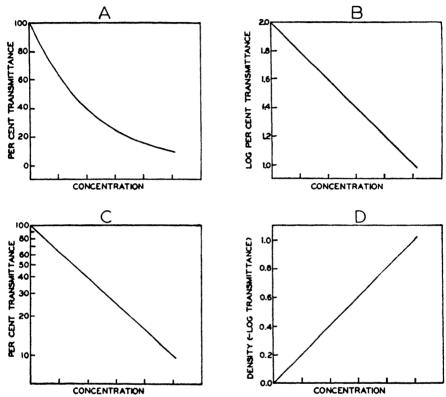

Fig. 146. Illustrating various ways of showing graphically the relation between light transmittance and concentration in a photometric procedure.

(A) Per cent transmittance plotted directly against concentration. (B) Log per cent transmittance against concentration. (C) Per cent transmittance against concentration on semilogarithmic paper. (D) Density (- log transmittance, or 2 - log per cent transmittance), against concentration.

plotted in any one of four different ways, as shown in Fig. 146. If the transmittance is plotted directly against concentration on ordinary cross-section paper, the curve of Fig. 146A is obtained. To obtain a straight line rather than a curve, and thus permit the accurate establishment of the relationship between transmittance and concentration at only one or two concentrations instead of the many required for a curve, advantage is taken of the fact that in accordance with Beer's law the equation for the curve is:

$$log T = -k \times c$$

the constant depth of solution permitting the incorporation of l into k.

Thus if the *logarithm* of the transmittance is plotted against concentration (Fig. 146B), or if transmittance is plotted on the logarithmic axis of semi-logarithmic paper (Fig. 146C), straight lines with negative slopes will result. Finally, if the Beer's law equation is written as follows:

$$-\log T = k \times c$$

and the values of $-\log T$ plotted against c, a straight line with a positive slope results (Fig. 146D).

Of these four methods for relating transmittance to concentration, the last is to be preferred. The quantity $-\log T$ has already been defined as the optical density, D, of the solution. Where Beer's law is applicable, the optical density is directly proportional to concentration, or

$$D = k \times c$$

This represents the simplest possible relation between light absorption and concentration and it is the major advantage obtained by expressing transmittance in terms of optical density rather than as per cent.

The established relationship between transmittance and concentration for a particular analytical procedure is known as the calibration for that procedure. If this relationship is shown in the form of a graph, as in Fig. 146, the graph is called the calibration curve. Every analytical procedure requires a separate calibration, over a specified range of concentration and at a given wavelength and depth of solution; and in general the calibration established for one photometer is not applicable to another photometer, even of the same make. The most accurate way to establish the calibration for a particular procedure, and the one which should be used whenever possible, is in terms of the reading of a simultaneously prepared standard (or, in some instances, series of standards) for that procedure, just as in accurate visual colorimetry, and for the same reasons. In practically all of the common colorimetric or photometric procedures, the substance being determined is subjected to a series of reactions leading to the final production of a color which is used as the basis for estimation The many factors aside from concentration which influence the final color intensity in most if not all colorimetric procedures have been discussed on p. 454 in connection with colorimetric analysis; they are of equal if not greater importance in photometry. Furthermore, since photometric measurements are ordinarily made individually and in a sense "against the instrument itself." rather than by comparison against a standard color, variations in mechanical, optical, and electrical properties of the photometer may likewise influence the calibration. Thus the calibration for a particular procedure may vary from day to day, from one photometer to another, and from laboratory to laboratory. If calibration is established in terms of the reading of a simultaneously prepared standard at the time the analysis is carried out, these various factors other than concentration which may influence the actual readings exert the same effect on the standard and on the solution being analyzed, and thus do not influence the relative evaluation of one in terms of the other.

To calibrate a procedure in terms of the reading of a simultaneously

prepared standard, advantage is taken of the fact that optical density (or extinction) is directly proportional to concentration where Beer's law is applicable, as it is to practically all photometric procedures under the proper conditions. Therefore, for two solutions of the same substance at different concentrations, at the same wavelength and depth of solution, the relation between their respective densities, D_1 and D_2 , and concentrations, c_1 and c_2 , is as follows:

$$\frac{D_1}{D_2} = \frac{c_1}{c_2}$$

If one of these two solutions is a standard of known concentration and the other is of unknown concentration, then if their respective densities are measured the concentration of the unknown is given by the calculation:

$$Concentration of Unknown = \frac{Density of Unknown}{Density of Standard} \times \frac{Concentration of Standard}{Standard}$$

Thus the concentration of an unknown in a photometric procedure which shows agreement with Beer's law may be calculated from the determined density and the density of a known standard, and this method of obtaining results in a photometric analysis is used where applicable for all of the photometric procedures described in this chapter and elsewhere in this book.

The calculation is obviously quite similar to that used for visual colorimetric analysis with the Duboscq colorimeter (see p. 459), except for the direct instead of inverse proportionality between concentrations and readings. It is subject to the same limitations concerning the use of concentration rather than amount; if amount is used in the above equation rather than concentration, the unknown and standard must have the same total volume, otherwise the right-hand side of the equation is multiplied by $V_{\rm x}/V_{\rm s}$, where $V_{\rm x}$ is the total volume of unknown and $V_{\rm s}$ the volume of standard. To express results in terms of 100 ml. of blood, per liter of urine, or on some other arbitrary basis, the obtained result must be multiplied by a factor representing the relationship between the actual amount of sample used and the desired basis, as for colorimetric calculations.

To use this method of calculating results with photometers whose scale reads only in terms of per cent transmittance, it is necessary to change the transmittance value into its equivalent optical density. This may be done using a table of logarithms, or more simply by reference to the accompanying table, which gives the value of the optical density for all values of per cent transmittance. Thus in an analysis, if the per cent transmittance of standard and unknown are determined, readings are converted into density values by reference to the table, and results calculated as described above. If the photometer scale gives the density values directly, or reads in units which are proportional to density, the scale reading is used directly in the calculations. This is obviously more convenient, and a photometer scale of this type is to be preferred over one which is in terms of per cent transmittance only.

Relation between Transmittance (T) and Optical Density (D)

Notes. 1. Intermediate values not shown on the table may be obtained by interpolation. For example, if % T=95.5—i.e., halfway between 95 and 96—D is halfway between 0.022 and 0.018, or 0.020.

2. On photometers equipped with a linear scale reading from 0 to 100, D corresponds to the value of $2 - \log G$ where G is the galvanometer or microammeter reading relative to an initial setting at the 100 mark.

Calculation of photometric results by the method described can of course only be used over the range of concentration where Beer's law is valid, i.e., where there is a linear relationship between optical density and concentration. For practically all photometric procedures in common use, conditions of wavelength, depth of solution, and concentration may be so selected that Beer's law is obeyed over the range of concentration apt to be encountered in an analysis. It is important in describing the details of a procedure to define these conditions, as has been done for the photometric procedures described in this chapter and elsewhere in this book.

For a few procedures, of which the determination of blood creatinine by the alkaline picrate reaction (p. 506) is an example, it is found that Beer's law is not followed under any analytical conditions. In such cases, a calibration curve must be constructed and results obtained by reference to the curve as described below; for the most accurate results such a curve should be constructed with each series of analyses unless it is found to be highly reproducible. Instances of deviation from Beer's law are fortu-

nately very rare. It is more common to find an apparent deviation from Beer's law when agreement is expected. This is usually the fault of the photometer. In most instances, agreement with Beer's law can be expected only when essentially monochromatic light is used, particularly when photovoltaic cells with their inherent varying spectral sensitivity are used in the photometer. If a wide rather than a narrow portion of the spectrum is used for measurement, as is unfortunately the case with some types of photometers, or if the photocell circuit is such that current output is not proportional to light intensity, the relationship between optical density (or $-\log T$) and concentration will not be linear, and results must be based upon a calibration curve. Photometers with such characteristics are therefore undesirable as a basis for accurate photometric analysis, since they do not permit the analytical precision associated with the application of Beer's law to the procedure.

Another commonly used method for obtaining results in a photometric analysis is based upon the use of previously prepared graphs of the type shown in Fig. 146, or of tables based upon the graphical data. The graph or table is established for a particular procedure by determining the transmittance values for a sufficient number of solutions of known and varying concentration with respect to the substance being determined. In future analyses, the transmittance of the solution of substance in unknown concentration is determined, and its concentration is then found from the graph or table, without running a standard at the same time ("colorimetry without standard solutions"). It is not necessary that the color reaction show agreement with Beer's law, since the relation between photometer reading and concentration is established empirically; this type of procedure therefore finds its greatest use where for one reason or another there is lack of agreement with Beer's law. An analogous procedure in instances where Beer's law is valid is to establish the density of a known standard and to use this value in future analyses, i.e., the concentration of unknown is obtained by multiplying its determined density by a factor representing the established relationship between the standard and its density (see the photometric determination of hemoglobin, p. 562, for examples). The extinction coefficient of a substance may also be used in a similar wav.

It is assumed in the use of such previously obtained calibration data that a particular transmittance or density will always represent a particular concentration in an analysis. In practice this may or may not be true. The many factors which influence color intensity aside from concentration have already been emphasized. Even for substances such as hemoglobin where the light-absorbing power is an integral property of the molecule itself, variations in environmental conditions or in the photometer itself may influence readings. Thus the use of a previously prepared calibration curve may be at best only an approximation, and gross errors are known to have resulted from its use. Colorimetry without standard solutions does not exist; the use of a previously prepared calibration curve simply represents a decision that the standard is to be prepared and read at one time and the unknown at some other time and possibly under

different conditions, rather than to have standard and unknown prepared and read under the same conditions. It may be stated without equivocation that the greater desirability of the latter procedure has never been seriously challenged.

It is true that in some instances, as where the standard substance is difficult to obtain or maintain stable in solution, or the scope of the analytical problem permits the sacrifice of accuracy to convenience, a calibration curve may satisfy analytical requirements. If such a curve is used, it should be constructed in one's own laboratory using the reagents and photometer which will actually be employed in the analysis. Calibration data obtained from the literature or from the manufacturer of the photometer should never be used without checking, and this checking must be repeated at frequent intervals if satisfactory results are to be expected, particularly if there has been a change in the reagents or photometer. The analyses must be carried out with rigorous control of the various steps involved, reproducing as far as possible the conditions under which the curve was constructed. Only in this way can the occurrence of serious errors be prevented.

Relation between Transmittance and Wavelength. The relation between the transmittance or optical density of a solution containing light-absorbing material and the wavelength of light passing through the solution is given by the so-called absorption spectrum of the substance. The absorption spectrum is established quantitatively by measuring the transmittance for a particular concentration and depth of solution at various wavelengths, and plotting the results in the form of a curve relating transmittance or optical density (the latter is preferred) to wavelength. Two general types of relatively simple absorption spectra are illustrated in Fig. 147; more complex curves are frequently found. The absorption spectrum of a substance is usually characteristic of the substance and may serve for identification as well as furnishing information of analytical value. The application of absorption spectra is not limited to the visible region of the spectrum but may be applied equally well to characterization of the ultraviolet or infrared absorption of many substances.

For a particular substance, absorption curves at different concentrations will be generally similar in shape but will differ in their position along the transmittance axis (curves a and b in Fig. 147A). It will be noted that for a particular substance at a given concentration, there may be a certain amount of light absorption (transmittance less than 100 per cent) at most wavelengths, but that this absorption is relatively greater in some spectral regions than in others. In the visible region of the spectrum, this difference in relative light absorption at various wavelengths is of course the cause of color, since when white light containing all wavelengths passes through the solution, the emergent light contains a greater proportion of some wavelengths than of others, and hence appears colored.

As the concentration of substance in solution is increased (curve b relative to curve a) there is usually increased light absorption at all wavelengths where any light is absorbed at all, but this increase is usually

concentration at some wavelength other than that representing maximum light absorption. For example, in the case of substances with absorption spectra similar to that of Fig. 147B, the wavelength of maximum sensitivity is one intermediate between the regions of high and low light absorption. Thus knowledge of the absorption spectrum at one concentration alone is not necessarily sufficient for deciding upon the wavelength of maximum sensitivity; wherever possible, data at several concentrations should be known or given.

Maximum sensitivity is not per se the chief consideration in the selection of the proper wavelength for photometric measurement. From an analytical point of view, the most satisfactory wavelength is the one which, at a given depth of solution, shows agreement with Beer's law over as wide a range as possible of the concentrations apt to be encountered in an analysis, and which permits this range to be read within the most accurate region of the photometer scale. The most accurate region of the scale corresponds to densities between about 0.05 and 1.00 (90 to 10 per cent transmittance). Readings outside this range represent solutions which are either too light or too dark for accurate measurement; thus at 95 per cent transmittance an absolute error of 0.5 per cent in the transmittance measurement corresponds to a 10 per cent error in an analysis; and at the other end of the scale, for dark solutions unit change in transmittance represents a disproportionately large change in concentration. The sample should therefore read between the scale limits specified if maximal accuracy is to be obtained.

To fulfill these requirements in the case of the Folin-Wu blood sugar method, for example (see p. 520), a wavelength may be selected which represents a very low sensitivity, so that the normal glucose standard representing 100 mg, per cent blood sugar will have a low light absorption. This would permit reading blood sugar values well above normal, which is the usual direction of change in this procedure, under the same conditions. If the usual direction of change is below the normal value, as in hemoglobin determinations, conditions are selected such that the normal sample has a high light absorption. In general, to adapt a procedure to photometric measurement which was originally developed for visual colorimetry and hence may yield a more intense color than is required for photometric measurement, and in a larger volume of solution, it is better to modify the light absorption. This may be done by selection of a suitable wavelength or use of a small depth of solution rather than by such procedures as taking a smaller sample or diluting the final color, since these may seriously affect the accuracy of the procedure. However, the greater sensitivity of photometric measurement, and the possibility of using very small volumes of solution, is obviously conducive to the development of micro-analytical methods, of which many have been and are being developed, and this represents an important contribution of photometry to analytical chemistry.

Other factors which may influence the choice of wavelength for photometric measurement include the possibility that agreement with Beer's law will be found to be more satisfactory over a wider range of concentra-

tion at one wavelength than at another, or that the color will be more stable when exposed to light of one wavelength than to another wavelength. Even if such selection entails a decrease in sensitivity, the enhancement of the analytical value of the procedure may make the wavelength of lesser sensitivity the one of choice. If two or more light-absorbing substances are present together, and it is desired to measure the change in optical density related to variation in amount of only one of these substances, it is sometimes possible to select a wavelength at which there is only minimal light-absorption by extraneous material, and thus prevent such material from interfering significantly in an analysis. Such photometric separation is rarely complete; it is usually better to effect preliminary analytical separation, or to include the light absorption from extraneous material in the blank solution used for the initial setting of the photometer.

Knowledge of the complete spectral characteristics of a light-absorbing compound is of fundamental importance in defining the conditions under which satisfactory photometric analysis is possible. Wherever possible such information should be available in the description of a photometric procedure, as has been done in many instances for the various photometric procedures described in this chapter and elsewhere in this book. The detailed description of the spectrophotometric characteristics of the Nessler reaction with ammonia, given in Chapter 32, illustrates the applicability of absorption spectrum data to photometric procedures.

Light Filters and Filter Photometers. The wavelength at which photometric measurements are made may be established either by the use of light filters or by the production of a complete spectrum and isolation of the desired portion. Instruments based upon the first principle are known as filter photometers; those based upon the second principle are called spectrophotometers (see p. 483). Most types of photometers in current use are filter photometers. They are less expensive than spectrophotometers, require less technical skill in operation, and if well designed are just as satisfactory for most analytical purposes, particularly in the visible region of the spectrum. Except for special instances, spectrophotometers must ordinarily be used for photometry in the ultraviolet and infrared portions of the spectrum.

Light filters consist of selected glass (or sometimes dyed gelatin) which is capable of transmitting light over a limited portion of the spectrum only. Thus by placing such a filter in the light path of the photometer, measurements may be made in the spectral region corresponding to the transmittance range of the filter. Various filters differ principally with regard to (a) the spectral region of light transmittance, (b) the width of the transmitted band. By suitable selection of various types or combinations of glass, it is usually possible to obtain a filter whose transmittance is limited to almost any desired portion of the spectrum. A selection of such filters is illustrated in Fig. 148. Suitable filters may be obtained from the manufacturers of the photometer, or they may be constructed in the laboratory if suitable glass is available. They are sometimes called "monochromatic" filters, but they are not monochromatic in the sense

that light of a single wavelength is monochromatic, since they transmit a narrow range of wavelengths rather than a single wavelength. It is customary to designate a filter in terms of the wavelength of peak transmittance, thus a filter called "No. 540" or "No. 54" has its peak

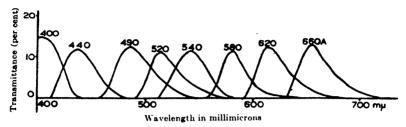

Fig. 148. Light transmittance of selected light filters. (Courtesy, Rubicon Co.)

transmittance at a wavelength of 540 millimicrons. This practice is not universal, nor is the wavelength designation always accurate, and when a filter of any kind is used in a photometric procedure the wavelength of peak transmittance should be stated also. If this information is not known, it may usually be obtained from the manufacturer of the filter or glasses used. When the wavelength required for a particular photometric

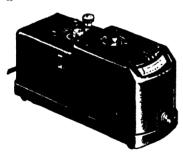

Fig. 149. Cenco photelometer. (Courtesy, Central Scientific Co.)

procedure is stated in the description of the procedure, as for example "at 540 m μ ," this corresponds to the use in a filter photometer of a filter with a peak transmittance at this wavelength.

The most satisfactory filters are those which transmit as narrow a spectral region as possible, since this represents an approach to truly monochromatic light. A good filter for photometric purposes will show a transmittance of about 85 per cent or more of the total light over a spectral width of 30 to 50 m μ or so, centered around the wavelength of peak transmittance.

This information concerning a filter may be obtained from its transmittance curve, as illustrated in Fig. 148. Filters with a broader range of transmittance are in general unsatisfactory, since they may result in apparent deviations from Beer's law, as discussed on p. 473.

Representative types of filter photometers commercially available are illustrated in Figs. 149, 150, and 152. Many other types are on the market, some of which are doubtless as satisfactory as those illustrated. The Cenco "photelometer" (Fig. 149) is an example of the single photocell type of

⁴⁸ Manufacturers of satisfactory photometers include the Central Scientific Co., Chicago; Rubicon Co., Philadelphia; Klett Manufacturing Co., New York; Fisher Scientific Co., Pittsburgh; American Instrument Co., Silver Springs, Md.; Coleman Instruments, Inc., Maywood, Ill.; Photovolt Corp., New York; Pfalts and Bauer, New York; and others, Some of these concerns likewise manufacture fluorometers. Information concerning various types available usually may be secured from any laboratory supply house.

photometer, with built-in meter, the scale of which reads linearly from 0 to 100, and hence gives transmittance in per cent. Various designs of this instrument are available, with accessories providing for measurement at various depths of solution and for the use of either rectangular glass cuvettes or the much less expensive (and equally satisfactory) cylindrical container. A 6-volt bulb is used as light source, operated either from a storage battery or from the 110-volt a.c. line through a built-in constant-voltage transformer. In operation, the instrument is adjusted to a scale reading of 100 with the reference solution and a suitable filter in place; the

reference solution is then replaced by the solution under examination, and the scale reading noted. This value gives the transmittance of the sample, in per cent. To convert transmittance into optical density, the value of $2 - \log R$ is obtained, where R is the scale reading, or the table on p. 472 may be used. Users of this instrument appear to prefer the "calibration curve" method of obtaining results, rather than calculation based upon optical density. This is probably because earlier models were not equipped with filters of sufficiently narrow spectral transmission to permit the general applicability of Beer's law. Later models are an improvement in this respect.

The Evelyn "photoelectric colorimeter" (Fig. 150) is likewise a single photocell photoelectric filter photometer, with uniform test tubes customarily employed as solution containers, and with readings made on a sensitive

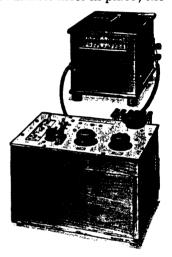

Fig 150. Evelyn photoelectric colorimeter. (Courtesy, Rubicon Co.)

galvanometer which is separated from the rest of the instrument. The galvanometer scale is graduated linearly, from 0 to 100, so that readings here are also in terms of per cent transmittance. A diagram illustrating the schematic construction of the Evelyn instrument is shown in Fig. 151. With a suitable filter in place, the reference fluid in a special test tube is placed in the instrument and the light intensity adjusted by resistance control until the meter reads 100. The reference fluid is then replaced by the sample, in a second similar test tube, and the galvanometer reading noted. Its value gives the per cent transmittance of the sample. To convert transmittance into optical density, the value of $2 - \log G$ is obtained, where G is the galvanometer reading; or the table on p. 472 may be used.

The light source is a 6-volt bulb, operated from a storage battery to provide constancy of illumination, which is essential with all single cell photometers. The filters used with this instrument are particularly satisfactory from the point of view of narrowness of spectral band; the selection available is shown in Fig. 148. The test tubes require a minimum of about 6 ml. of solution for a reading; a microcolorimeter, requiring much less fluid, is also available for use with the instrument. The use of test

tubes as solution containers or cuvettes has the great advantage that many colorimetric procedures may be carried out partially or wholly in the same tube which will be used for the final reading. The Evelyn test tubes have dimensions such that they correspond roughly to a 2-cm. solution thickness, so that the optical density for a particular concentration of substance will be about twice that expected at 1 cm. depth, which is the usual basis of reference, and which is used throughout this chapter. This means that in the Evelyn instrument, a sensitivity and concentration range specified for 1 cm. solution depth will correspond to about

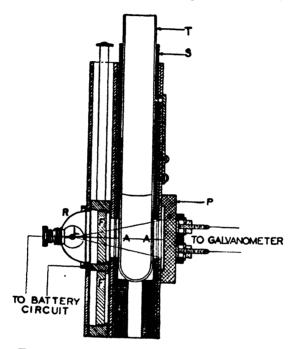

Fig. 151. Schematic diagram of Evelyn photoelectric colorimeter. (A) Apertures, (F) filter, (L) lamp, (B) reflector, (S) shield, (T) test tube, (P) photocell.

twice the sensitivity, over the lower half of the specified concentration range only; higher concentrations will prove to be too dark to read accurately. This must be considered in interpreting data obtained by this instrument or for use with it.

Advantages of single photocell photometers such as the two just described include the simplicity of construction and the fact that readings are made on a direct-reading meter which does not require manual adjustment. Thus even relatively unstable colors, such as that obtained in the antimony trichloride reaction for vitamin A, may be read immediately or at successive small time intervals for extrapolation. The major disadvantage of the single photocell type is the requirement for a stable light source, to eliminate the possibility of error due to a change from the

initial light intensity during a measurement. To provide a constant current for the light source, storage batteries or constant-voltage transformers are used; the former is generally more satisfactory, since the efficiency

of constant-voltage regulators may depend upon the type of power supply available. Another disadvantage of single photocell photometers is that they usually incorporate meters designed primarily for current measurement and not for photometric purposes, with linear graduation and frequently a small total scale length. which may make precise reading difficult. Meters should be accurately readable to one-third of a scale division, for example, if a reading error of 1 per cent or less is expected over onethird of the scale range. Linear graduation of the scale requires the use

Fig. 152. Klett-Summerson photoelectric colorimeter. (Courtesy, Klett Manufacturing Co.)

of logarithms or conversion tables to convert per cent transmittance values into optical density, which is a much more satisfactory basis for photometric analysis. Some types of single cell photometers are equipped with scales reading in terms of optical density as well as, or

rather than, per cent transmittance; it is not unreasonable to hope that this practice will be extended.

To overcome some of the disadvantages of single photocell photometers, various types of photometers employing two photocells in a balanced circuit have been developed, of which the Klett-Summerson instrument

(Fig. 152) is an example. The details of construction of this instrument are shown in Fig. 153. In operation, with a suitable filter in place, the reference solution contained in a test tube is placed in the path of light striking one of the two photocells, which are arranged in a potentiometric circuit so that the current from one cell is opposed to that from the other through a null-point instrument (low-sensitivity galvanometer). With the photometer scale set at zero (corresponding to zero optical density) the current output from the second photocell is adjusted so that it exactly balances that coming from the photocell which is subject to the light emerging from the solution. This balance is indicated by a zero reading on the galvanometer. The reference solution is then removed and replaced by the solution under examination. Any light absorption by this solution will throw the two photocells out of electrical balance; balance is then restored by turning the potentiometer dial until the galvanometer again reads zero. The reading on the potentiometer scale at this point is the measure of the light absorption of the solution.

The light source is a 100-watt bulb operated directly from an ordinary power supply; the balanced circuit prevents fluctuations in light intensity from influencing readings. The instrument is designed for use with light filters of relatively narrow spectral transmission; the selection available is similar to that shown in Fig. 148. The test tubes require about 5 ml. of solution for a reading; micro-tubes requiring about 2 ml. may also be used. The test tubes may be used for color development as well as for reading, and may be centrifuged if necessary. The effective solution depth is approximately 1 cm., so that photometric data based on this depth of solution are directly applicable to the instrument. Models permitting the use of glass cells at other solution depths are also available.

The scale on the Summerson instrument deserves comment, since it is somewhat unusual. It is graduated in units which are proportional to optical density; the actual numerical values represent the optical density divided by two and with the decimal point omitted. Thus a scale reading of 250 corresponds to an optical density of 0.500; of 100, to 0.200, and so on. In general, the relation between scale reading R and optical density D is as follows:

$$\frac{1000 \times D}{2} = R$$

Thus the fractional values of optical density (see table on p. 472) have been replaced by whole numbers, to facilitate use in photometric calculations; since the scale readings bear a constant relation to optical density, they may be used directly in place of density values in the calculations of photometric analysis.

An interesting recent development in filter photometry is the "flame photometer" (Fig. 154). This was designed primarily to facilitate the rapid and accurate analysis of such metallic elements as sodium and

^{4b} The Perkin-Elmer Corp., Glenbrook, Conn. For a review of flame photometry, see Barnes, Richardson, Berry, and Hood: *Ind. Eng. Chem. Anal. Ed.*, 17, 605 (1945). Also Berry, Chappell, and Barnes: *Ind. Eng. Chem. Anal. Ed.*, 18, 19 (1946).

potassium, which have intense and characteristic flame spectra. The sample in solution is blown in the form of a fine spray into a colorless flame, and the intensity of the resulting flame spectrum is determined by the response of a photoelectric cell, as measured on a galvanometer or microammeter. The instrument is calibrated for a particular metal by running a series of standards containing varying concentrations of the

metal ion. No ashing or other preliminary preparation of the sample is ordinarily required; sodium and potassium determinations on blood plasma or serum for example require merely appropriate dilution with water. This instrument is known to give excellent results, and promises to be quite valuable in the particular analyses for which it is fitted.

Spectrophotometers. In place of using light filters for isolating the narrow spectral region usually required for photometric analysis, a device

for producing the complete light spectrum and isolating the desired portion may be used. Instruments based upon this principle are known as spectrophotometers. In the Beckman photoelectric spectrophotometer (Figs. 155 and 156), the spectrum is produced by the use of a quartz prism; a diffraction grating may also be used, as in the Coleman instru-

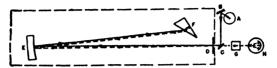

Fig. 156. Schematic diagram of Beckman spectrophotometer. (Courtesy, Cary and Beckman: J. Opt. Soc. Am., 31, 682 (1941). (A) Light, (B, C, and E) mirrors, (D) slit, (F) prism, (G) cuvette, (H) phototube.

ment (Fig. 157). The spectral band is focused on a narrow slit mounted in front of the solution being examined, and by shifting the band across the plane of the slit the desired spectral region is obtained. Spectrophotometers are usually more expensive than filter photometers, the cost

Fig. 157. Coleman junior spectrophotometer. (Courtesy, Coleman Instruments, Inc.)

increasing with increased sensitivity, spectral range, and narrowness of the spectral region isolated.

For routine analytical purposes, particularly in the visible region of the spectrum, spectrophotometers have the advantage over filter photometers of greater convenience and flexibility in choice of wavelength; this is offset to a certain extent by the increased cost as compared to filter photometers of equal or greater accuracy, and by the increased technical skill required in operation and maintenance. The wavelength setting is an extra adjustment connected with each analysis; variation or alteration is obviously more likely

to occur than if a stable glass filter of suitable optical characteristics is used for controlling the spectral range. Errors due to inaccurate wavelength setting may be minimized in an analysis if results are obtained in terms of a standard prepared and read under the same conditions as for the unknown, but in any event frequent checking of the accuracy of the wavelength setting is important. The major use of spectrophotometers in photometric analysis at the present time is in connection with substances whose light absorption is in the ultraviolet or

Manufacturers of spectrophotometers include the National Technical Laboratories, Pasadena, Calif. (the Beckman instrument); Coleman Instruments, Inc., Maywood, Ill.; and the Central Scientific Co., Chicago. Information may also be obtained from the larger laboratory supply houses.

infrared regions of the spectrum, since no other type of instrument can be used for this particular purpose, and for the establishment of the complete spectral characteristics of a color (i.e., the absorption spectrum).

The Beckman quartz spectrophotometer is especially adapted to measurements in the ultraviolet and has had wide application in the study of vitamin A, sterols, hormones, etc. An infrared model is also available.

Choice of Photometers. The choice of photometers from the many types commercially available is largely a question of the requirements of the individual laboratory. For routine analytical purposes based upon established procedures, any good type of filter photometer will prove satisfactory. Instruments equipped for the use of test tubes as solution containers are preferable to other types, because of the convenience and low cost of this type of cuvette; in some laboratories, however, measurements may have to be made at varying depths of solution, and an instrument capable of being used with different sizes of containers will be required. If a single photocell type instrument is desired, the stability on the laboratory current should be tested before use, or facilities for maintaining a storage battery must be available. Filter photometers differ considerably in the width of spectral band transmitted by the filters supplied with the instrument; in general, the narrower the band the more satisfactory will be the photometer; agreement with Beer's law cannot be expected with filters transmitting a wide range of wavelengths. For analytical purposes, a spectrophotometer covering only the visible and neighboring portions of the spectrum is little better than a good filter photometer, except for the convenience of wavelength selection. For investigational purposes the spectrophotometer should be usable in the ultraviolet and near infrared regions as well as in the visible region; an ideal combination would include such a spectrophotometer for investigational purposes, and a good filter photometer for analytical purposes.

Turbidimetry. The light transmittance of a fluid is influenced not only by the amount of light-absorbing material present in solution but also by the presence of light-scattering or light-obstructing material such as insoluble substances in suspension. Quantitative analysis of substances in suspension based upon this principle is known as turbidimetry, or, less commonly, as nephelometry. These two terms are substantially equivalent, although nephelometry is usually considered to include the use of the intensity of scattered light (i.e., light at right angles to the incident beam) as a measure of turbidity, as well as methods based on transmittance measurements. Of the two principles mentioned (light-scattering and transmittance) the latter is more commonly used.

Turbidimetric measurements may be carried out by the same procedure and instruments used for the measurement of substances in solution, i.e., by comparison against a series of standards, by dilution, by varying the depth of solution, or by direct measurement of the light transmittance. Transmittance measurement, particularly when used in instruments equipped with photoelectric cells, is the most sensitive and satisfactory. The relationship between the amount of a substance in suspension and the turbidity or transmittance of the fluid is much more empirical than

for substances in solution, depending as it does not only on the amount of material present but also on the size and shape of the suspended particles, their relative opacity or transparency, the relation between particle size and the wavelength of light used, and the uniformity with which a given turbidity may be reproduced. For a particular procedure, however, it may be found that over a limited range of concentration the turbidity or transmittance is directly proportional to concentration, and thus resembles optical density or extinction for substances in solution. In such an instance, turbidity measurement is carried out and results calculated in the same manner as for light absorption. In other cases, results must be obtained from a calibration curve constructed from known standards; it is even more important here than for substances in solution that the conditions prevailing at the time the standard turbidities were obtained be reproduced as closely as possible in an analysis.

If the substance in suspension is colorless in a colorless solvent, it may appear at first glance that the choice of wavelength or filter for photometric measurement is immaterial. This is not so, because of the influence of particle size on the scattering of light of different wavelengths ("Tyndall effect"). In general, light of shorter wavelength (at the blue end of the spectrum) is relatively more highly scattered than light of longer wavelength (red end of the spectrum), therefore the change in transmittance for unit change in turbidity will be greater with short wavelengths than with long wavelengths. Thus the sensitivity of the procedure, or the relationship between scale readings and turbidity, may be considerably influenced by the wavelength employed. Other considerations may of course enter into the choice of wavelength; occasionally the interference of extraneous colored material in solution may be minimized by selection of a wavelength which is not absorbed by such material.

Turbidimetric measurements are employed not only for analytical purposes but also for the evaluation of particle size, and for determining the approximate number of plant or animal cells (yeast, bacteria, etc.) present in a fluid; this latter has had wide application, particularly in the field of microbiological assay. Turbidimetric estimation of red blood cell count has not as yet been successfully achieved. The use of turbidimetric methods in analytical chemistry has not been great, largely because of the difficulty of achieving a reproducible turbidity for a given concentration. Use has sometimes been made of a protective colloid to stabilize suspensions and promote uniformity; unfortunately, protective colloids usually distort the relationship between turbidity and concentration in such a way as to require a calibration curve which is highly empirical, and their use cannot be said to have solved the problems of turbidimetric analysis.

Fluorometry. Certain substances are capable of absorbing light at one wavelength and radiating a portion of this absorbed light at some other wavelength. This phenomenon is known as fluorescence and may be used for analytical purposes, the intensity of fluorescence serving as a measure of concentration. Instruments designed for this purpose are known as fluorometers. The fluorescence of the unknown may be compared visually

against a standard or series of standards, or the intensity of the fluorescent light may be measured directly using a light-sensitive device such as a photoelectric cell. A fluorometer utilizing the latter principle is illustrated in Fig. 158.

The exciting light is usually in the ultraviolet portion of the spectrum, generally between 300 and 400 m μ , and the radiated light is usually in the visible region, but the applications of fluorescence are not limited to these conditions. Since the intensity of fluorescence is determined not only by those factors which affect light absorption (concentration, depth of solution, wavelength) but also by the intensity of the exciting light, measurements must be made at a uniform or controlled incident light intensity.

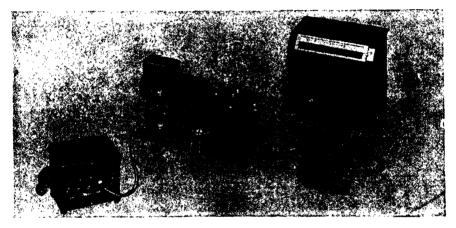

Fig. 158, Photofluorometer. (Courtesy, Pfaltz and Bauer.)

and the sample viewed or measured from the side of the light beam, to prevent interference from light transmitted through the solution. With photoelectric fluorometers, results are usually obtained from a calibration curve relating the intensity of fluorescence to known concentrations of the substance; this relationship may be linear over a certain concentration range, in which case results can be obtained by calculation in terms of the fluorescence of a known standard. Permanent fluorescent standards such as uranium glass or solutions of quinine sulfate may also be used to control the calibration. Some substances show a "bleaching" or decrease in fluorescence during exposure to the exciting light; errors from this source may be minimized by rapid reading (short exposure), extrapolation, or the use of a low intensity of exciting light. Blank determinations to correct for intrinsic fluorescence of containers and reagents may be necessary; specificity may sometimes be enhanced by measuring the change in fluorescence after specific (e.g., enzymatic) destruction of the substance being determined. Quantitative analysis based upon fluorescence is limited at present to the determination of certain vitamins (see Chapter 35), drugs, dyes, and inorganic ions, but its usefulness should increase with further study.

EXPERIMENTS ON PHOTOMETRY

- 1. Characteristics of Photometer: Examine the photometer available and note the general principles of its design and operation. (This information may be obtained from the instructor or from the manual usually supplied by the manufacturer of the instrument.) Is it a filter photometer or a spectrophotometer? Note particularly the type of scale used, and whether it is graduated in terms of per cent transmittance, optical density, or units proportional to optical density. Place some distilled water in a photometer cuvette and insert the cuvette in the instrument. Select any particular filter or wavelength setting, turn on the light, and adjust the photometer to its initial setting, which will represent either zero optical density or 100 per cent transmittance—which is used? Now remove the cuvette from the light path. Does the adjustment change? Replace the cuvette. Does the reading return to its initial value? If it does not, allow the light to burn for about 5 minutes, re-set to zero (or 100) and repeat the test of stability. Is there any increase in stability after the light has been on a short while? Why is it necessary for photometer readings to be based on a constant initial setting?
- 2. Beer's Law: Obtain some defibrinated or oxalated blood. Dilute 1 ml. of this to 100 ml. in a volumetric flask with dilute ammonia solution (4 ml. of concentrated ammonium hydroxide per liter of water). Mix well by inversion. Prepare a series of known dilutions of this "stock standard" as follows: into test tubes place 0.0, 1.0, 2.0, 3.0, etc., up to 10.0 ml. portions of the stock solution, and add sufficient dilute ammonia solution to each tube to make the final volume 10 ml. in each case. Mix. Using light of 520 mg wavelength, adjust the photometer to zero optical density (or 100 per cent transmittance) with the contents of the first tube, which is a "reagent blank." Determine the photometer readings for each of the other solutions, checking the initial setting with the blank solution once or twice during the series of readings; if any change has occurred re-set the photometer before continuing with the readings.

On a sheet of cross-section paper, plot the photometer readings on the y-axis against equivalent concentration (0, 1, 2, 3, etc., up to 10) on the x-axis, and connect the points by a smooth curve. Which of the four types of curves shown in Fig. 146, p. 469, do you obtain? What is the relation between photometer readings and concentration? If the photometer scale reads in terms of per cent transmittance, (a) compute the value of log T for each concentration and plot this value against concentration on a second sheet of cross-section paper (or plot T on the logarithmic axis of semilogarithmic paper, against concentration on the linear axis), and (b) convert transmittance into optical density by the use of the table on p. 472, and plot optical density against concentration, using ordinary cross-section paper. What types of curves should be obtained if Beer's law is valid? Do your results indicate that hemoglobin solutions obey Beer's law under the conditions you are using? How may your results be used as a basis for the photometric determination of hemoglobin?

Assume that one of your solutions is a "standard," of known concentration, and that the others are "unknowns." Calculate their concentrations relative to that of the "standard," from the determined optical densities, as described on p. 471. Is Beer's law applicable over the entire range of concentration you are using? What must be done in a photometric analysis if (a) the procedure does not obey Beer's law, or (b) a reading falls outside the range of application of Beer's law?

3. Relation Between Transmittance and Wavelength: Repeat Exp. 2, but use a wavelength in (a) the blue portion of the spectrum, and (b) the red portion. Plot the results graphically for each wavelength used, and compare with the results of Exp. 2. How may the wavelength chosen influence the sensi-

- tivity of a photometric procedure? What is the indication on your graphs of the "sensitivity" of this particular procedure? Suppose hemoglobin were a contaminant of a solution, instead of the substance being measured; at what wavelength would its presence cause the least error?
- 4. Relation Between Transmittance and Depth of Solution: Repeat Exp. 2, but make measurements at some other depth of solution, if such facilities are available. If not, compute the theoretical reading for each concentration at a depth of solution twice that used in Exp. 2. Plot the data graphically and compare with the previous results. What is the effect of solution depth on the transmittance value for a given concentration? How may this be used to increase the sensitivity of a photometric procedure?
- 5. Correcting for a Blank Color: Set up the aliquots of 1:100 hemoglobin stock solution used in Exp. 2 (up to 9 ml.) but before diluting to 10 ml. with dilute ammonia solution, add to each 0.5 ml. of a dilute ammonia solution to which a few drops of blood have been added, sufficient to give a noticeable pink color. Thus each solution now contains a relatively known amount of hemoglobin, plus a constant "blank" color. Adjust the photometer to its initial setting with the blank tube, and read the other solutions relative to this, as before. Plot the data as described for Exp. 2. Does the presence of a constant blank color influence the photometric calibration, if the photometer is set to its initial reading with the blank solution? Since optical density is additive—i.e., the total optical density of a solution is the sum of the densities due to the various light-absorbing substances present—what other way can you suggest for correcting for the density of a blank?
- 6. Effect of Time of Standing on Transmittance: Obtain some defibrinated blood, and dilute 0.1 ml. to 25 ml. with 0.1 N hydrochloric acid. Mix by inversion, transfer a portion to a photometer cuvette, and read immediately, the photometer having been previously set to zero optica! density at 520 my with the dilute acid alone. Repeat the reading on this same sample at suitable time intervals, say every five minutes, for one hour or until the reading becomes constant. Be sure to check the initial setting of the photometer before each reading. Plot the relationship between time of standing and photometer reading. Many of the colors produced in common photometric procedures show a similar behavior with respect to time of standing. What does this experiment show concerning the desirability of time control in photometric analysis?
- 7. Calibration of Test Tubes Used as Cuvettes: Many types of photometers are designed to use interchangeable test tubes of uniform dimensions as solution containers or cuvettes. If the tubes are truly interchangeable, they should all give the same reading for a given colored solution, and they may be tested on this basis. Prepare a stable colored solution of such intensity that it shows by trial a reading about in the middle of the photometer scale. A dilute solution of hemoglobin, as described in previous experiments, may be used; an equally satisfactory test solution may be made by diluting ordinary India ink with water to a suitable intensity. Place portions of this test solution in each of the test tubes, and read them in the photometer, using water for the initial setting and checking this setting at suitable intervals. Select all those tubes which give identical or nearly identical readings, and discard the remainder. Sometimes two lots of tubes may be obtained, the readings for each lot centering with the desired accuracy around a particular reading, but a different reading in each case. Each lot may then be used independently, but they should be marked so that the lots will not be mixed. It is also well to mark the tubes so that they will always be placed in the photometer in the same position. Test tubes calibrated in this way are as accurate for photometric purposes as rectangular cuvettes, and much more convenient. A tube should be discarded when it becomes scratched, or when checking shows it to have lost its interchangeability.

GENERAL PROCEDURES IN BLOOD ANALYSIS

1. Drawing Blood for Analysis: Draw a tourniquet (of soft, firm rubber tubing or a strip of bandage) tightly about the arm of the patient a couple of inches above the elbow. Have the patient clench his fist firmly. Wash the skin surface about the most prominent vein on the inner surface of the elbow (usually the median basilic) with 70 per cent alcohol, allow to dry, hold the vein immobile with the thumb, and into the vein insert a sharp, sterile hypodermic needle (No. 18, an inch and a half long) which is attached to a dry sterile syringe of suitable capacity. The needle should penetrate the vein from the side and at an angle of about 50° with the surface of the arm, the bevel or opening of the needle being kept upward or to the side. As soon as blood is seen to enter the syringe, retract the plunger slowly until the desired amount of blood has entered the syringe. Before removing the needle from the vein, loosen the tourniquet, have the patient unclench his fist, and on the skin at the point of entrance of the needle hold in place a small pad of folded gauze moistened with 70 per cent alcohol. Withdraw the needle, detach it from the syringe, and into a suitable container eject the blood from the syringe (not too vigorously, which might cause hemolysis). Pressure on the gauze pad for a few minutes will effectively prevent bleeding from the skin puncture.

The use of a syringe is not essential; the needle alone may be used. The blood is allowed to flow from the free end of the needle into a suitable container until the desired amount has been obtained. The needle is then withdrawn as described above. For special precautions to be used in drawing blood where the maintenance of physiological gas tensions is important, as in the determination of carbon dioxide content, etc., see Chapter 24.

2. Preparation of Whole Blood and of Plasma. When whole blood or plasma is desired for analysis, the blood must be treated with anti-coagulant before clotting commences. The most convenient way to do this is to have containers for the blood already prepared with sufficient anti-coagulant in the form of a thin dried film over the inside surface (see below). The thin film promotes quick solubility and mixing with the added blood. Test tubes or small wide-mouth bottles of approximately 1 ounce capacity may be used as containers.

Procedure: Transfer the blood, as quickly as possible after drawing, from the syringe to a container which has sufficient anticoagulant in the form of a thin dried film to prevent clotting of the blood. Mix by rotation gently but thoroughly to dissolve and distribute the anticoagulant. The blood is now ready for use. To obtain plasma, centrifuge and remove the supernatant plasma with a rubber-bulb pipet.

Blood specimens are best taken in the morning before breakfast, to minimize the influence of food ingestion. Analyses are preferably made as soon as possible after the blood is drawn; during any interval between drawing and analysis, the blood should be kept cold and well stoppered to minimize evaporation. For blood sugar analyses in particular, the proteinfree filtrate should be prepared as soon as possible, to minimize loss of sugar by glycolysis. Protein-free filtrates will keep better than whole

⁵ Denis (J. Biol. Chem., 44, 203 (1920)) has shown that for the Folin-Wu sugar method, blood may be preserved for four days or more at room temperatures if 1 drop of commercial formalin (40 per cent) solution is added to each 5 ml. of blood.

blood or plasma, particularly if kept cold and in the presence of a drop of toluene as preservative.

3. Anticoagulants. The most commonly used anticoagulant is neutral potassium oxalate, of which from 1 to 2 mg. are required per ml. of blood. Only an amount of anticoagulant sufficient for the quantity of blood to be received should be employed; excessive amounts of anticoagulant may interfere with some analyses, may cause hemolysis, or may produce an abnormal distribution of water and electrolytes between cells and plasma.

Procedure: To prepare containers with sufficient potassium oxalate for 6 to 10 ml. of blood, prepare a stock solution of 10 per cen't neutral potassium oxalate and pipet 0.1 ml. of this into each container. Rotate to produce maximal spreading, then place in an incubator (or oven at 100° C.) to dry. The oxalate should form a thin dry film on the sides of the container. For smaller quantities of blood, use half as much stock solution. It is good practice to have two sets of containers, suitably labeled, one for 3 to 5 ml. of blood, and one for 6 to 10 ml. of blood.

Other anticoagulants, and the amounts required per ml. of blood, include sodium citrate (5 mg.), lithium or sodium oxalate (1 to 2 mg.), sodium fluoride (10 mg.), and heparin (0.2 mg.). Containers may be prepared with the proper amounts of these anticoagulants in a manner similar to that described above for potassium oxalate. Of the various anticoagulants, heparin is by far the most satisfactory and should be more widely used. Sodium fluoride acts as a preservative and has the advantage of inhibiting glycolytic decomposition of blood sugar, but interferes with certain methods. A special mixture (Heller and Paul) of ammonium oxalate (3 parts) and potassium oxalate (2 parts) has the advantage of causing no change in red cell volume, and hence is useful for hematocrit determinations and for methods involving the measurement of specific gravity of whole blood or plasma. It cannot be used in ordinary blood analytical procedures because of the presence of ammonia.

4. Preparation of Blood Serum for Analysis: When serum rather than whole blood or plasma is desired for analysis, place the freshly drawn blood directly into a small test tube without anticoagulant. Allow to clot at room temperature and then chill thoroughly in the refrigerator. Centrifuge down the clot and remove the supernatant serum with a rubber-bulb pipet.

If a centrifuge is not available, the blood may be allowed to clot with the tube in a slanting position, then after chilling overnight in an upright position the serum may be poured off from the side of the tube opposite the slanting clot.

• John (Arch. Path. Lab. Med., 1, 227 (1926)) after an extensive study of blood preservatives, recommends sodium fluoride and thymol in the proportion of 20:1, using 20 mg. of the mixture per 10 ml. of blood. Roe, Irish, and Boyd (J. Biol. Chem., 75, 685 (1927)) find 10 mg. NaF per ml. blood preserves for 10 days as far as nonprotein nitrogen, uric acid, creatinine, sugar, and cholesterol are concerned, provided the blood is sterile. If not, at least 20 mg. are required, but even this gives poorer results than are obtained with sterile blood. Interference of NaF with urease action is overcome by dilution with 7 to 10 volumes of water if not over 30 mg. of NaF per ml. are used.

Heller and Paul: J. Lab. Clin. Med., 19, 777 (1934).

5. Measurement of Blood. Because of its physical characteristics and the presence of suspended red cells, whole blood is much more difficult to measure exactly than ordinary fluids. Serious errors have been traced to faulty measurement of blood. Before measurement, the sample must be

thoroughly mixed to ensure uniform distribution of

cells and plasma.

Procedure: To mix whole blood without trapping air bubbles, if the sample is in a test tube use a small footed stirring rod which is raised and lowered in the sample a sufficient number of times to ensure complete mixing. If the sample is in a wide flat bottle, place the bottle firmly on the table top and vigorously trace a 1-foot circle with the bottle flat against the table top, for at least a dozen times or until the blood is uniformly mixed. Measure out the portion of blood immediately after mixing, and repeat the mixing procedure before each new measurement.

To measure blood accurately, draw the blood up into a transfer pipet until the level is a little above the graduation mark. Wipe off excess blood from the pipet tip, allow to drain slowly until the blood level is exactly at the mark, and again wipe off excess blood. Deliver the blood into the receiver slowly, adjusting the rate of delivery by finger pressure on the mouthpiece of the pipet so that as the blood drains from the pipet, the pipet walls remain clear and there is no visible film of blood remaining behind. When the blood has drained completely, blow out the last drop into the receiver.8

Ordinary pipets may be used for blood measurement, with slight error due to the fact that they are usually calibrated for the delivery of water rather than blood. Pipets calibrated "to contain" ("TC"), such as are commonly used in micro-analyses, are not subject to this error, since they are designed for delivery of the blood into a second fluid, the resulting

mixture then being used to rinse out any blood remaining in the pipet. Folin proposed the use of the Ostwald type pipet (Fig. 159), which has less surface per unit volume than the ordinary pipet, and no sharp shoulders to impede drainage, and these have found favor in many laboratories. Where the amount of blood available is limited and it is desired to use as much as possible, a pipet graduated to the tip is useful (Fig. 160). In using this type of pipet, the greatest error is at the tip, particularly when the tip is imperfect, and if possible the measurement should exclude this portion (i.e., for a 5-ml. portion, measure from the 6-ml. mark to the

Fig. 159. Ostwald-Folin pipet.

⁸ This is for transfer pipets which are calibrated for "blowout" delivery. Such pipets are commonly marked by the manufacturer with an etched ring around the pipet near or at the top. If the pipet is calibrated for drainage delivery, allow to drain for I minute with the tip of the pipet touching the wall of the receiver. For graduated pipets, allow the blood to run out either to the desired graduation mark, or to the tip if the pipet is graduated to the tip.

1-ml. mark). In general, the most accurate method of measurement is by careful drainage between two accurately established graduation marks. Volumetric pipets constructed on this principle are not generally available; ordinary graduated pipets should be used in this manner whenever possible.

PREPARATION OF THE PROTEIN-FREE BLOOD FILTRATE

1. Method of Folin and Wu: Principle. The proteins of whole blood, plasma, or serum are removed by precipitation with tungstic acid (formed by the interaction of sodium tungstate and sulfuric acid) and filtration. The filtrate is suitable for the determination of the following: nonprotein nitrogen, urea, uric acid, creatine and creatinine, sugar, amino acids, and chlorides. Sufficient filtrate for one or two determinations is provided by 2 ml. of blood; for all the determinations, about 10 ml. of blood are needed.

Procedure:10 Transfer a measured quantity of blood to a flask having a capacity at least 15 times that of the volume taken. For each volume (A ml.) of oloo i taken, add from a buret exactly 7 volumes (7 × A ml.) of water and mix. Add 1 volume (A mgl.) of 10 per cent sodium tungstate solution, and mix. Finally add slowly and with shaking 1 volume (A ml.) of two-thirds normal sulfuric acid. Stopper the flask and shake it. Only a few bubbles should form as a result of this shaking if all the proteins have been precipitated. Let stand for 10 minutes. The color of the mixture should change from red to dark brown. If this change in color does not occur, the coagulation is incomplete, usually because too much oxalate is present. In such an emergency the sample may be saved by adding 10 per cent sulfuric acid, drop by drop with shaking, until there is no foaming and until the dark brown color has set in.

Pour the mixture on a dry folded filter large enough to hold it all. Cover the funnel with a watch

• Folin and Wu: J. Biol. Chem., 38, 81 (1919).

10 Reagents Required: Sodium tungstati, 10 Per Cent Solution. Dissolve 100 g. of reagent-grade, carbonate-free sodium tungstate (Na₂WO₄2H₂O) in water and dilute to 1 liter. Stable indefinitely.

Two-thirds Normal Sulfuric Acid. Weilgh out 35 g. of concentrated sulfuric acid in a small tared beake, r, dilute to 1 liter with water, and mix. Check by titration again to standard alkali and adjust if necessary. The two-thirds normal acid is intended to be equivalent to the sodium tungstate, so that twhen equal volumes are mixed substantially the whole of the tingstic acid is set free without the presence of an excess of sulfuring acid. The liberated tungstic acid is taken up almost quantitatively by the blood proteins, to yield a filtrate which is only slightly acid.

Fig. 160. Diluting pipet. (Courtesy, Folin and Wu: J. Biol. Chem., 38, 81 (1919).)

5

glass to minimize evaporation. Collect the filtrate in a clean dry container. If the first few drops of filtrate are not absolutely clear, return this portion to the funnel and replace the receiver with a fresh one. Allow to filter until as much filtrate as possible has been obtained.

For plasma or serum the procedure is similar except that 8 volumes of water and only one-half volume of both tungstate and acid are used.

The following modifications of the Folin-Wu precipitation employ fewer solutions and yield more filtrate.

'en's' Modification: Add directly to the blood from a buret, eight volumes of 1'0 per cent sodium tungstate, shake well, and filter, as above.

Van Slyky? and Hawkins' 13 Modification: Add directly to the blood, nine volumes by a mixture of 8 parts N/12 sulfuric acid and one part 10 per cent sodium tungstate. Shake and filter, as above. The precipitating solution should by a clear and not more than two weeks old.

Blood filtrate's prepared by any of the above methods represent a 1:10 dilution of the sample; that is, 1 ml. of filtrate corresponds to 0.1 ml. of original material. Since any error in measurement of the added reagents will produce a corresponding error in calculations, which are based upon the assumption of an exact 1:10 dilution, all measurements must be made carefully, preferably by the use of calibrated pipets or burets.

The protein-free filtrates are not acid enough to prevent bacterial decomposition. If the filtrates are to be kept more than about 12 hours a few drops of toluene or xylene should be added. For optimum precipitation of protein, the filtrate should not be more alkaline than pH 2.8.14 A drop of 0.04 per cent brompher tol blue added to a few drops of filtrate on a test plate should give a yellow, or greenish-yellow color, alkalinity being denoted by a pure blue shade.

2. Other Methods of Deproteinization. Although tungstic acid filtrates prepared as described above, are the most satisfactory for general purposes, many other reagents have been used for the deproteinization of blood and other biological fluids. Examples of the use of certain of these (zinc and copper hydroxides, trichloroacetic acid, etc.) will be found subsequently in this chapter. In most cases they are employed in particular analytical techniques in which tungstic acid filtrates have been found unsatisfactory for one reason of the temperature of common protein precipitants. Benedict and Newton¹⁶ remmend the use of tungstomolybeic acid in place of tungstic acid for the preparation of blood filtrates, not only for general purposes but also specifically for the determination of blood ergothioneine, for which tungstic acid filtrates are

 Benedict and Newton: J. Biol. Chem., 82, 357 (1929).

unsatisfactory. Folin¹⁷ has suggested the preparation of tungstic acid filtrates from *unlaked* blood, the blood being treated with tungstic acid in the presence of a hypertonic concentration of sodium sulfate, which prevents hemolysis of the corpuscles. It is claimed that this minimizes interference in certain analyses, notably for glucose and uric acid, since interfering material is largely in the corpuscles. There are certain theoretical and practical objections to this procedure, however, and it has not been widely adopted.

DETERMINATION OF NONPROTEIN NITROGEN

- 1. Introduction. The nonprotein nitrogen (N.P.N.) of the blood is a collective concept and includes the nitrogen from all of the nonprotein nitrogenous constituents of blood which are found in a protein-free filtrate, such as urea, uric acid, creatine and creatinine, amino acids, glutathione, and many others in small amount, some of which are of unknown nature. Of these various substances, the compound urea contributes by far the largest share to the total, urea nitrogen representing ordinarily about 45 per cent of the blood N.P.N. The nonprotein nitrogen content of blood is usually determined by various micro modifications of the standard Kjeldahl method for the determination of total nitrogen (see Chapter 32).
- 2. Method of Folin and Wu: ¹⁸ Principle. Nitrogen is determined in a portion of the protein-free blood filtrate by a micro-Kjeldahl method, using a sulfuric and phosphoric acid mixture for the digestion, the ammonia formed being determined colorimetrically after direct nesslerization of the digestion mixture.

Procedure: 19 Transfer 5 ml. of blood filtrate to a large test tube (pyrex) 200 mm. × 25 mm., graduated at 35 ml. and 50 ml. The test tube should either be dry or rinsed with alcohol to reduce the danger of bumping. Add 1 ml. of diluted acid mixture and a quartz pebble. Boil vigorously over a microburner until the characteristic dense fumes begin to fill the tube. This will happen in from three to seven minutes, depending on the size of the flame. When the test tube is nearly full of fumes reduce the flame sharply so that the speed of the boiling is reduced almost to the vanishing

Standard Ammonium Sulfate Solution. Dissolve exactly 0.236 g. of reagent-grade ammonium sulfate in water, transfer quantitatively to a 1-liter volumetric flask with rinsings, add a few drops of concentrated sulfuric acid, make up to volume with water, and mix. This solution is stable indefinitely and contains 0.05 mg. of nitrogen per ml. Dry the ammonium sulfate before weighing it out by heating in an oven overnight at 100°.

In all nitrogen analyses involving the determination of small amounts of ammonia, only the highest purity ammonia-free reagents may be used, and solutions must be kept protected to prevent the absorption of ammonia from the air. Distilled water containing ammonia cannot be used; to free it from ammonia, re-distil in the presence of a little suffuric acid in an all-glass still, and protect the distillate from exposure to ordinary laboratory air by a trap containing dilute sulfuric acid.

¹⁷ Folin: J. Biol. Chem., 86, 173 (1930).

¹⁸ Folin and Wu: J. Biol. Chem., 38, 81 (1919). For a gasometric method, see Van Slyke: J. Biol. Chem., 71, 235 (1927).

¹⁸ Reagents Required: Diluted Acid Mixture. Made by diluting "regular acid mixture" with an equal volume of water. To prepare "regular acid mixture," add 300 ml. of 85 per cent phosphoric acid, reagent grade, to 50 ml. of a 5 per cent copper sulfate solution. Add 100 ml. of reagent-grade concentrated sulfuric acid and mix. Keep well stoppered to prevent absorption of ammonia from the air.

Nessler's Solution. See Appendix.

point. Cover the mouth of the test tube with a watch glass. Continue the gentle heating for two minutes, counting from the time the test tube became filled with fumes. If the oxidation is not visibly finished at the end of two minutes the heating must be continued until the solution is nearly colorless. At the end of two minutes remove the flame and allow the digestion mixture to cool for 70 to 90 seconds. Then add 15 to 25 ml. of water. Cool further approximately to room temperature and then fill with water to about 1 cm. under the 35-ml. mark. Set aside until the standard is ready, since in this determination it is important that color development be carried out in both unknown and standard under as nearly identical conditions as possible.

A standard suitable for either colorimetric or photometric measurement is prepared as follows: transfer 3 ml. of a standard solution of ammonium sulfate, containing 0.15 mg. of nitrogen, to a graduated tube similar to that used for the blood filtrate, add 1 ml. of the diluted phosphoric-sulfuric acid mixture, to balance the acidity of the unknown, and dilute with water to about 1 cm. under the 35-ml. mark. For photometric measurement a third or blank tube is required, containing 1 ml. of diluted acid mixture alone, made up with water as described for unknown and standard.

When all the tubes are ready, nesslerize each individually as follows: measure out 15 ml. of Nessler's solution in a graduated cylinder, set the tube contents in motion by gentle rotatory shaking, and in one continuous motion pour the Nessler solution into the tube. Do not wait for the Nessler solution to drain completely from the cylinder, since the exact amount of Nessler solution is relatively unimportant, but immediately add water to the tube contents up to the 50-ml, mark, insert a clean rubber stopper, and mix by inversion. Proceed immediately to the nesslerization of the remaining solutions in a similar manner. Allow the solutions to stand 10 minutes after adding the Nessler reagent and mixing, to permit maximum color development, and read within the next 10 minutes or so. Prolonged standing may lead to the development of a turbidity which renders the color comparison difficult or even worthless.20 Occasionally a turbidity is present before nesslerization, due to the action of the acid digestion mixture on the glass of the tube. This turbidity can be removed by centrifuging a portion of the colored solution before color comparison.

For colorimetric measurement, match the standard against itself at 28 mm. in the usual way, and then compare the unknowns against the standard. For photometric measurement, transfer portions of the colored solutions to suitable containers and determine the densities in the photometer at 480 to 540 mm (see below), setting the photometer to zero density (100 per cent transmittance) with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknow.}} \times 0.15 \times \frac{100}{0.5} = \text{mg. of N.P.N. per 100 ml. of blood.}$$

The standard indicated is satisfactory for the range of 15 to 60 mg. per cent blood N.P.N. For amounts outside this range; repeat the analysis using less or more filtrate as necessary, and correct the calculations accordingly.

²⁶ Chilling all solutions in cold water for 10 minutes prior to adding the Nessler reagent has been recommended to prevent the formation of turbidity before reading, as has also the addition of a few drops of 2 per cent gum ghatti solution (see Appendix) to standard and unknowns just before nesslerization. The use of gum ghatti solution is not recommended unless absolutely necessary; for further discussion, see footnote 29, p. 500.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.15 \times \frac{100}{0.5} = \text{mg. of N.P.N. per 100 ml. of blood.}$$

The spectrophotometric characteristics of the Nessler reaction with ammonia are illustrated in Fig. 261, Chapter 32. For the amounts of nitrogen which are concerned here, satisfactory agreement with Beer's law is found with any filter or wavelength setting between 480 and 540 m μ , the choice depending largely upon the sensitivity desired. In 1-cm. cuvette, at 480 m μ , the density of the standard prepared as described above is approximately 0.250. This means that up to about 120 mg. per cent blood non-protein nitrogen may be accurately determined under these conditions. For higher values, or with deeper cuvettes, where the range is proportionately reduced, use less filtrate for the analysis and correct the calculations accordingly.

Interpretation.²¹ The nonprotein nitrogen content of normal blood ranges from 25 to 35 mg. per 100 ml. Variations in blood N.P.N. content are ordinarily due largely to variations in urea content. Increased values for nonprotein nitrogen are observed in nephritis, more especially in the chronic types and in terminal stages, where they may have prognostic significance, although uremic symptoms may develop without marked elevation of nonprotein nitrogen. The direction of change will impart greater information than the magnitude of an isolated determination.

In regard to the choice of determining either the nonprotein or the urea N as a clinical test of renal function, the advantages seem to be in favor of the latter, for the following reasons: urea covers a relatively wider range of variation in disease; it is a single chemical compound rather than a mixture of partly undetermined composition; it is simple to determine clinically, especially if direct nesslerization of the Folin-Wu filtrate is employed. It is of interest, however, that the urea fraction of the non-protein nitrogen, which usually rises in renal disease, shows subnormal values in cases of eclampsia, suggesting an increase in the "rest N" fraction which may contain toxic split-products of protein metabolism.

3. Method of Koch and McMeekin:²² Principle. This method differs from the preceding one in that sulfuric acid and hydrogen peroxide are used in the digestion.

Procedure: 12 Transfer 5 ml. of the 1:10 protein-free filtrate to a 200 \times 25 mm.

11 For review, see Folin: Physiol. Rev., 2, 460 (1922); also Peters and Van Slyke's book

(see Bibliography at end of chapter).

*** Koch and McMeekin: J. Am. Chem. Soc., 46, 2066 (1924). A stronger acid digestion mixture containing perchloric acid is used by Rose: J. Biol. Chem., 64, 253 (1924). A saturated solution of NH₂-free potassium persulfate is recommended by Wong: J. Biol. Chem., 55, 431 (1923). There is some evidence that both hydrogen peroxide and perchloric acid may yield inconstant results, possibly through oxidation of a portion of the ammonia, although the procedures appear to be sufficiently reliable for routine clinical purposes. Selenium is coming into use as an oxidation catalyst, and appears to give good results (see Campbell and Hanna: J. Biol. Chem., 119, 1 (1937).)

²³ Reagents Required: Sulfuric Acid, 1:1. With stirring, carefully add 50 ml, of concentrated sulfuric acid to 50 ml, of water. Cool and keep well stoppered to prevent absorption

of ammonia from the air.

30 Per Cent Hydrogen Peroxide. Only the highest grade, low-nitrogen reagent (Merck's or

pyrex test tube, add 1 ml, of 1:1 sulfuric acid and a small quartz pebble, and heat over a microburner to evaporate off the water. When charring begins and white fumes begin to appear in the tube, reduce the size of the flame or raise the tube so that the tip of the flame just touches the bottom of the tube. Continue heating until no further darkening occurs. Remove the flame, allow the tube contents to cool for about one minute, and then add 1 drop of 30 per cent hydrogen peroxide, allowing it to drop directly into the solution. Replace the flame and heat again to boiling. If the solution is not decolorized repeat the addition of the hydrogen peroxide. Finally boil gently for five minutes. Cool, transfer to a 50-ml. volumetric flask with about 35 ml, of water, and set aside until the standard is ready. Test tubes graduated at 35 and 50 ml. as described for the previous procedure may be used here instead of volumetric flasks. To prepare the standard, transfer 3 ml. of standard ammonium sulfate solution, containing 0.15 mg. of nitrogen, to a 50-ml. volumetric flask, add 1 ml. of 1:1 sulfuric acid, and dilute to about 35 ml. with water. For photometric measurement a blank is prepared in a third flask by diluting 1 ml. of 1:1 sulfuric acid to about 35 ml.

When ready, to each flask add 12 ml. of modified Nessler reagent from a graduated cylinder, swirling the contents of the flask just before adding the Nessler reagent to promote quick and uniform mixing. Dilute immediately with water to the 50-ml. mark, stopper, and mix by inversion. Allow to stand 10 minutes before reading. Read in the colorimeter or photometer exactly as described for the previous method, using the same calculations.

Interpretation. See previous method.

4. Other Methods. As has been indicated, most of the modifications in the micro-Kieldahl determination of blood nonprotein nitrogen by direct nesslerization involve changes in the digestion mixture. Alternate procedures for the determination of the ammonia formed include gasometric estimation (Van Slyke, loc, cit.); aeration of the ammonia from the alkalinized digest as described for the determination of urea (see next section); or steam distillation of the ammonia (see Chapter 32). In both aeration and steam distillation, the recovered ammonia is absorbed in acid and may be estimated by titration or by nesslerization; the advantage of nesslerization after separation of the ammonia from interfering material is that crystal-clear colored solutions are invariably obtained. A steam distillation device such as that illustrated in Fig. 262, Chapter 32, or its equivalent, is convenient, almost automatic in operation, and requires but a few minutes for each sample. Steam distillation prior to estimation of ammonia is recommended for all precise micro-Kjeldahl analyses. For very small amounts of nitrogen (ammonia), the micro-diffusion method of Conway (see Chapter 32) has given excellent results.

DETERMINATION OF UREA

1. Introduction. Practically all of the methods in use at the present time for the determination of the urea content of blood are based upon incubation with preparations of the enzyme urease,²⁴ whereby urea pres-

Baker's are satisfactory) may be used. This reagent is extremely corrosive to the skin and must be dispensed with care, preferably by the use of a rubber-bulb pipet. Keep in the refrigerator when not in use.

Modified Nessler Solution. See Appendix.

Standard Ammonium Sulfate Solution. See previous method.

24 Marshall: J. Biol. Chem., 15, 487 (1913).

ent is converted into ammonium carbonate. The ammonia formed may then be determined directly by colorimetric methods, or separated by either aeration or distillation and then determined either colorimetrically or titrimetrically. The carbon dioxide produced by decomposition of ammonium carbonate may also be measured gasometrically.²⁵ Several methods which do not involve the use of urease have also been described.²⁶ The choice of procedure among the many available appears to be largely a question of the facilities and requirements of the individual laboratory.

2. Method of Folin and Svedberg:²⁷ Principle. The ammonia produced by the action of urease on the protein-free blood filtrate is distilled off and determined colorimetrically by reaction with Nessler's reagent. For a discussion of the accuracy of this method see Gentzkow (*J. Biol. Chem.*, 143, 540 (1942)).

Procedure:²⁸ Transfer 5 ml. of tungstic acid blood filtrate to a pyrex test tube of 30 ml. capacity (tubes which previously contained Nessler solution should be rinsed with concentrated nitric acid and then with water before use). Add 2 drops of acetate buffer solution and either 1 ml. of urease solution (prepared the same day) or a piece of urease paper. Insert a cork and

- 25 Van Slyke: J. Biol. Chem., 73, 695 (1927).
- ¹⁶ Ormsby: J. Biol. Chem., 146, 595 (1942); Barker: ibid., 152, 453 (1944); Archibald: ibid., 157, 507 (1945). See also method of Leiboff and Kahn (p. 506).
 - ²⁷ Folin and Svedberg: J. Biol. Chem., 88, 77 (1930).

²⁸ Reagents Required: Acetate Buffer Solution. Dissolve 15 g. of crystallized sodium acetate in a 100 ml. volumetric flask by the help of 50 to 75 ml. of water. Add 1 ml. of glacial acetic acid, dilute to volume, and mix.

Urease Solution. Transfer 0.5 g. of jack bean meal to a clean 50-ml. flask; add 20 ml. of 30 per cent (by volume) alcohol. Shake for 10 minutes and filter or centrifuge. This extract should always be prepared on the day it is to be used, because on standing even in an icebox it will develop ammonia and will yield too high results. One should therefore not use more extract or a stronger extract than is really necessary. Koch (J. Lab. Clin. Med., 11, 776 (1926)) obtains a stable and active urease preparation by making a 75 per cent glycerol extract of jack bean meal.

Urease Paper. Transfer to a clean 200-ml. flask 30 g. of jack bean meal and 100 ml. of dilute alcohol (30 ml. of 95 per cent alcohol diluted to 100 ml.). Add 1 ml. of the buffer mixture described above. Stopper tightly and shake vigorously for at least five minutes and then shake less hard for about 10 minutes. Filter, or preferably centrifuge half an hour in 15-ml. tubes, the mouths of which have been covered with tinfoil. Transfer the extract to a porcelain dish and at once take it up on strips of rather heavy filter paper, Schleicher and Schüll, No. 597, and hang these up to dry over two threads about 15 cm. apart. While drying, the papers should not be exposed to air currents, for blasts of air seem to destroy the enzyme so long as water is present. As soon as the paper strips are thoroughly dry cut them up into pieces about 1 cm. by 2.5 cm. and preserve in wide-mouth bottles. These urease papers will retain their activity for many months and even for years. The urease becomes fixed in the paper and it is only by shaking the solution several times during the digestion that one secures adequate contact and quantitative hydrolysis of the urea.

Antibumping Tube. As illustrated in Fig. 161. Made preferably from pyrex glass, 2 mm. in diameter at open end. May be obtained from Eimer and Amend, New York.

Antifoaming Oil Mixture. To one volume of crude fuel oil add about 1Q-volumes of toluene. Saturated Borax Solution. Dissolve about 40 g. of reagent grade sodium tetraborate (borax) in 1 liter of boiling water and allow to cool to room temperature. If unsaturated, add more borax and again heat.

0.1 N Acid. Either hydrochloric or sulfuric may be used, and it need not be standardized. Standard Ammonium Sulfate Solution. Prepare a stock standard solution as follows: Dissolve 0.944 g. of dry reagent-grade ammonium sulfate in water, transfer with rinsings to a 1 liter volumetric flask, add a few drops of concentrated sulfuric acid, dilute to volume with water, and mix. This solution contains 1 mg. of nitrogen in 5 ml. and is stable indefinitely. To prepare the dilute standard used in the procedure, dilute 5 ml. of stock standard to 100 ml. with water. This solution contains 0.1 mg. of nitrogen in 10 ml., and is prepared fresh daily.

then either let stand at room temperature for 25 minutes or immerse for 10 minutes in 700 ml. of water, having an initial temperature of about 45°. Longer digestion does no harm. If urease paper is used the tube must be shaken occasionally during the digestion period. Cool the tube if warm and add an antibumping tube, 2 drops of antifoaming oil mixture, and 2 ml. of saturated borax solution. Connect at once with the delivery tube and a test tube receiver graduated at 25 ml. as shown in Fig. 161. The receiver contains 1 ml. of 0.1 N acid and 1 ml. of water. Fasten the boiling

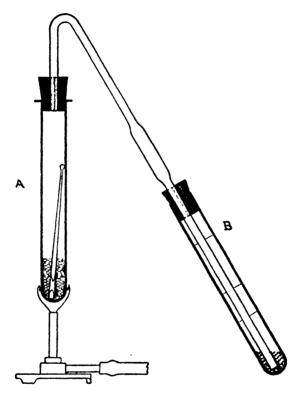

Fig. 161. Micro-distillation apparatus for urea determination. Note anti-bumping tube inside tube A (Folin and Syedberg).

tube in a clamp and start the distillation by applying the flame of a microburner, preferably surrounded by a shield to prevent fluctuation of the flame due to air currents. As soon as the contents are nearly boiling, reduce the flame partially so that the first minute of boiling is very gentle. Then boil briskly for about three minutes and finally another minute with the delivery tube slightly raised from the surface of liquid in the receiver. To another test tube like the receiver, transfer 10 mi. of standard ammonium sulfate solution (containing 0.1 mg. of N), and 1 mi. of 0.1 N scid. Dilute both to a volume of about 20 ml., 20 add 2.5 ml. of Nessler solution, dilute to the mark, mix and make the color comparison, using either a colorimeter or a photometer. For photometric measurement, prepare a blank tube

²⁰ In the original procedure of Folin and Svedberg, 1 ml. of gum ghatti solution (see Appendix) is added at this point. This is ordinarily not necessary and its use should be avoided if possible, since it decreases color intensity and alters the relationship between color intensity and concentration. If used, it must be added to both standard and unknown.

containing 1 ml. of 0.1 N acid, water to about 20 ml., add 2.5 ml. of Nessler solution, dilute to 25 ml., and mix. Set the photometer to zero density with the blank, and determine the densities of standard and unknowns as described for the determination of nonprotein nitrogen on p. 496.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.1 \times \frac{100}{0.5} = \text{mg. of urea N per 100 ml. of blood}$$

The standard is satisfactory for blood values between 8 and 40 mg. per cent. For higher values, repeat the determination with less filtrate plus water.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.1 \times \frac{100}{0.5} = \text{mg. of urea N per 100 ml. of blood}$$

Under the photometric conditions specified on p. 497, the standard has a density of roughly 0.300. Up to 60 mg. per cent blood urea N may be measured satisfactorily. For higher values, or with cuvettes of greater depth than 1 cm., the analysis is carried out on less filtrate plus water, and the calculations corrected accordingly.

For separation of ammonia by aeration rather than distillation, see the next procedure.

Interpretation. Normally, the urea nitrogen of whole blood varies between 10 and 15 mg. per 100 ml. On a restricted hospital diet, however, values below 20 mg. should not be regarded as abnormal. In early nephritis the urea nitrogen may rise to 30 or 40 mg., but in the terminal stages of chronic nephritis and in some cases of acute nephritis marked urea retention may occur. High values may also be found in other conditions associated with damaged renal function, such as mercury bichloride poisoning, double polycystic kidney, intestinal obstruction, prostatic obstruction (in which case the urea N constitutes a valuable guide to surgical risk), lead poisoning, certain infections, cardiac failure, and so on. Relatively low figures for urea nitrogen are found in nephrosis (nonhemorrhagic nephritis with edema), which is probably of metabolic rather than renal origin.

The blood urea concentration has greater significance when interpreted with relation to urea excretion, as in the urea clearance test (Chapter 32).

3. Method of Van Slyke and Cullen: Principle. Whole blood is treated with urease under optimal conditions for conversion of the urea to ammonium carbonate. The mixture is then made alkaline with potassium carbonate and aerated. In the original procedure, the aerated ammonia is absorbed in standard acid and the acid back-titrated with standard alkali. In the modification described here, the ammonia is absorbed in boric acid solution and titrated directly with standard acid. ²¹

^{*} Van Slyke and Cullen: J. Biol. Chem., 11, 211 (1914); 24, 117 (1916).

²¹ As developed by Prof. W. H. Summerson for use at the New York Hospital.

Procedure: 12 Into a large test tube (200 imes 28 mm., preferably thick-walled and lipless)33 place 2 ml. of phosphate buffer, 5 drops of caprylic alcohol, and 0.5 ml. of 10 per cent urease solution. Add exactly 2 ml. of blood, mix gently, stopper loosely with a rubber stopper carrying the long inlet tube and the short outlet tube shown in Fig. 162, and allow to stand at room temperature for 10 minutes. This is tube "A." During the time of standing, prepare tube "B" by placing 25 ml. of boric acid solution containing indicator in a second large test tube similar to the first, add a drop of caprylic alcohol, and stopper tightly with a rubber stopper likewise carrying inlet and outlet tubes.34 Place in a test tube rack or wooden block alongside tube "A," and connect the long inlet tube of "B" with the short outlet tube of "A" by means of a short length of rubber tubing, 35 as shown. When the 10-minute period is up, raise the stopper of "A" and add 5 ml. of a saturated solution of potassium carbonate down the side of the tube. Immediately replace the stopper and tighten it firmly in place. Attach the long inlet tube of "A" by rubber tubing to a large test tube or wash bottle half-full of N sulfuric acid, plus a few drops of caprylic alcohol, and so arranged that when air is

22 Reagents Required: Phosphate Buffer. Dissolve 6 g. of monopotassium phosphate (KH2PO4) and 2 g. of anhydrous disodium phosphate (Na2HPO4) in water, dilute to 1 liter, and mix. Add a few drops of chloroform as preservative.

Caprylic Alcohol, Dispense from a dropping bottle.

10 Per Cent Urease Solution. Stir up 1 g. of Squibb's "double strength" urease in a little water, sufficient to make a paste, and then add water, a little at a time, with stirring, to make the final volume 10 ml. Keep in the refrigerator when not in use, and make up only enough for each day's use, discarding the remainder, if any. "Arlco" urease (Arlington Chemical Co., Yonkers, N.Y.) may also be used. The activity of each bottle of urease should be tested by running through the standardization procedure on a urea solution as described below.

Boric Acid Solution, 2 Per Cent, with Indicator. Dissolve 20 g. of reagent-grade boric acid in about 500 ml, of hot water, cool, add 2 ml, of 0.1 per cent bromcresol green in alcohol (the aqueous solution of the sodium salt may also be used), dilute to 1 liter, and mix. This solution need not be prepared accurately, and may be prepared in large volume sufficient for several weeks' use. If the color fades on standing, more indicator may be added to the remaining portion. Only bromeresol green indicator may be used, since in the presence of caprylic alcohol other indicators (e.g., methyl red) are sufficiently altered in tint so that comparison of the end point with a control, as described in the text, becomes impossible. The 2 per cent strength of boric acid is recommended rather than 4 per cent because of the better end point and because it has been found capable of absorbing all the ammonia likely to be present, even in an analysis of urine (see Chapter 32).

Saturated Potassium Carbonate Solution. To 900 g. of pure dry potassium carbonate add 1 liter of water. Stir to dissolve as completely as possible.

Standard Sulfuric Acid Solution. This is to be of such strength that 1 ml, represents 0.2 mg. of nitrogen. Theoretically, a 0.0143 N solution is required. Practically, it is better to standardize the acid against pure urea as described here and adjust to the required strength. Measure exactly 15.0 ml. of N sulfuric acid from a buret into a 1-liter volumetric flask, dilute to the mark with water, and mix. Prepare a standard urea solution containing 1.07 g. of pure dry ures in 1 liter. Analyze a 2-ml. portion of the ures solution by the procedure described in the text, replacing the blood by the urea solution, and titrating with the acid. Multiply 15.0 by the number of ml. of acid used in the titration and divide the result by 5.00 to find the exact volume of N acid which must be diluted to 1 liter for the correct strength.

Thus if 4.77 ml. of acid were used in the titration, $\frac{15.0}{5.00} \times 4.77 = 14.3$ ml. Discard the first lot

of acid and prepare a second using the correct volume of N sulfuric acid. Check by repeating the standardization; exactly 5.00 ml. of acid should be required in the titration. The acid solution is stable indefinitely and may be made up in large volume at one time.

Both Kimble No. 49050 and Corning No. 7980 are satisfactory.
It is good practice to have marked fitted stoppers for the "A" and "B" tubes separately and not to interchange them, thus avoiding the possibility of error due to traces of carbonate on an "A" inlet tube entering the boric acid of a "B" tube.

*5 Thick-walled stethoscope tubing is satisfactory. Cut in 6-inch lengths, scrub with a buret brush, then boil for 30 minutes in 10 per cent sodium hydroxide solution, making sure that the tubes are filled with the solution. Rinse thoroughly in tap water and distilled water. Do not use acid for washing the tubes.

drawn through "A" it must first bubble through the wash bottle, thus freeing it of any ammonia. Attach the short outlet tube of "B" by rubber tubing to a suitable source of suction (water pump or vacuum line). When

everything is ready, turn on the suction carefully and draw air slowly through "A" and "B" for about one minute, then increase the rate of air passage until the air is passing through as rapidly as possible. Continue the aeration for one hour. At the end of this time, slow down the rate of air passage (but do not stop it entirely) and disconnect the tubes, starting at the point farthest removed from the source of suction, to prevent any effects of back pressure. Remove the stopper and tubes from "B," rinse down the long tube with a little water, and place the stopper aside. Titrate the contents of "B" with the standard sulfuric acid, preferably using a buret of 10 ml. capacity. The end point is when the more or less blue solution is exactly restored to its original yellow-green shade. This is best seen by having a control tube similar to "B" and containing 25 ml. of the boric acid-indicator solution. The contents of "B" are titrated until they exactly match the color of the control solution.

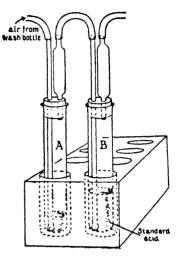

Fig. 162. Van Slyke and Cullen aeration apparatus.

The end point is usually sensitive to about 0.02 ml. of the standard acid.

Calculation. The strength of the acid is such that 1 ml. represents 0.2 ml. of nitrogen. Since 2 ml. of blood are used for analysis, the calculation is as follows:

Ml. standard acid required × 10 = mg. urea N per 100 ml. of blood

As many pairs of tubes as desired may be connected in series as described, thus permitting the carrying out of a number of determinations at the same time. According to Van Slyke and Cullen, 75 liters of air will remove the ammonia satisfactorily from a solution half-saturated with potassium carbonate. The time required for complete aeration thus depends upon the rate of air passage, and may be shorter than that specified. It may be established by treating portions of standard ammonium sulfate solution with an equal volume of saturated potassium carbonate solution and aerating into boric acid for varying periods of time, testing for completeness of recovery of the ammonia by titration as described.

The aeration inlet tubes should have a perforated bulb at the tip as shown, to break up the air, but this is not absolutely necessary. If the blood foams excessively and more caprylic alcohol is of no value, a few ml. of ethyl alcohol may be added to the mixture.

Interpretation. See previous method.

Variations of the Aeration Method. The aerated ammonia may be absorbed in 25 ml. of 0.01 N sulfuric acid containing alizarin or methyl red indicator, and the excess acid titrated with 0.01 N sodium hydroxide,

as described in the original procedure of Van Slyke and Cullen. The aeration procedure may also be applied to the Folin-Wu filtrate after urease treatment, the liberated ammonia being absorbed in dilute acid and determined colorimetrically. The ammonia aerated from urease-treated whole blood may also be determined colorimetrically instead of by titration. For details, see the Eleventh Edition of this book.

4. Method of Gentzkow: ³⁶ Principle. Diluted whole blood is treated with urease to convert urea into ammonium carbonate, the proteins are then precipitated at a 1:10 dilution by the Folin-Wu method, and the ammonia in the filtrate is determined by direct nesslerization in the presence of persulfate and gluconate as stabilizers. Color measurement is carried out with light of wavelength 490 to 510 m μ , to minimize interference from substances other than ammonia present in the filtrate.

Procedure:37 Transfer 5 ml. of oxalated whole blood to a small flask and from a buret add 35 ml. of water. Add 10 to 20 mg. of urease powder (the estimated amount may be picked up on a knife blade). Mix well, and let stand at room temperature (not below 20°) for 20 minutes. Then add 5 ml. of 10 per cent sodium tungstate solution, followed by 5 ml. of 3% normal sulfuric acid. Shake well, let stand for 10 minutes, and filter through a good grade of qualitative filter paper. After 10 minutes' filtration, return the filtrate to the funnel for re-filtering. The first portion of the filtrate will be found to give high values unless re-filtered as described.

Transfer 5 ml. of the filtrate to a test tube graduated at 20 and 25 ml. In a similar tube place 5 ml. of standard ammonium sulfate solution, containing 0.075 mg. of nitrogen. Dilute the contents of each tube to the 20-ml. mark with water, and mix. To each tube add 4 ml. of the freshly prepared special Nessler reagent, dilute with water to the 25-ml. mark, stopper with paraffined corks, and mix by vigorous shaking. Allow to stand 15 minutes for color development, then read in the colorimeter or photometer within the next hour. Keep the tubes stoppered during the time of standing.

For colorimetric measurement, remove the blue "daylite" filter if present, and cover the light box with a Wratten filter No. 75 mounted between microscope slides or place a piece of Wratten filter No. 75 mounted beween cover slips on the eyepiece of the colorimeter. Incorrect results will be obtained without the use of the filter as described. Compare the standard

³⁶ Gentzkow: J. Biol. Chem., 143, 540 (1942).

²⁷ Reagents Required: Urease. Squibb, "double strength," powdered.

¹⁰ Per Cent Sodium Tungstate, and Two-thirds Normal Sulfuric Acid. The Folin-Wu reagents are used (p. 493).

Filter Paper. Whatman No. 2 is satisfactory. Do not use "acid-washed" filter paper, as this may contain appreciable amounts of ammonia.

Standard Ammonium Sulfate Solution. Prepare a stock standard as follows: dissolve 7.074 g. of dry reagent-grade ammonium sulfate in 0.1 N sulfuric acid and dilute to 1 liter with the acid. This solution is stable indefinitely and contains 1.5 mg. of nitrogen per ml. Prepare the working standard by diluting 5 ml. of the stock standard to 500 ml. with 0.01 N sulfuric acid. This solution contains 0.075 mg. nitrogen in 5 ml.

Potassium Gluconate. Dissolve 1 g. of potassium gluconate in water and dilute to 100 ml. Store in the refrigerator and make up fresh weekly.

Potassium Persulfate. Dissolve 2.5 g. of reagent-grade nitrogen-free potassium persulfate in 100 ml. of water. Prepare fresh weekly and keep in the refrigerator at all times.

Special Nessler Reagent. (a) Place 500 ml. of 10 per cent sodium hydroxide solution in a 1-liter volumetric flask, add 150 ml. of the Folin-Wu Nessler reagent (see Appendix), dilute to 1 liter with water, and mix. Allow to stand three days for sedimentation of any precipitate. (b) Just before an analysis, mix one part of the gluconate solution and one part of the persulfate solution, and pour into an equal volume (two parts) of the clarified modified Nessler solution. Do not prepare more of this than needed, and use within 15 minutes, discarding any remaining solution.

against the unknown in the usual way. For photometric measurement, determine the densities of standard and unknowns at 490 my, setting the photometer to zero density with water.

Calculation. For colorimetric measurement:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 15 = \text{mg. of urea nitrogen per 100 ml. of blood}$

If the blood contains less than 8 or more than 30 mg. per cent of urea nitrogen, repeat the analysis using a more appropriate standard, or take less filtrate for nesslerization, and correct the calculations accordingly.

For photometric measurement:

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 15 = \text{mg. of urea nitrogen per 100 ml. of blood}$

For considerations determining the choice of wavelength in this procedure, see the original article.

Interpretation. See previous methods.

5. Method of Karr:³⁸ Principle. By the action of urease, the urea in a protein-free filtrate is converted to ammonium carbonate which is nesslerized in the presence of gum ghatti as a protective colloid. The interference of peptones and amino acids (Folin and Wu) is regarded as so slight and uniform as not to influence the clinical value of the results.

Procedure: 39 Transfer 5 ml. of Folin-Wu blood filtrate to a test tube, and in a similar tube place 5 ml. of standard urea solution, containing 0.075 mg. of nitrogen. To each tube add 0.5 ml. of buffer solution and 5 drops of urease solution. Place in a bath at 50° for 15 minutes. Transfer the contents of each tube, with rinsings, to separate test tubes of graduated at 22.5 and 25 ml., and dilute with water to the 22.5-ml. mark. Add 3 drops of gum ghatti solution, followed by Nessler solution to the 25-ml. mark. Mix, allow to stand for 10 minutes, and read within the next 20 minutes, using either a colorimeter or photometer. For photometric measurement, follow

²⁸ Karr: J. Lab. Clin. Med., 9, 3 (1924). The use of gum ghatti as a stabilizing colloid by Folin (J. Biol. Chem., 81, 231 (1929)) in his sugar method (p. 526) suggested its application in the urea method to Looney (J. Biol. Chem., 88, 189 (1930)).

²⁹ Reagents Required: Standard Urea Solution. Dissolve 0.3215 g. of pure dry urea in water and dilute to 500 ml. in a volumetric flask. Add a little chloroform or toluene as a preservative. This solution contains 0.3 mg. of urea nitrogen per ml. To prepare the working standard, dilute 5 ml. of stock standard to 100 ml. with water in a volumetric flask, and mix. Prepare fresh daily. This solution contains 0.075 mg. of urea nitrogen in 5 ml.

Buffer Solution. Dissolve 20 g. of crystalline sodium acetate in water, add 2.2 ml. of 10 per cent acetic acid, dilute to 100 ml. with water, and mix. Add a little toluene or chloroform as preservative.

Urease Solution. Place 15 g. of jack bean meal (obtainable from the Arlington Chemical Co., Yonkers, N.Y.), about 2 g. of "permutit" (see Appendix), 16 ml. of 95 per cent alcohol, and 84 ml. of water in a 200-ml. flask. Shake more or less continuously for about 15 minutes. Pour onto a filter and allow to filter overnight in the refrigerator. Keep the filtrate in the cold, transferring a portion to a dropping bottle for daily use. Prepare fresh every three to four weeks, or when a blank analysis shows the presence of significant amounts of ammonia.

Gum Ghatti Solution. See Appendix.

Nessler Solution. The Koch-McMeekin preparation is recommended (see Appendix).

40 Separate tubes for nesslerisation are necessary because of the "poisoning" action of mercury on urease. When this is suspected in the conversion tubes they should be cleaned with strong nitric acid.

the conditions specified on p. 497 for the determination of nonprotein nitrogen, setting the photometer to zero density with a blank prepared by treating 5 ml. of water with buffer, urease, etc., exactly as described above for a blood filtrate.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.075 \times \frac{100}{0.5} = \text{mg. of urea N per 100 ml. of blood}$$

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.075 \times \frac{100}{0.5} = \text{mg. of urea N per 100 ml. of blood}$$

Interpretation. See under method of Folin and Svedberg above.

6. Method of Leiboff and Kahn:⁴¹ Principle. The urea in the Folin-Wu blood filtrate is converted to ammonia by acid hydrolysis under pressure and directly nesslerized. The slight conversion of non-urea substances to ammonia is unimportant clinically. By the elimination of urease, turbidity after nesslerization is claimed to be avoided even with filtrates high in urea. For a description of the apparatus and procedure, see the Eleventh Edition of this book.

DETERMINATION OF CREATININE

- 1. Introduction. Blood creatinine is ordinarily determined by reaction in a protein-free filtrate with alkaline picrate to form a red color (the Jaffe reaction), which is then compared with a standard. A color reaction of creatinine with dinitrobenzoate has also been described. It is well recognized that the Jaffe reaction is by no means specific for creatinine, and that other substances are present in blood (chiefly in the red cells) which contribute to the color, so that results on whole blood filtrates are undoubtedly too high. Practically all of the chromogenic material in plasma, however, appears to be creatinine, and therefore plasma is preferred to whole blood for analysis. Most of the results in the literature have been obtained on whole blood. A specific method for creatinine determination appears to be the measurement by the Jaffe reaction before and after treatment with a bacterial preparation which destroys creatinine.
- 2. Method of Folin and Wu: 45 Principle. A portion of the blood filtrate is treated with alkaline picrate solution and the color developed is compared in a colorimeter or photometer with that produced by a known amount of creatinine under the same conditions.

⁴⁴ Miller and Dubos: loc. cit.; Allinson: J. Biol. Chem., 157, 169 (1945).

⁴⁴ Folin and Wu: J. Biol. Chem., 38, 81 (1919). See also Peters: J. Biol. Chem., 146, 179 (1942); Bonsnes and Taussky: ibid., 158, 581 (1945).

Procedure: Transfer 10 ml. of 1:10 tungstic acid filtrate of whole blood or plasma (preferably the latter) to a small flask or test tube. In a second container, place 5 ml. of standard creatinine solution, containing 0.03 mg. of creatinine, and add 15 ml. of water. Add 5 ml. of freshly prepared alkaline picrate reagent to the blood filtrate, and 10 ml. to the diluted creatinine standard. Mix, and allow to stand for 15 minutes for complete color development. Read in the colorimeter or photometer within the next 15 minutes.

For colorimetric measurement, first match the standard against itself carefully, and then compare with the unknowns in the usual way. For photometric measurement, transfer the solutions to suitable containers and determine the densities in the photometer at 520 my (see Fig. 163). Set the photometer to zero density with water alone. Determine the density of a blank prepared by treating 10 ml. of water with 5 ml. of the alkaline picrate reagent, and subtract this value from the observed densities of standard and unknown to obtain their true values.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. of creatinine in standard} \times \frac{100}{1} \times \frac{15}{30}$$
= mg. of creatinine per 100 ml. of blood or plasma

In connection with this calculation, it is to be noted that the standard is made up to twice the volume of the unknown, so that a volume correction factor (15%) is introduced. The standard specified corresponds to a blood creatinine of 1.5 mg. per cent, and is satisfactory for the range of 1 to 2 mg. per cent only, because of the presence of the high blank color of the alkaline picrate and the significant deviation from Beer's law (see p. 508) shown by this color reaction. It is good practice, therefore, to prepare several standards at different concentration levels, to provide for values outside the indicated range. If a high creatinine should be encountered without several standards ready, the determination may be saved by diluting the unknown with an appropriate amount of the alkaline picrate solution which has first been diluted with two volumes of water, to preserve equality of picric acid and alkali concentration. It is better, however, to repeat the analysis if possible, using less filtrate plus water to 10 ml., correcting the calculations accordingly.

For photometric measurement, values up to about 5 mg. per cent blood creatinine may be calculated as follows:

46 Reagents Required: Standard Creatinine Solution. Prepare a stock standard by dissolving 1 g. of pure dry creatinine in 0.1 N hydrochloric acid and diluting to 1 liter with the acid. This solution is stable indefinitely, and contains 1 mg. of creatinine per ml. To prepare the working standard, transfer 3 ml. of stock standard, containing 3 mg. of creatinine, to a 500-ml. volumetric flask, add 50 ml. of 0.1 N hydrochloric acid, dilute with water to 500 ml., and mix. This standard contains 0.03 mg. of creatinine in 5 ml., and is stable for a week or more if preserved by the addition of a few drops of toluene.

Alkaline Picrate Reagent. (a) Prepare a saturated solution of purified picric acid (see Appendix). It is essential that this solution be saturated, otherwise serious error may result. A 10-ml. portion, titrated with 0.1 N alkali in the presence of phenolphthalein as indicator, should require 5.2 to 5.4 ml. of alkali for neutralisation. (b) To prepare the fresh alkaline picrate reagent, transfer 25 (or 50) ml. of the saturated picric acid solution to a flask, add 5 (or 10) ml. of 10 per cent sodium hydroxide solution, and mix. Use within a short time after preparing. On standing, crystals may form in the solution which do not impair its effectiveness but render measurement difficult.

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. of creatinine in standard} \times \frac{100}{1} \times \frac{15}{30}$ = mg. of creatinine per 100 ml. of blood or plasma

For higher values, repeat the analysis with 5 ml. of filtrate plus 5 ml. of water, and multiply the results by 2. At 520 m μ and in a 1-cm. cuvette, the density of the standard described, corrected for the blank, is approximately 0.050.

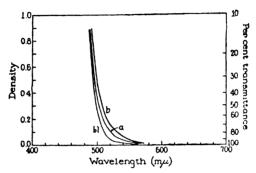

Fig. 163. Absorption spectra of colored solutions obtained in Folin-Wu blood creatinine method; alkaline picrate alone (bl); alkaline picrate plus 0.03 mg. of creatinine (a); plus 0.06 mg. of creatinine (b). Solution depth, 1 cm.

This calculation is an approximation only, suitable for routine clinical purposes but not for precise work, since it is based on Beer's law, and the creatinine color does not follow Beer's law exactly at any concentration ordinarily encountered. For more exact work, a calibration curve relating observed densities to concentration must be prepared and results read from this curve. To obtain such a curve, prepare a standard creatinine solution which is twice as strong as that used in the procedure by transferring 6 ml. of the stock 0.1 per cent creatinine solution to a 500-ml. volumetric flask, adding 50 ml. of 0.1 N acid, and diluting to the mark with water. This solution contains 0.06 mg. of creatinine in 5 ml. Transfer the following amounts of this solution (preferably in duplicate) to small flasks: 0.0, 5.0, 10.0, 15.0, and 20.0 ml. Add sufficient water to each flask to make the final volume 20 ml., and then add 10 ml. of alkaline picrate reagent to each. Mix, allow to stand 15 minutes, and determine the densities in the photometer under the conditions described in the text. The first flask is a blank; subtract its average value from the other average values to obtain their true densities. The amounts of creatinine in the various flasks are 0.06, 0.12, 0.18, and 0.24 mg., respectively, corresponding under the conditions of analysis to blood creatinine contents of 3, 6, 9, and 12 mg. per cent. Plot the true densities against the equivalent mg. per cent concentrations on cross-section paper and draw a smooth curve to include all the points. A curve similar to that shown in Fig. 164 should be obtained. From such a curve, the concentration of an unknown may be read off if its density has been established.

In using such a curve, it is important to remember that it is valid only if the analysis of an unknown is carried out under conditions similar to those prevailing at the time the curve was established. In general, the calibration for one photometer is not applicable to another instrument, even of the same make, and changing the wavelength setting or filter will

influence the curve. The curve should be checked when a new lot of saturated picric acid⁴⁷ is prepared, although correcting for the blank as indicated will ordinarily take care of slight variations in the color of the alkaline picrate reagent. Time control and temperature control are important; the curve at 30° is not the same as at 20°. All of these precautions are necessary for obtaining accurate results.

Interpretation. Creatinine is the least variable nitrogenous constituent of the blood in which it exists to the extent of 1 to 2 mg. per 100 ml. of whole blood; the average value for plasma is nearer 1 mg. per cent. In early nephritis, values of from 2 to 4 mg. are noted, and in chronic hemorrhagic nephritis with uremia, 4 to 35 mg. Creatinine is more readily excreted by the kidneys than urea or uric acid,

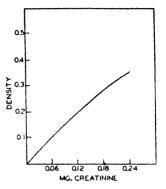

Fig. 164. Typical calibration curve for blood creatinine determination, at 520 m μ , 1 cm. solution depth.

and an increase of creatinine to 4 or 5 mg. or over per 100 ml. is evidence of marked impairment of kidney function. Such high creatinine values in chronic hemorrhagic nephritis indicate an unfavorable prognosis, although high values may obtain in acute cases over long periods.

DETERMINATION OF CREATINE

1. Introduction. The creatine of blood is ordinarily determined by the Folin-Wu procedure of heating the protein-free filtrate with acid, which converts creatine to creatinine. The total creatinine present is then determined by the procedure used for blood creatinine. The value for preformed creatinine, as established by separate analysis, is subtracted from the total creatinine value, to give the amount of creatine, expressed as creatinine. There is no satisfactory method for the direct determination of blood creatine. The specificity of the method based on acid treatment and the Jaffe reaction for creatinine is open to question. Increased specificity is undoubtedly obtained by the use of the creatinine-destroying bacteria of Miller and Dubos; few applications of this principle to knowledge of blood creatine have as yet been made.

⁴⁷ Peters (*loc. cit.*) recommends a picric acid solution containing 11.75 g. per liter, rather than a saturated solution, to minimise differences in solubility of picric acid at summer and winter temperatures.

⁴⁶ Allinson: J. Biol. Chem., 157, 169 (1945). For application of the bacterial method to the determination of creatine in tissues, see Miller, Allinson, and Baker: J. Biol. Chem., 139, 383 (1939); Borsook and Dubnoff: ibid., 132, 559 (1940).

Procedure: Transfer 5 ml. of a 1:10 tungstic acid filtrate of whole blood to a test tube graduated at 25 ml. Add 1 ml. of normal hydrochloric acid. Cover the mouth of the test tube with tin foil and heat in the autoclave to 130° C. for 20 minutes or to 155° C. for 10 minutes. Cool. Add 5 ml. of freshly prepared alkaline picrate solution (as used for blood creatinine determination) and let stand for 8 to 10 minutes, then dilute to 25 ml. At the same time, prepare a standard creatinine solution by adding to 10 ml. of creatinine solution, containing 0.06 mg. of creatinine, in a 50-ml. volumetric flask, 2 ml. of normal acid, and 10 ml. of the alkaline picrate reagent, and after 10 minutes, diluting to 50 ml. Read in the colorimeter or photometer as described for the determination of blood creatinine (p. 507). The blank for photometric measurement is prepared by treating 10 ml. of water in a 50-ml. volumetric flask with 2 ml. of acid and 10 ml. of alkaline picrate reagent and diluting to 50 ml. with water.

In the case of uremic bloods containing large amounts of creatinine, 1, 2, or 3 ml. of blood filtrate, plus water enough to make approximately 5 ml., are substituted for the 5 ml. of filtrate, and calculations corrected

accordingly.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.06 \times \frac{100}{0.5} \times \frac{25}{50}$$
= mg. of "total creatinine" per 100 ml.

Subtract the preformed creatinine content, as determined by separate analysis (p. 506), from the "total creatinine," to obtain the creatine content, expressed as creatinine. The same precautions as were described for the determination of blood creatinine, concerning deviation from Beer's law and the use of several standards if necessary, must be observed.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.06 \times \frac{100}{0.5} \times \frac{25}{50}$$
= mg. of "total creatinine" per 100 ml.

Determine creatine by subtracting preformed creatinine value as described above.

As with the determination of creatinine, the calculation given is only an approximation because of deviation from Beer's law, and for precise results a calibration curve similar to that described on p. 508 should be constructed and used. The calibration curve prepared for the preformed blood creatinine determination cannot be used here because of the presence of acid and the different proportion of alkaline picrate used. In preparing this curve, remember that only 5 ml. of filtrate are used for analysis instead of 10 ml. as in the creatinine determination, so that a given amount of creatinine in the standard corresponds to twice as high a total creatinine content per 100 ml. of blood as in the calibration for preformed creatinine. Thus the standard described, containing 0.06 mg. of creatinine in a final volume of 50 ml., is equivalent in an analysis to a total blood creatinine of 6 mg. per cent, with other amounts in proportion.

Interpretation. Blood creatine content as determined by this and other methods ranges between 3 to 7 mg. per 100 ml. of whole blood. The creatine of blood is found almost entirely in the red cells, variations in

cell count therefore presumably influencing results. Except in the case of infants and pregnant women, the amount of creatine in plasma is quite small; Allinson (loc cit.) reports values ranging from 0.4 to 0.8 mg. per cent.⁴⁹ No significant variations have as yet been associated with pathological conditions, so the determination has little clinical value at the present time. Increases have been noted after severe muscular injury and following experimental removal of the kidneys.

DETERMINATION OF URIC ACID

- 1. Introduction. Blood uric acid is ordinarily determined by colorimetric procedures based upon the reaction between uric acid and certain complex phosphotungstic acid reagents (or their equivalent) usually in the presence of cyanide, 50 to form a blue color. Procedures utilizing the reducing action of uric acid on ferricvanide have also been described. 51 The determination of blood uric acid has been the subject of much criticism and study. It appears probable that a portion of the blood uric acid is lost during precipitation of the proteins; up to now, there appears to be no simple way to avoid this. 52 The use of the various color reagents on a blood filtrate directly, without preliminary separation of interfering material, is felt by many investigators to be unsound, because of both the nonspecificity of the color reaction and the possible presence of substances which inhibit color development with uric acid itself. A combination of these effects (one tending to increase color, the other decreasing it) is felt by some to be responsible for the apparently satisfactory results obtained in some procedures. Interfering material appears to be present largely in the red cells of blood; the use of plasma or serum for analysis is therefore gaining ground and is to be preferred. Increased specificity is also obtained by separating the uric acid from interfering material prior to analysis. Color development before and after treatment with preparations of the enzyme uricase, which oxidizes uric acid, has also been proposed as a basis of specificity. 53 Of the three procedures described below. two are based on separation of interfering material before color development. The third, the method of Brown, is a direct method which appears to be as satisfactory as any that have been described, and simpler than most.
- 2. Method of Folin (Isolation Procedure):⁵⁴ Principle. Uric acid is precipitated as silver urate, directly from the blood filtrate. The uric

⁴⁹ See also Tierney and Peters: J. Clin. Invest., 22, 595 (1943).

¹⁰ For a procedure not involving the use of cyanide, see Kern and Stransky: Biochem. Z., 290, 419 (1937).

⁵¹ See Bulger and Johns: J. Biol. Chem., 140, 427 (1941).

⁵² See, however, Kern and Stransky (loc. cit.)

⁵³ Blauch and Koch: J. Biol. Chem., 130, 443 (1939). For a description of a uricase procedure applied to the determination of uric acid in urine, see Chapter 32, Urine: Quantitative Analysis.

¹⁴ Folin: J. Biol. Chem., 101, 111 (1933); 106, 311 (1934). The Folin "direct method" is similar to the procedure described here and requires the same reagents, except that the precipitation with acid silver solution is omitted. A 5-ml. portion of the blood filtrate is treated directly with the cyanide-urea solution, uric acid reagent, etc., exactly as described in the text. Calculations and directions for photometric and colorimetric measurement are the same.

acid is set free by means of acid chloride solution and determined colorimetrically or photometrically after the addition of phosphotungstic acid, which gives a blue solution.

Procedure: 55 Transfer 5 ml. of the blood filtrate 56 to a centrifuge tube. Add 2 ml. of the acid silver solution. Centrifuge at once. All the uric acid, down to the last trace, will now be in the precipitate. Decant the supernatant solution as completely as possible, and add 1 ml. of a 10 per cent solution of sodium chloride in 0.1 N hydrochloric acid. Stir thoroughly with a fine glass rod; add 4 ml. of water, and stir again. Centrifuge. Pour the super-

⁵⁵ Reagents Required: Acid Silver Solution. To 5 ml. of 85 per cent lactic acid add 100 ml. of water and 5 g. of Na₂CO₃ and boil. Dissolve 25 g. of silver nitrate in about 700 ml. of water, add the partly neutralized lactic acid solution, and dilute to 1 liter. After a few days' exposure to sunlight and filtering, this reagent keeps fairly well. When used only occasion-

ally, however, it should be filtered before using.

Standard Uric Acid Solution. The solution made as follows will keep for at least five years. Weigh out on a watch glass exactly 1 g. of uric acid and transfer it to a liter volumetric flask by means of a not too small, dry funnel. Tap the funnel, so as to transfer nearly the whole of the uric acid to the flask. Transfer 0.6 g. of lithium carbonate to a 250-ml. Florence flask, add 150 ml. of water; shake about five minutes until dissolved. Some insoluble material remains and it is usually best to filter. Heat the solution or filtrate to 60°. Also, warm the liter flask under running warm water. Pour the warm lithium carbonate solution into the liter flask, incidentally washing into it the traces of uric acid which adhered to the watch glass and funnel. Shake so as to dissolve the uric acid promptly. A little additional warming under hot tap the is permissible. The lithium carbonate solution is not always perfectly clear, even when filtered, and one should not mistake this little turbidity for undissolved uric acid and keep warming and shaking too long. In five minutes all of the uric acid should be dissolved. Shake the flask under cold running water without undue delay. Add 20 ml. of 40 per cent formalin, and half fill the flask with distilled water. Finally add, from a pipet, rather slowly and with shaking, 25 ml, of normal sulfuric acid. Dilute to volume, mix thoroughly, and transfer to a clean, tightly toppered bottle. This stock solution, containing 1 mg. of uric acid per ml., should be kept away from light.

To prepare the working standard, dilute 1 ml. of the stock solution, with water only, to 250 ml. It behaves exactly like a lithium carbonate solution of uric acid and keeps perfectly

for many days. (5 ml. = 0.02 mg. of uric acid.)

Urea-Cyanide Solution (Poisonous!). Transfer 75 g. of Merck's Blue Label sodium cyanide to a 2-liter beaker, add 700 ml. of water, and stir until the cyanide is completely dissolved. Add 300 g. of urea and stir. Then add 4 to 5 g. of calcium oxide and stir for about 10 minutes. Filter, at once if necessary for immediate use, but preferably not until the next day. To the filtrate add about 2 g. of powdered lithium oxalate, shake occasionally for 10 to 15 minutes, and filter.

Uric Acid Reagent. Transfer 100 g. of sodium tungstate (free from molybdate, cf. footnote 56 (below) to a 500 ml. Florence flask. Mix 32 to 33 ml. of 85 per cent phosphoric acid with 150 ml. of water. Pour the resulting solution on to the tungstate and mix. Add a few pebbles and boil very gently over a microburner for 1 hour. Loss of liquid during the boiling is prevented by using, as a condenser, a funnel holding a 200 ml. flask filled with cold water. At the end of the boiling period decolorize with a little bromine water, boil off the excess bromine, cool, and dilute to 500 ml.

If the resgent so obtained is not perfect (in other words, if it gives a blank with Merck's urea-cyanide or with urea-cyanide plus tyrosine), add 3 to 5 g. of sodium tungstate (but no more) and boil for another 10 to 15 minutes, then cool, and decolorize as before. The addition of a little extra tungstate and the short second boiling can also be made without

first testing the reagent for a blank.

The tungstic acid deproteinization preceding estimation of uric acid by this method must be made with sodium tungstate entirely free from molybdate. A product meeting this specification is made by the Mallinckrodt Chemical Co. The absence of molybdate should be confirmed on each new batch of sodium tungstate by applying the following xanthate test (Folin and Trimble: J. Biol. Chem., 60, 473 (1924)): Dissolve 1 g. of sodium tungstate in 5 to 10 ml. of water. The solution should be alkaline. Add about 0.2 g. of solid potassium ethyl xanthate (Eastman, or prepare as directed in original paper). Shake until dissolved. Add dropwise with shaking, 20 per cent H_8SO_4 , until the curdy tungstic acid precipitate dissolves. In the presence of molybdenum, as the solution becomes definitely acid, a pink to deep plum color forms. The colored compound, molybdenum xanthate, is soluble in shloroform.

natant solution as completely as possible into a test tube graduated at the 25-ml. mark. Remove the last drop by touching the lip of the centrifuge tube to the side of the graduated test tube. Prepare two standards by placing 3 ml. (plus 2 ml. of water) and 5 ml. respectively of standard uric acid solution, containing 0.02 mg. of uric acid in 5 ml., in separate test tubes, and for photometric measurement prepare a blank tube containing 5 ml. of water only. To each tube add 10 ml. of urea-cyanide solution (Poisonous! from a buret) and mix well by lateral shaking. Add 4 ml. of the uric acid reagent to each tube, mix well by lateral shaking, and note the time. Let stand for 20 minutes, dilute to the 25-ml. mark with water, stopper, and mix by inversion. Read in the usual way within the next half-hour in the colorimeter or photometer. For photometric measurement, determine the densities at 420 my, setting the photometer to zero density with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. of uric acid in standard} \times \frac{100}{0.5}$$

$$= \text{mg. of uric acid per 100 ml. of blood or plasma}$$

Read the unknown against the standard which most closely matches it on inspection, and substitute the proper value for the uric acid content of the standard (0.012 or 0.020, as the case may be) in the calculation formula above. The stronger standard corresponds to a blood with 4 mg. per cent uric acid; up to 8 mg. per cent may be read satisfactorily. For higher values, instead of using the entire supernatant from the acid extraction of the precipitated silver urate as described, pipet out 2.5 ml. at this point, add 2.5 ml. of water, and continue with the addition of ureacyanide, color development, etc., as described, multiplying the final results by 2.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. of uric acid in standard} \times \frac{100}{0.5}$$
= mg. of uric acid per 100 ml. of blood or plasma

Either standard may be used, therefore only one is necessary. At 420 m μ , and in a 1-cm. cuvette, the density of the stronger standard, corresponding to 4 mg. per cent blood uric acid, is approximately 0.500. Up to 8 mg. per cent may be accurately read under these conditions. For higher values, or with deeper cuvettes, use half of the supernatant fluid from the acid extraction as described above under colorimetric measurement, and multiply the results by 2.

Interpretation.⁵⁷ Normal human whole blood usually contains from 2 to 3.5 mg. of uric acid per 100 ml. by this method. The normal range for plasma is 3 to 5 mg. per cent. In early nephritis values of from 3 to 10 mg. may be noted, and in advanced cases values as high as 25 mg. are observed. The determination of blood uric acid is generally regarded as an unsatisfactory index of renal impairment since its level may be affected

¹⁷ See reviews by Folin, Berglund, and Derick: J. Biol. Chem., 60, 361 (1924), and Rome: Physiol. Rev., 3, 544 (1923). See also Myers and Muntwyler: Ann. Rev. Biochem., 9, 303 (1940).

by a chemical destructive process as well as by excretion, which might account for the observed inconsistencies between hyperuricemia and other

nonprotein nitrogen retention.

In gout high uric acid values (4 to 10 mg.) are usually found. Determination of uric acid is of diagnostic value in gout prior to the stage of tophi formation, particularly since normal values, in the absence of salicylate or dietary therapy, would ordinarily exclude a positive diagnosis. However, uric acid is similarly increased in early nephritis and many cases of gout with high uric acid values also show defective kidney function by other tests. The same difficulty is met with in considering the high values (2 to 8 mg.) obtained in other arthritic conditions, usually associated with increases in urea also. The existence of nephritis in such cases has not been entirely excluded and many typical cases of arthritis show values below 3 mg. Salicylates and atophan (cincophen) tend to reduce the uric acid content of the blood.

The excessive breakdown of nuclear material in leukemia is accompanied by elevated uric acid values. In addition to the numerous conditions resulting in renal damage, such as mercury or lead poisoning, eclampsia, acute infections, malignancy, etc., the blood uric acid is also increased in certain cardiac conditions which ultimately involve the

kidneys.

3. Method of Newton: Principle. Interfering material in the blood filtrate is removed by the acid silver chloride precipitation method of Benedict and Behre, 59 The uric acid remaining is determined colorimetrically by reaction at room temperature in the presence of cyanide with a special arsenotungstate reagent.

Procedure: ⁶⁰ The blood proteins are precipitated with the molybdotungstic acid reagent of Benedict and Newton rather than by the Folin-Wu tungstic acid method, although this latter filtrate may also be used. Transfer 1 vol-

Newton: J. Biol. Chem., 120, 315 (1937).
 Benedict and Behre: J. Biol. Chem., 92, 161 (1931). For the complete uric acid pro-

cedure of these authors, see the Eleventh Edition of this book.

60 Reagents Required: For Protein Precipitation: Tungstomolybdate Solution. Boil 10 g. of reagent-grade ammonia-free molybdic acid with 50 ml. of normal sodium hydroxide for 4 to 5 minutes. Filter, and wash the residue on the filter with 150 ml. of hot water. Cool the filtrate and washings and add to a solution of 80 g. of sodium tungstate dissolved in 600 ml. of water. Dilute to 1 liter and mix. 0.62 N Sulfuric Acid. Dilute 620 ml. of N sulfuric acid to 1 liter with water, and mix. Both these solutions are stable indefinitely.

Acid Lithium Chloride. Dissolve 7.5 g. of lithium chloride in water, add 35 ml, of concentrated hydrochloric acid, dilute to 1 liter with water, and mix. Stable indefinitely.

Silver Nitrate Solution. Dissolve 29 g. of reagent-grade silver nitrate in water, dilute to

1 liter, and mix. Keep in a brown bottle. "Acid Blank" Solution (for photometric measurement only). Dilute 7 ml. of concen-

trated hydrochloric acid to 1 liter with water and mix.

Cyanide-urea Reagent (Poisonous!). Dissolve 100 g. of urea in 500 ml. of water. Add 25 g. of reagent-grade sodium cyanide and stir to dissolve. This solution is usable for 1 month or so. Fresh solution must be prepared if color develops in a blank test run as described for photometric measurement in the text.

Lithium Arsenotungstate Reagent (Poisonous!). Dissolve 100 g. of reagent-grade sodium tungstate in 500 ml. of water, and add 140 g. of reagent-grade arsenic pentoxide. Boil under a reflux condenser for 1 hour. Remove the condenser and continue boiling until the volume is reduced to about 200 ml. Pour this solution onto 100 g. of solid lithium chloride in a beaker. Stir until all of the lithium chloride has gone into solution. Chill the contents of the beaker to at least 10° for 2 hours but no longer. Filter off the precipitated lithium arsenotungstate by suction and suck as dry as possible. Excess water may also be removed by

ume of blood to a small flask and add 7 volumes of water to lake. Add 1 volume of tungstomolybdate solution followed by 1 volume of 0.62 N sulfuric acid, with shaking. Allow to stand for a few minutes, then pour onto a dry filter and collect the filtrate in a small dry flask. For plasma or serum, use 8 volumes of water and 0.5 volume of the tungstomolybdate and acid.

Transfer 5 ml. of the 1:10 filtrate prepared as described to a 15-ml. centrifuge tube, add 1 ml. of acid lithium chloride, and mix. Add 1 ml. of silver nitrate solution and shake well. Centrifuge at once and pour the supernatant fluid⁶¹ into a test tube, allowing time for complete drainage. Touch the lip of the centrifuge tube to the test tube to obtain the last drop. In a second test tube place5 ml. of the standard uric acid solution, containing 0.02 mg. of uric acid, and add 2 ml. of water. For photometric measurement prepare a third tube containing 5 ml. of "acid blank" solution plus 2 ml. of water. To each tube add from a buret 3 ml. of the cyanide-urea reagent (poisonous), mix by lateral shaking, and follow with 1 ml. of the diluted lithium arsenotungstate reagent from a buret (poisonous). Stopper and mix by inversion. Allow to stand 10 minutes, and then read in a colorimeter or photometer. For photometric measurement, determine the densities at 520 my, setting the photometer to zero density with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{0.5}$$
= mg. of uric acid per 100 ml. of blood or plasma

With the standard at 15 mm., readings of the unknown between 10 mm. and 30 mm. are reliable. For higher values, use less filtrate plus water to 5 ml. in the acid silver chloride precipitation, and correct the calculations accordingly.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.02 \times \frac{100}{0.5} = \text{mg. of uric acid per 100 ml.}$$

At 520 m μ , and in a 1-cm. cuvette, the standard described has a density of 0.180 (Fig. 165). Under these conditions, measurements are reliable up to 10 mg. per cent uric acid. For higher values, or with a deeper cuvette, use less filtrate plus water to 5 ml. in the acid silver chloride precipitation,

pressing the precipitate between filter papers. About 130 g. of material should be obtained. Dissolve in water and dilute to 500 ml. This stock solution keeps indefinitely. Before use, a portion is diluted with 4 volumes of water. This diluted reagent is used in the procedure. The salt may also be prepared in quantity, preserved in the dry state, and dissolved in water as needed.

Standard Uric Acid Solution (Benedict). A stock solution is prepared as follows: Dissolve 9 g. of disodium hydrogen phosphate and 1 g. of sodium dihydrogen phosphate (pure crystaline salts) in about 200 to 300 ml. of hot water. If not perfectly clear, filter. Dilute the clear solution to 500 ml. with hot water and pour upon exactly 200 mg. of pure uric acid suspended in a few ml. of water in a liter volumetric flask. Mix until solution is complete. Cool, add exactly 1.4 ml. of glacial acetic acid, dilute to mark, and mix. Add 5 ml. of chloroform to prevent bacterial or mold growth. (5 ml. = 1 mg. of uric acid.) The working standard is prepared fresh weekly as follows: Transfer 10 ml. of stock solution to a 500 ml. volumetric flask, dilute to 400 ml., add 3.5 ml. of concentrated hydrochloric acid, dilute to mark, and mix. (5 ml. = 0.02 mg. of uric acid).

⁶¹ A slight opalescence may be noted, due to a trace of colloidal silver chloride, but this disappears after the addition of the cyanide solution, and does not affect the accuracy of the results.

and correct the calculations accordingly. The color in this procedure does not reach a constant value, changing gradually in intensity with time. This change takes place at about the same rate in the standard and in the unknowns. In serial analyses it is necessary, therefore, to re-read the standard at suitable intervals and to calculate results in terms of the

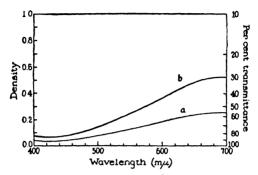

Fig. 165. Absorption spectra of colored solutions obtained in Newton blood uric acid method, for standards containing 0.01 mg. of uric acid (a), and 0.02 mg. of uric acid (b). Solution depth, 1 cm.

density of the standard at approximately the time the density of an unknown is determined.

'Interpretation. Results on human blood by this procedure are closely similar to those obtained by the previous method. Occurrence of turbidity is much less frequent than for other methods. For further interpretation see p. 513.

4. Method of Brown: 62 Principle. The tungstic acid filtrate is treated directly with a special uric acid reagent in the presence of optimal amounts of cyanide-urea solution. The color developed is compared with that of a uric acid standard treated similarly.

Procedure:61 Transfer 2 ml. of 1:10 tungstic acid filtrate to a test tube or cylinder graduated at 10 ml. In a similar tube place 2 ml. of standard uric

62 Brown: J. Biol. Chem., 158, 601 (1945).

Reagents Required: Sodium Cyanide Solution, 12 Per Cent. Dissolve 12 g. of pure sodium cyanide in water in a beaker, transfer to a 100-ml. cylinder, add water to the mark, and mix with a stirring rod. Handle this solution carefully, as it is extremely poisonous. Keep in the refrigerator. It should be usable for about 2 weeks. Bring to room temperature before transferring a portion to a buret for daily use.

Urea Solution. Dissolve 50 g. of urea in sufficient water to make 100 ml. This solution

keeps indefinitely at room temperature.

Uric Acid Reagent. Dissolve 100 g. of reagent-grade sodium tungstate and 20 g. of anhydrous disodium hydrogen phosphate in about 150 ml. of water in a flask with the aid of heat. Mix 25 ml. of concentrated sulfuric acid with about 75 ml. of water and pour the warm solution, slowly and with shaking, into the flask. Place a funnel in the mouth of the flask and in the funnel place a 200-ml. flask filled with ice water. Heat the mixture in the flask to boiling and boil gently for 1 hour, the funnel arrangement serving as a condenser. Cool and transfer to a 1-liter volumetric flask with rinsings, dilute to the mark with water, and mix.

Uric Acid Standard. Dilute 1 ml. of the Folin stock uric acid standard, containing 1 mg. of uric acid (see footnote 55) to 400 ml. with water and mix. This solution contains 0.005 mg. of uric acid in 2 ml., and keeps well for several days, particularly if kept cold.

acid solution containing 0.005 mg. of uric acid, and for photometric measurement prepare a third or "blank" tube containing 2 ml. of water. To each tube add 2 ml. of cyanide solution from a buret; this reagent is highly poisonous and must never be dispensed from a pipet. Mix by lateral shaking, and add 2 ml. of urea solution to each tube. Again mix. Finally add 1 ml. of the uric acid reagent, mix by lateral shaking, and allow to stand at room temperature for 50 minutes. Dilute to the 10-ml. mark with water, stopper, and mix by inversion. Read in the colorimeter or photometer in the usual way. For photometric measurement, read at 520 my, setting the photometer to zero density with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.005 \times \frac{10}{2} \times 100$$

= mg. of uric acid per 100 ml. of blood

The standard described corresponds to a blood uric acid content of 2.5 mg. per cent. For values over 5 mg. per cent, repeat the analysis using 1 ml. of filtrate plus 1 ml. of water, and multiply the results by 2.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.005 \times \frac{10}{2} \times 100$$

= mg. of uric acid per 100 ml. of blood

At 520 m μ and in a 1-cm. cuvette, the density of the standard (corrected for the blank) is approximately 0.200. Satisfactory agreement with Beer's law is found up to blood concentrations of 6 mg. per cent. For higher values, or with deeper cuvettes, use 1 ml. of filtrate plus 1 ml. of water for the analysis, and multiply the results by 2.

Interpretation. By this method human whole blood shows a normal range of 2.2 to 3.5 mg. per cent for males and 1.9 to 2.9 mg. per cent for females. Results are lowered by only about 10 per cent or less when the uricase procedure (see p. 511) is applied to establish specificity. For further interpretation, see p. 513.

DETERMINATION OF AMINO ACIDS

1. Principle. The color developed by the reaction between amino acids and β -naphthoquinone-4-sulfonic acid in alkaline solution is the basis of this method. Originally proposed by Folin, the method was considerably improved by Danielson, ⁶⁴ and this procedure is essentially the one described here, with heating to develop the color as suggested by Sahyun, ⁶⁵ and with photometric measurement according to Frame, Russell, and Wilhelmi. ⁶⁶

Procedure: 67 Prepare a tungstic acid filtrate of whole blood or plasma at a 1:10 dilution in the usual way (see p. 493). Transfer 5 ml. of protein-free

⁴⁴ Danielson: J. Biol. Chem., 101, 505 (1933).

⁶⁸ Sahyun: J. Lab. Clin. Med., 24, 548 (1938-1939).

Frame, Russell, and Wilhelmi: J. Biol. Chem., 149, 255 (1943). See also Russell: J. Biol. Chem., 156, 467 (1944), for a slightly modified procedure, claimed to give better results.
 Reagents Required: Amino Acid Standard Solution. A mixed standard containing gly-

filtrate to a test tube graduated at 15 ml. In a similar tube place 5 ml. of amino acid standard solution, containing 0.03 mg. of amino acid nitrogen, and for photometric measurement prepare a blank tube containing 5 ml. of water. 63 Add 1 drop of 0.25 per cent alcoholic phenolphthalein solution to each tube, followed by 0.1 N sodium hydroxide solution drop by drop until a permanent pink color is obtained. Adjust by adding a little water where necessary so that all tubes are at approximately the same volume. To each tube add 1 ml. of borax solution, mix by tapping, and then add 1 ml. of freshly prepared naphthoquinone solution. Mix by tapping, and place the tubes immediately in a boiling water bath. Allow to remain 10 minutes, then remove and place in cold water for 5 minutes. To the cooled contents of each tube add 1 ml. of acid-formaldehyde solution, mix immediately, add 1 ml. of 0.1 N sodium thiosulfate solution, dilute immediately to the 15-ml. mark with water, and mix by inversion. Allow to stand for 10 to 30 minutes before reading in the colorimeter or photometer. For colorimetric measurement, match the unknown against the standard in the usual way. For photometric measurement, transfer the solutions to suitable containers and read in the photometer at 490 mu, using the blank solution for setting the photometer to zero density.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{100}{0.5}$$

= mg. of amino acid nitrogen per 100 ml. of blood or plasma

If the unknown has an amino acid nitrogen content outside the range of 4 to 8 mg. per cent, repeat the determination using smaller portions of filtrate or standard as required, made up to 5 ml. with water, and correct the calculations accordingly.

cine and glutamic acid is recommended for colorimetric measurement because of better match with blood filtrates. Glycine Standard. Dissolve exactly 0.268 g. of pure dry glycine in water and transfer with rinsings to a 500-ml. volumetric flask. Add 35 ml. of N hydrochloric acid and 1 g. of sodium benzoate. Add water to dissolve and dilute to 500 ml. with water. Mix. Glutamic Acid Standard. Dissolve exactly 0.525 g. of pure dry glutamic acid in water, transfer to a 500-ml. volumetric flask, add 35 ml. of N hydrochloric acid and 1 g. of sodium benzoate as above, dilute to 500 ml. with water, and mix. Each of these stock standards contains 0.1 mg. of amino acid nûrogen per ml. They are stable indefinitely. To prepare the mixed standard, transfer 3 ml. of both the glycine and glutamic acid standards to a 100-ml. volumetric flask, dilute to the mark with water, and mix This standard contains 0.03 mg. of amino acid nitrogen in 5 ml. and is usable for one week if kept in the cold.

0.25 Per Cent Alcoholic Phenolphthalein. Dissolve 0.25 g. of phenolphthalein in 95 per cent alcohol and dilute to 100 ml.

0.1 N Sodium Hydroxide. Dilute 10 ml. of N sodium hydroxide solution to 100 ml. with water and mix.

Borax Solution. Dissolve 15 g. of borax (sodium tetraborate, Na₂B₄O₇·10H₂O) in water and dilute to 1 liter. Stable indefinitely.

Naphthoquinone Solution. Dissolve 0.25 g. of β -naphthoquinone-4-sulfonic acid in water and dilute to 50 ml. Prepare immediately before using, and discard remaining solution.

Acid-Formaldehyde Solution. Dilute 11.3 ml. of 40 per cent formaldehyde to 1 liter with water. Mix 4 volumes of this solution with 3 volumes of 1.5 N hydrochloric acid and 1 volume of glacial acetic acid. Stable indefinitely.

0.1 N Sodium Thiosulfate Solution. This need not be standardized. Dissolve 25 g. of crystalline sodium thiosulfate in water, dilute to 1 liter with water, and mix. Usable indefinitely.

⁶⁵ A water blank is valid only if the reagents used in preparing the blood filtrate (tung-state, acid) are substantially ammonia-free.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{100}{0.5}$$

= mg. of amino acid nitrogen per 100 ml. of blood or plasma

For the spectrophotometric characteristics of the color obtained in this method, see Frame, Russell, and Wilhelmi (loc. cit.). At 490 m μ and in a 1-cm. cuvette, the density of the standard is approximately 0.400; at 520 m μ , which may be used with slightly less accuracy, the density is about 25 per cent less. Up to about 15 mg. per cent amino acid nitrogen may therefore be determined accurately under these conditions; for higher levels, repeat the analysis with a smaller portion of filtrate.

Interpretation. The amino acid nitrogen content of whole blood as determined by this method ranges from 5 to 8 mg, per cent. A slight increase is noted after the ingestion of protein foods but no significant change is found in fasting. High values have been observed in uremic nephritis although a remarkable constancy is observed in most pathological conditions. Increases have, however, been noted in leukemia and particularly in acute vellow atrophy of the liver. Insulin markedly reduces the amino acid content of blood. Plasma averages around 4 to 5 mg. per cent, with serum slightly higher: according to MacFadyen, 69 this increase is due to release of amino acids during clotting. The concentration of amino nitrogen in corpuscles is about twice that of whole blood. Of naturally occurring interfering substances, glutathione is of chief significance; since this substance is present largely in the corpuscles, interference from this source is minimized if plasma (or an "unlaked" blood filtrate⁶⁴) is taken for analysis. Uric acid at a concentration of 1 mg, per cent gives color equivalent to 0.1 mg, per cent amino acid nitrogen; 66 correction may be necessary on bloods with high uric acid content. The sulfonamides also interfere if present, a free sulfonamide level of 10 mg, per cent being equivalent to 0.8 mg. per cent amino acid nitrogen;66 correction may also be applied here. Despite these limitations, the method is considered to be reliable and satisfactory for blood analysis.

2. Other Methods. Other colorimetric methods are not as satisfactory as the one described here. Gasometric methods include the classical nitrous acid method of Van Slyke, 70 which is based upon the measurement of nitrogen liberated from α -amino acids on treatment with nitrous acid; and the gasometic ninhydrin method of Van Slyke and Dillon, 71 in which the carbon dioxide liberated from the carboxyl group of α -amino acids on boiling with ninhydrin is measured. For description of the ninhydrin method as applied to the determination of the amino acid content of urine, see Chapter 32. Microbiological methods for the determination of individual amino acids are described in Chapter 33.

DETERMINATION OF GLUCOSE

- 1. Introduction. The majority of methods for the determination of blood glucose are based upon the ability of glucose in hot alkaline solution to reduce certain metallic ions, of which the cupric and ferricyanide ions are most commonly used. The extent of reduction is then established by colorimetric, titrimetric, or gasometric methods. Methods involving or including yeast fermentation,72 while undoubtedly the most specific for glucose, are not used routinely. It has long been known that there are reducing substances other than glucose present in blood, and that these may occur in sufficient amount to increase considerably the "apparent" glucose value. The term "saccharoid" has been proposed to designate the non-glucose reducing fraction of blood.73 The various blood sugar methods differ in their specificity for glucose, and therefore tend to give slightly or even significantly different values for both normal and pathological blood. In using a method, or in interpreting results obtained by it, particularly in the early literature, it is important to know the relationship between the values obtained by the particular method and the "true glucose" values, as well as the values obtained by other and possibly more specific methods. It is also important to know whether the method employs venous or arterial (capillary) blood, since this may influence the interpretation of results (see p. 527). Because of the free diffusibility of glucose between red cells and plasma, distinction between the analysis of whole blood and plasma is relatively unimportant except for methods which include the reduction due to saccharoids, which are found chiefly in the red cells.
- 2. Method of Folin and Wu:74 Principle. The protein-free blood filtrate is heated with alkaline copper solution, using a special tube to prevent re-oxidation. The cuprous oxide formed is treated with a phosphomolybdic acid solution, a blue color being obtained which is compared with that of a standard.

Procedure:75 Transfer 2 ml. of the tungstic acid blood filtrate (or 1 ml. plus 1 ml. of water if very high blood sugar values are expected) to a Folin-Wu

⁷² See Somogyi: J. Biol. Chem., 78, 117 (1928); Van Slyke and Hawkins: ibid., 83, 51 (1929); Holden: ibid., 119, 347 (1937); Winzler: Science, 99, 327 (1944).

⁷² Benedict: J. Biol. Chem., 92, 141 (1931). According to Fashena (J. Biol. Chem., 166, 357 (1933); Fashena and Stiff: ibid., 137, 21 (1941)) the saccharoid fraction of normal human blood is accounted for almost entirely by glutathione and glucuronic acid.

⁷⁴ Folin and Wu: J. Biol. Chem., 41, 367 (1920). Folin (J. Biol. Chem., 67, 357 (1926); 82, 83 (1929)) has critically examined and improved this method to obtain a more accurate measure of true sugar and better proportionality between sugar concentration and color intensity. The original Folin-Wu method is here described because it continues to have wide usage, especially in hospital laboratories.

⁷⁵ Reagents Required: Standard Sugar Solutions. Three standard sugar solutions should be on hand: (a) a stock solution, 1 per cent glucose made up in saturated benzoic acid solution; (b) a solution containing 2 mg. of sugar in 1 ml. (20 ml. of stock solution diluted to 100 ml. with water); (c) solutions containing 0.2 and 0.4 mg. of sugar in 2 ml., made by dilution of (b) with water. The dilute standards are best made up fresh a couple of times a week. Merck's highest purity dextrose is satisfactory.

Alkaline Copper Solution. Dissolve 40 g. of pure anhydrous sodium carbonate in about 400 ml. of water and transfer to a liter flask. Add 7.5 g. of tartaric acid, and when the latter has dissolved add 4.5 g. of crystallized copper sulfate. Mix and make up to a volume of 1 liter. If the chemicals used are not pure a sediment of cuprous oxide may form in the course

sugar tube graduated at 25 ml. (Fig. 166) and to other similar tubes add 2 ml. of standard sugar solutions containing 0.2 and 0.4 mg. respectively of glucose. To each tube add 2 ml. of the alkaline copper solution. The

surface of the mixtures must now have reached the constricted part of the tube. Transfer the tubes to a rapidly boiling water bath and heat for 8 minutes. Cool in running water without shaking. To each tube add 2 ml. of phosphomolybdic acid reagent. After about one minute dilute to the mark with water and mix. It is essential that adequate attention be given to this mixing because the greater part of the blue color is formed in the bulb of the tube. Compare in a colorimeter using the standard which most nearly matches the unknown. For photometric measurement, transfer the solutions to suitable containers and determine the densities at 420 mu. setting the photometer to zero density with a blank obtained by treating 2 ml. of water with alkaline copper reagent, heating, etc., just as in the analysis of the blood filtrate.

Calculation. For colorimetric measurement, use the standard which most closely matches the unknown, and calculate as follows:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. of glucose in standard}$

$$\times \frac{100}{0.2}$$
 = mg. of glucose per 100 ml. of blood

Unless the readings of the standard and unknown are within a few millimeters of each other, results obtained by this calculation are somewhat incorrect because the color is not strictly proportional to the concentration of glucose. Correction of observed blood sugar values⁷⁶ may be of importance when the values are near the critical levels corresponding to hypoglycemia and to the threshold range. Instead

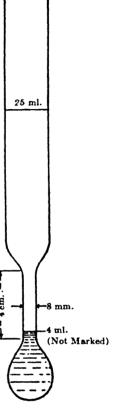

Fig. 166. Folin-Wu sugar tube.

of applying corrections it may be advisable to employ, in place of the usual standards, standards containing 0.1 and 0.3 mg. of glucose in 2 ml. (corresponding to blood sugar values of 50 and 150 mg. per 100 ml., respec-

of one or two weeks. If this should happen, remove the clear supernatant reagent with a siphon, or filter through a good quality filter paper. The reagent seems to keep indefinitely. To test for the absence of cuprous copper in the solution, transfer 2 ml. to a test tube and add 2 ml. of the molybdate phosphate solution; the deep blue color of the copper should almost completely vanish. In order to forestall improper use of this reagent attention should be called to the fact that it contains extremely little alkali, 2 ml. by titration (using the fading of the blue copper tartrate color as indicator) requiring only about 1.4 ml. of normal acid.

Phosphomolybdic Acid Solution. To 35 g. of molybdic acid and 5 g. of sodium tungstate, add 200 ml. of 10 per cent sodium hydroxide and 200 ml. of water. Boil vigorously for 20 to 40 minutes so as to remove nearly the whole of the ammonia present in the molybdic acid. Cool, dilute to about 350 ml., and add 125 ml. of concentrated (85 per cent) phosphoric acid. Dilute to 500 ml.

¹⁰ Oser and Karr (J. Biol. Chem., 67, 319 (1926)) have published tables and curves correcting for the deviation from Beer's law.

tively) or to dilute to an approximate color match (using the graduated sugar tubes of Rothberg and Evans)⁷⁷ prior to matching in the colorimeter.

For photometric measurement, only one standard and a blank are required, and the calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. of glucose in standard} \times \frac{100}{0.2}$$

= mg. of glucose per 100 ml. of blood

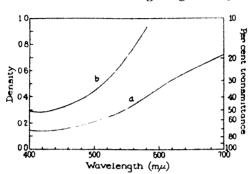

Fig. 167. Absorption spectra of colored solutions obtained in Folin-Wu blood sugar method, for standards containing (a) 0.2 mg. and (b) 0.4 mg. of glucose. Solution depth, 1 cm.

At 420 m μ and in a 1-cm. cuvette, the density of the standard containing 0.4 mg. of glucose, corresponding to 200 mg. per cent of blood glucose, is approximately 0.300 (Fig. 167). Satisfactory agreement with Beer's law is found under these conditions up to about 400 mg. per cent blood glucose. For higher values, or with deeper cuvettes, carry out the analysis using less filtrate plus water to 2 ml., and correct the calculations accordingly.

Interpretation. The normal range of fasting venous blood sugar values by this method is 90 to 120 mg. per 100 ml. of whole blood. This range is undoubtedly "enhanced" to the extent of possibly 20 to 30 mg. per cent by the effect of non-glucose reducing substances (saccharoids), but the saccharoid fraction appears to be relatively constant and therefore its presence does not influence unduly the interpretation of variations in blood sugar level as obtained by this procedure. Most of the early data in the American literature on blood sugar content were obtained by this method, but it is gradually being superseded by the more specific methods described subsequently.

In mild diabetes values of 140 to 300 mg. per cent are obtained and in severe diabetes values up to 1200 mg. per cent have been noted. Hyperglycemia is also observed in severe nephritis, pancreatic disease, hyperthyroidism, and in certain hepatic disorders. Experimentally, the administration of adrenaline and the induction of ether anesthesia lead

¹⁷ Rothberg and Evans: J. Biol. Chem., 58, 443 (1923).

to elevated blood sugar values. Low blood sugar values are found after the administration of insulin, in such hypoendocrine disturbances as Addison's disease, hypopituitarism, cretinism, and myxedema, and in the clinical condition known as hyperinsulinism. For carbohydrate tolerance test, see p. 529.

3. Method of Benedict:78 Principle. The protein-free filtrate is heated with an alkaline copper reagent containing tartrate, alanine, and bisulfite. The reduced copper is determined colorimetrically after treatment with phosphomolybdic acid. The alkaline copper reagent used here is practically unaffected by the non-sugar reducing materials present in blood, hence the method gives values distinctly lower than with the Folin-Wu method, and presumably nearer the true glucose content. The reagent is also adapted to the determination of the non-sugar reducing value of blood (see original paper).

Procedure: 79 Place 2 ml. of 1:10 protein-free filtrate 80 in a Folin-Wu sugar tube, and in a second similar tube place 2 ml. of standard glucose solution. To each tube add 2 ml. of the copper reagent containing bisulfite. Mix by lateral shaking, and place in a vigorously boiling water bath for six minutes. Cool by placing in cold water for one to two minutes (avoid shaking at this stage). To each tube add 2 ml. of color reagent, mix by vigorous lateral shaking, and after about one minute dilute with water to the 25-ml. mark. Mix the contents thoroughly by repeated inversion, allow to stand at least 10 minutes, and read in the colorimeter or photometer within the next 30 minutes or so. For colorimetric measurement, compare against the standard in the usual way. For photometric measurement, transfer portions of the solutions to suitable containers and determine the densities in the photometer under the same conditions as described for the Folin-Wu method, p. 522.

Calculation. Same as for Folin-Wu method.

This procedure gives better proportionality between color and concentration than the Folin-Wu method. A standard glucose solution containing 0.2 mg. of glucose, equivalent to 100 mg. per cent blood sugar, is therefore suitable in colorimetric comparison for values up to 200 mg. per cent

⁷⁸ Benedict: J. Biol. Chem., 92, 141 (1931).

Reagents Required: Copper Reagent. Dissolve 15 g. of anhydrous sodium carbonate, 3 g. of alanine, and 2 g. of Rochelle salt in about 250 ml. of distilled water. Dissolve 3 g. of crystalline copper sulfate in about 100 ml. of distilled water and add this solution with stirring to the carbonate-alanine-tartrate solution. Dilute to 500 ml. and mix. Keep in a cool place. This reagent will keep ready mixed from 4 to 6 weeks. If, after several weeks, there may be a slight growth of mold in the solution, it may be removed at any time by pouring the solution through a loose plug of absorbent cotton in a funnel, leaving the efficiency of the reagent unaffected.

¹ Per Cent Sodium Bisulfite Solution. Kept in a 100-ml. dropping bottle. The solution should be prepared fresh about once a month.

Copper Reagent Containing Bisulfite. Measure into a cylinder a volume of the copper reagent which will be used up in one or two days, and add 1 drop of the bisulfite solution for each ml. of copper reagent, or 1 ml. of bisulfite for each 20 ml. of reagent. Mix. Do not use after the second day.

Color Reagent. To 150 g. of pure molybdic acid and 75 g. of anhydrous Na₂CO₂ in a large Erlenmeyer flask, add 500 ml. of water in small portions while shaking. Heat to boiling. Filter. Wash residue on filter with hot water until filtrate plus washings equal 600 ml. Add 300 ml. of 85 per cent H₂PO₄, cool, and dilute to 1 liter.

Standard Glucose Solution. See footnote 75, p. 520.

¹⁰ Benedict uses a tungstomolybdate filtrate (Benedict: J. Biol. Chem., 92, 135 (1931)). A Folin-Wu filtrate may also be used.

blood sugar. For higher levels, use a stronger standard or less filtrate plus water to 2 ml. In photometric measurement, agreement with Beer's law is excellent up to 500 mg. per cent blood sugar, at 420 m μ , and in a 1-cm. cuvette. For higher values, or with a deeper cuvette, carry out the analysis using less filtrate plus water to 2 ml., and correct the calculations accordingly.

Interpretation. Normal values on whole blood by this method range from 70 to 100 mg. per cent blood glucose. The interpretation of variation from the normal range is similar to that already presented in connection with the Folin-Wu method.

4. Somogyi-Shaffer-Hartmann Method:⁸¹ Principle. Hemolyzed blood is deproteinized with zinc hydroxide, giving a filtrate containing practically no reducing substances other than sugar. The sugar is estimated by iodometric titration of reduced copper. Precipitation of the protein with copper salts is just as satisfactory in the case of whole blood and is better for plasma or serum. ⁸²

Procedure: (a) Deproteinization: Lake 1 volume of blood with 7 volumes of water. Add 1 volume of 10 per cent solution of ZnSO₄·7H₂O. Mix. Add with continuous shaking 1 volume of 0.5 N NaOH. Stopper the flask, shake well, and filter after a few minutes through dry filter paper. For accurate work measure the blood with an Ostwald pipet calibrated "to contain" and rinse with the laking water. For serum or plasma dilute with 8 volumes of water and add 0.5 volume of each of the reagents. Another procedure for whole blood is to add 8 volumes of an acid zinc solution (12.5 g. of ZnSO4.7H2O and 125 ml. of 0.25 N H₂SO₄ with water to make 1 liter) and 1 volume of 0.75 N NaOH. Shake vigorously and filter after a few minutes, 50 ml, of the acid zinc solution should require 6.7 to 6.8 ml. of 0.75 N NaOH to give a permanent pink with phenolphthalein. Determine sugar as below, For micro-technic introduce into a test tube or 25-ml. Erlenmeyer flask 5.8 ml. of water, add 0.2 ml. of blood from an accurate capillary pipet, rinsing several times with the laking water. Mix. Add 1 ml. of 1.8 per cent ZnSO4-7H₂O. Mix. Add with continuous shaking 1 ml. of 0.1 N NaOH. 22 Stopper, shake well, and filter after a few minutes through a dry thin paper (Schleicher and Schüll No. 597, 70 mm.). Use 5 ml. of filtrate equivalent to 0.125 ml. of blood. Determine sugar by procedure described.

(b) Determination of Sugar: Measure 5 ml. of the copper reagent¹⁴ into a

**Somogyi: J. Biol. Chem., 86, 655 (1); 70, 599 (1926). Urea, creatinine, and creatine may also be determined in the zinc filtrate but only traces of uric acid are found. Lower but significant values for nonprotein nitrogen may be obtained (J. Biol. Chem., 87, 339 (1930)). For an improved procedure, suitable for colorimetric as well as titrimetric determination, see Somogyi: J. Biol. Chem., 160, 61, 69 (1945).

⁹² Somogyi: J. Biol. Chem., 90, 725 (1931). Lake 1 volume of blood in 7 volumes of water. Add 1 volume of 7 per cent CuSO. 5H₂O and mix. Then add, with continuous shaking, 1 volume of 10 per cent Na₂WO. 2H₂O. Stopper the flask. Shake well. Filter through dry filter paper after a few minutes. For plasma or serum use the same procedure but use 5 per cent copper sulfate and 6 per cent sodium tungstate solutions.

*10 ml. of the sinc sulfate solution diluted with 60 ml. of water and slowly titrated with the NaOH should require 12 to 12.2 ml. for a permanent pink with phenolphthalein.

st Copper Reagent. Dissolve 12 g. of Rochelle salt, 20 g. of sodium carbonate (anhydrous), and 25 g. of sodium bicarbonate in about 500 ml. of water. Into this pour with stirring 6.5 g. of copper sulfate (crystalline) dissolved in about 100 ml. of water. Dissolve 10 g. of potassium iodide, 0.80 g. (weighed to cg.) of potassium iodate, and 18 g. of potassium oxalate in about 200 ml. of water. Add to the main solution and dilute to 1 liter.

Thiosulfate. For preparation of 0.1 N solution see Appendix. Dilute this every day or two

as needed to 0,005 N.

large test tube (25 \times 250 mm.) and add 5 ml. of the sugar solution. containing not less than 0.1 nor more than 2.0 mg. of glucose. Shake gently to mix, cover the tube with a small funnel, bottle cap, or glass bulb, and keep in a boiling water bath for 15 minutes. Cool (avoid shaking) by placing in a shallow dish of water until the temperature falls to 35° to 40° C. (not below 30°). Add 1 ml. of 5 N $\rm H_2SO_4$ (or equivalent amount) and see that all Cu₁O is promptly dissolved. Avoid reoxidation of reduced copper or loss of iodine by too vigorous agitation. After about two minutes titrate with 0.005 N sodium thiosulfate, using starch as an indicator toward the end of the titration. Run a blank on 5 ml. of reagent after heating with an equal volume of water.

Calculation. From the blank titration subtract the titration of the unknown. This gives ml. of thiosulfate required. For the glucose equivalent consult the following table, which applies to the usual 1:10 dilutions of blood. For other cases the actual amount of glucose in the 5 ml. of solution used for the determination is obtained by dividing the value in the table by 200.

Interpretation. Normal values by this method range from 70 to 100 mg. per cent and are presumably very close to the true glucose values.

^{**} Strongly acid sugar solutions must be neutralised to phenol red. For above filtrates or tungatic acid filtrates this is not necessary.

The specificity for glucose appears to reside in the method of deproteinization, since filtrates prepared as described may be analyzed for glucose by the Folin-Wu or Benedict colorimetric methods to give results substantially identical with those obtained by the Shaffer-Hartmann iodometric titration. For the principle of the Shaffer-Hartmann procedure, see Chapter 32.

5. Micro-method for Glucose in 0.1 Mi. of Blood: (Folin and Malmros.)⁸⁶ Principle. The sugar is oxidized with alkaline potassium ferricyanide, and the ferrocyanide produced is measured colorimetrically or photometrically after conversion to Prussian blue.

Procedure: With an accurate 0.1-ml. pipet⁸⁷ collect 0.1 ml. of blood and transfer it to 10 ml. of dilute tungstic acid⁸⁸ in a centrifuge tube. Stir well and centrifuge. Transfer 4 ml. of the water-clear supernatant fluid to a test tube graduated (with a ring going all around) at 25 ml. Transfer 4 ml. of the standard sugar solution to another similar tube. To each tube add 2 ml. of the 0.4 per cent potassium ferricyanide solution and 1 ml. of the cyanide-carbonate solution. Heat immediately in boiling water for 8 minutes⁸⁹ and cool in running water for 1 to 2 minutes. Add 5 ml. of the ferric iron solution and mix. Let stand for 1 to 2 minutes and then dilute with water nearly, but not quite, to the 25-ml. mark. Add two drops of alcohol to cut the foam and dilute to the mark. Mix. Allow to stand 10 minutes and read within the next 30 minutes.

For colorimetric comparison, half fill the colorimeter cups with the green-colored standard, set the two plungers at a height of 20 mm., and cover the opening of the light box with the picric acid light filter. O Adjust

. ³⁶ Folin and Malmros: J. Biol. Chem., 83, 115 (1929); Folin: J. Biol. Chem., 77, 421 (1928). See also Horvath and Knehr: J. Biol. Chem., 140, 869 (1941). For a method based upon titration of the terrocyanide formed using ceric sulfate, see Miller and Van Slyke: J. Biol. Chem., 114, 583 (1936); MacFadyen and Van Slyke: ibid., 149, 527 (1943). See also the Hawkins and Van Slyke method, Chapter 32.

⁶⁷ A capillary pipet about 7 cm. in length per 0.1 ml., calibrated "to contain," using mer-

cury (0.1 ml. weighs 1.355 g.). Sold by dealers in laboratory supplies.

⁸⁵ Dilute Tungstic Acid Solution. Transfer 20 ml. of 10 per cent sodium tungstate to a liter volumetric flask. Dilute to about 800 ml. Add with shaking 20 ml. of 35 N sulfuric acid and dilute to volume.

Potassium Perricyanide Solution. Dissolve 2 g. of c.p. potassium ferricyanide in distilled water and dilute to a volume of 500 ml. Keep the major part of the solution in a brown bot-

tle in a dark closet. Keep the reagent in daily use also in a brown bottle.

Sodium Cyanide-Carbonate Solution. Transfer 8 g. of anhydrous sodium carbonate to a 500 ml. volumetric flask. Add 40 to 50 ml. of water and shake to promote rapid solution. With a cylinder, add 150 ml. of freshly pared 1 per cent sodium cyanide solution, dilute to volume, and mix.

Ferric Iron Solution. Fill a liter cylinder with water. Suspend on a copper wire screen, just below the surface, 20 g. of soluble gum ghatti, and leave overnight (18 hours). Remove the screen, and strain the liquid through a double layer of a clean towel. Add to this extract a solution of 5 g. of anhydrous ferric sulfate in 75 ml. of 85 per cent phosphoric acid plus 100 ml. of water. Add to the mixture, a little at a time, about 15 ml. of 1 per cent potassium permanganate solution to destroy certain reducing materials present in gum ghatti. The slight turbidity of the solution will disappear completely, if kept at 37° for a few days. The use of "Duponal," a synthetic detergent, has been recommended in place of gum ghatti (Klendshoj and Hubbard: J. Lab. Clin. Med., 25, 1102 (1939-1940); Horvath and Knehr: loc. cit.). It does not appear to be superior to gum ghatti.

Standard Glucose Solution. The working standard contains 0.01 mg. of glucose per ml.

(see footnote 75, p. 520).

⁵⁹ Heating for 20 minutes instead of 8 minutes, to ensure complete oxidation of glucose, has been recommended by Jourdonais: J. Lab. Clin. Med., 23, 847 (1937–1938); and by Horvath and Knehr: loc. cit.

** Dissolve 5 g. of picric acid in 100 ml. of methyl alcohol and add 5 ml. of 10 per cent NaOH. Place a pack of 8 to 10 heavy absorbent filter papers (Schleicher and Schüll, No. 604

the position of the colorimeter and of the mirror glass reflector until the two fields look exactly alike. The adjustment is easier if the colorimeter is kept on a piece of plate glass polished on one side and rough on the other. Rinse one colorimeter cup and plunger with the unknown solution and pour the unknown into the cup to a suitable height. Compare in the usual way.

For photometric measurement, transfer the solutions to suitable containers and determine the densities in a photometer at 520 my. Set the photometer to zero density with water alone, rather than using a blank (see below).

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.04 \times \frac{10}{4.0} \times \frac{100}{0.1}$$

= mg. of glucose per 100 ml. of blood

The proportionality between color and concentration is excellent in this method, so that readings between 5 and 40 mm. may be accepted, with the standard at 20 mm., if perfect equality as to light and color is obtained. If the blood glucose concentration is over 400 mg. per cent, repeat with 2 ml. of filtrate plus 2 ml. of water, and multiply the results by 2.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times \frac{10}{4.0} \times \frac{100}{0.1}$$

= mg. of glucose per 100 ml. of blood

At the wavelength specified, and in a 1-cm. cuvette, the standard corresponding to 100 mg. per cent blood glucose has a density of about 0.250, permitting accurate measurement up to about 400 mg. per cent blood glucose. For higher values, or with deeper cuvettes, use 2 ml. of filtrate plus 2 ml. of water in the analysis, and multiply the results by 2. With well-prepared reagents, the blank should have a density of less than one-tenth that of the standard given; in the presence of a blood filtrate the blank density is even less, and better agreement with Beer's law is noted if the blank is neglected and the photometer set to zero density with water alone as described.⁹¹

Interpretation. Normal values by this method range from 75 to 105 mg. per cent blood glucose. It must be noted that, if fingertip blood is used, this type of blood is essentially arterial, and resembles venous blood only in the fasting state. Thus during absorption or in a glucose tolerance test, higher glucose values will be obtained on fingertip blood

is good) on a level and smooth mat of newspapers. Pour the acid picrate solution over the filters until the papers are saturated and an excess of solution filters through. Allow to dry. When perfectly dry, pour over the pack an excess of a 3 per cent solution of paraffin in bensine. Allow to dry. All papers should be evenly stained. Cover the light box window of the colorimeter lamp with stained paper. Test the efficiency by comparing water and 0.2 per cent potassium ferricyanide solution both set at 20 mm. Adjust the colorimeter so that the two fields look alike. If the filter is inadequate, equality of the fields cannot be batined. A strong light is necessary. A filter in the form of a glass disk to be put on top of the ocular may be obtained from the Klett Manufacturing Co., New York. See Tauber: J. Lab. Clin. Med., 15, 766 (1930).

⁹¹ Unpublished results of Summerson and Robinson.

than for venous blood, although the reverse may obtain in severe diabetes. For further interpretation, see p. 522.

6. Determination of Sugar. Method of Hagedorn and Jensen:⁹² Principle. The blood protein is precipitated with zinc hydroxide. The filtrate is heated with potassium ferricyanide solution and the amount of ferricyanide reduced is determined by adding an iodide solution and titrating the iodine set free with sodium thiosulfate. The principal reaction is $2H_3Fe(CN)_6 + 2HI = 2H_4Fe(CN)_6 + I_2$. The reversal of the reduction reaction is prevented by precipitation of the ferrocyanide formed as a zinc salt.

Procedure: Into a test tube (15 × 150 mm.) pipet 1 ml. of 0.1 N NaOH and 5 ml. 0.45 per cent zinc sulfate solution. A gelatinous precipitate of zinc hydroxide forms. 0.1 ml. of blood from a capillary pipet is introduced, the pipet being washed out twice with the mixture and blown empty. Put in a boiling water bath for 3 minutes. Filter on a funnel of 3 to 4 cm. diameter, prepared with a small filter of washed, moistened, not tightly pressed cotton, into a test tube (30 × 90 mm.). Wash the funnel and filter with two 3-ml. portions of water. Add 2 ml. of alkaline potassium ferricyanide solution and heat in a boiling water bath for 15 minutes. Cool and add 3 ml. of the iodide-sulfate solution and 2 ml. of 3 per cent acetic acid solution. Titrate with 0.005 N sodium thiosulfate, using as an indicator 2 drops of 1 per cent solution of soluble starch in saturated sodium chloride solution.

³² Hagedorn and Jensen: *Biochem. Z.*, 135, 46 (1923) and 137, 92 (1923). For critical studies of this method, with suggested improvements, see Folin and Malmros: *J. Biol. Chem.*, 83, 121 (1929); Kramer and Steiner: *Biochem. J.*, 25, 161 (1931).

**Reagents Required: For Protein Precipitation. 0.1 N NaOH.—Zinc sulfate 0.45 per cent. These solutions are best prepared every eight days by dilution of 2 N NaOH and a zinc sulfate solution containing 45 g. of the salt in 100 ml. of solution. For Sugar Determination. Potassium ferricyanide 1.65 g. and sodium carbonate (fused) 10.6 g. in 1000 ml. of water. Protect from light. Iodide-sulfate-chloride solutions: KI, 5 g., zinc sulfate, 10 g., NaCl, 50 g., water to make 200 ml. It is best to prepare the solution without iodide and add the latter to portions of the solution as required. Free iodine can be almost completely removed by filtering through thick paper. The blank will take care of smaller errors. Acetic acid solution: 3 ml. of acetic acid (iron-free) with water to make 100 ml. Starch solution: 1 g. of soluble starch dissolved in 100 ml. of saturated NaCl solution. Sodium thiosulfate solution: 0.7 g. sodium thiosulfate in 500 ml. of water. 0.005 N Potassium iodate: This solution is permanent and is used to check the thiosulfate and ferricyanide solutions which keep less well. It alone need therefore be prepared very accurately. 0.356 g. potassium iodate (water-free) is dissolved in water to make 2000 ml.

Chemicals of highest purity must be used. Sodium carbonate is best recrystallized and fused in platinum. Acetic acid should be tested for iron, as should also the zinc sulfate, sodium chloride, and potassium iodide. The iodide should also be tested for iodate. Ordinary quantities of the mixed solutions will then give no test for iodine with starch but will give a test if 0.01 ml. of ferricyanide is added. Potassium ferricyanide is prepared by washing crystals of the ordinary product with water, dissolving in water with heat and filtering the boiling solution through paper, previously carefully washed with boiling water, into an evaporating dish set in ice-cold water. The fine crystals are filtered off with suction on another washed paper and again recrystallized. Dry at 50°. Keep away from sunlight during course of preparation.

The length of the 0.1 ml. pipet from the tip to the mark should be about 10 to 12 cm. and over-all length about 20 cm. Calibrate as follows: With the pipet measure out 0.1 ml. of 0.1 N potassium iodate solution into 10 ml. of water. Add acid and KI solution in the usual way and titrate with 0.02 N thiosulfate. Some of the same iodate solution is then diluted to 0.02 N and exactly 2.0 ml. of this in 10 ml. of water titrated with the same thiosulfate as before. The two titrations should agree within experimental error (about 0.5 per cent) if the pipet is accurate.

Calculation. Determine the blank obtained by carrying through the whole determination but without the addition of blood. Multiply A (the thiosulfate buret reading) by the factor for the thiosulfate (2.00/ml. of thiosulfate required for 2 ml. of 0.005 N iodate). Express this value (B) for unknown and for blank as mg. glucose by consulting the table which follows. Subtract the glucose value of the blank from the glucose value of the unknown. The difference is mg. glucose in 0.1 ml. of blood. Or calculate as follows: 2.00 - B = x (ml. of 0.005 N ferricyanide reduced). 2.00 ml. of ferricyanide are reduced by 0.385 mg. of glucose. Therefore

mg. per cent of glucose = $0.385 \times \frac{x}{2.0} \times 1000$.

Interpretation Similar to previous method.

MILLILITERS OF 0.005 N Na₂S₂O₃ Used and Milligrams of Glucose Present

7. Manometric Methods for Reducing Sugars. 96 See original papers.

CARBOHYDRATE TOLERANCE TEST

Principle. Blood sugar is determined at hourly periods following the ingestion of 1 g. of glucose per kilogram of body weight. Urinary sugar for the 24-hour period following the ingestion of the glucose is also determined.

^{**} Acetone and β-hydroxybutyric acid do not reduce the reagent. One mg. of uric acid gives a reduction equal to that of 0.53 mg. of glucose, and 1 mg. of creatinine a reduction equal to 0.47 mg. of glucose.
** Van Slyke and Hawkins: J. Biol. Chem., 79, 739 (1928); 83, 51 (1929).

Procedure: The first thing in the morning, collect a specimen of urine and one of blood to serve as controls. Then give the patient 1 g. of glucose per kilogram of body weight. The glucose may be given in 50 per cent solution. Collect three or four specimens of blood at hourly intervals and analyze for sugar. Following the taking of glucose collect a 24-hour specimen of urine and determine its sugar content. Brill⁹⁷ and others have proposed the use of a test breakfast instead of the glucose meal.

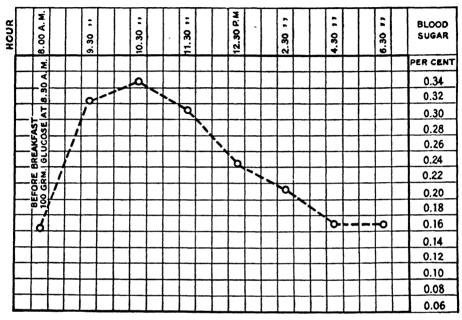

Fig. 168. Blood-sugar curve of diabetic after glucose ingestion. (Courtesy, Martin and Mason: Am. J. Med. Sci., 153, 50 (1917).)

Interpretation. In normal individuals, blood sugar rises from the normal value of about 100 mg. to about 150 mg. per 100 ml. at the end of the first hour, and returns to normal by the end of the second hourly period. In pathological conditions, the curve does not follow the normal course. Hyperthyroidism, diabetes mellitus, and nephritis show much greater values, depending on the severity of the disease, and the return to normal is delayed for three hours or more. The high sugar concentration in the blood during the test may or may not be accompanied by glycuresis, depending upon the "threshold point" of the kidney. In diabetes the threshold point is usually, and sometimes markedly, increased above its normal range of 160 to 180 mg. per 100 ml. In hypoendocrine conditions, in which the blood sugar is low ordinarily, the curve of blood sugar during a tolerance test is quite "flat." The curve of a diabetic is shown in Fig. 168. Wherever possible, it is better practice to obtain quarter-hour specimens of blood, during the first hour. This provides more information concerning the general nature of the curve and the height of the peak. John 98 believes that a diagnosis of diabetes is justified

⁹⁷ Brill: J. Lab. Clin Med., 8, 727 (1923).

⁹⁸ John: Am. J. Med. Sci., 169, 102 (1925); J. Metabolic Research, 1, 497 (1922).

if the curve remains high after three hours, irrespective of the height to which it has risen. Petty and Stoner⁹⁹ on the other hand regard the criterion as a rise above 180 mg. They base their claim on simultaneous determinations of respiratory quotients, which show very slight rise in diabetics, but follow the sugar curves in normal individuals and in renal glycosurics. In nondiabetics the peak of the curve is usually between one-half and one hour, while in diabetics it is nearer two hours.

It has been shown by Foster¹⁰⁰ that carbohydrate tolerance tests conducted on finger blood, which is practically arterial, give higher and sharper curves than venous blood collected simultaneously. It appears that some of the glucose of arterial blood is removed and oxidized or stored as glycogen by the tissues. The various mechanisms for glucose utilization appear to be stimulated to overactivity since the blood sugar curve frequently falls below its initial level. For further discussion of the application of sugar tolerance tests consult papers by Hamman and Hirschman, Hubbard and Wright, Bailey, Williams and Humphreys, Allen, Stillman and Fitz, Rabinowitch, Macleod, Foster, and du Vigneaud and Karr. (See references in footnote 100.)

DETERMINATION OF CHOLESTEROL

- 1. Introduction. The cholesterol of blood is present in the form of both free cholesterol and cholesterol esters. In the plasma both free and esterified cholesterol is found; in the red cells only the free form appears to be present. Plasma is preferred to whole blood for analysis, since pathological variations in the amount and in the distribution between free and ester forms occur largely in the plasma fraction. Free cholesterol is best determined by precipitation and isolation as the insoluble digitonide; the precipitate may be weighed, or treated with a cholesterol color reaction, or otherwise determined. Total cholesterol is most accurately determined in a colorimetric procedure after preliminary saponification to liberate ester cholesterol from combination, since free cholesterol and ester cholesterol may give different color intensities per unit amount of cholesterol present. Many methods which do not involve saponification have, however, been proposed, as discussed below.
- 2. Method of Schoenheimer and Sperry:¹⁰¹ Principle. An acetone-alcohol mixture is used to precipitate the proteins and extract the cholesterol and cholesterol esters from the sample of whole blood or (preferably) plasma or serum. The cholesterol is precipitated with

¹⁰¹ Schoenheimer and Sperry: J. Biol. Chem., 106, 745 (1934); Sperry, Am. J. Clin. Path., 8, Tech. Suppl. 2, 91 (1938); Sperry (personal communication). See also Fits: J. Biol. Chem., 109, 526 (1935); Sobel and Mayer: J. Biol. Chem., 157, 255 (1945). The original Schoenheimer-Sperry method is a micro-procedure, requiring but 0.2 ml. of sample. The procedure described here is a slightly modified version which uses a larger sample, requires less technical skill, and has been found satisfactory for routine use in several laboratories.

digitonin, either before saponification (free cholesterol) or after saponification (total cholesterol), and the separated digitonide is purified and subjected to the Liebermann-Burchard color reaction. The color is then compared with that produced by a standard cholesterol solution.

Procedure: 103 Place approximately 10 ml. of the acetone-alcohol mixture in a 25-ml. glass-stoppered volumetric flask and add 1 ml. of serum or plasma down the side of the flask below the graduation. After withdrawing the pipet, swirl the flask to produce a finely divided precipitate, then immerse the flask in boiling water, with swirling to prevent bumping, until the solvent boils. Remove, cool to room temperature and make up to volume with the alcohol-acetone mixture. Stopper, mix thoroughly, and pour onto a dry filter, collecting the clear filtrate in a dry test tube. Cover the funnel with a watch glass during filtration, to minimize evaporation of solvent.

Precipitation of Free Cholesterol: Transfer 6 ml. of filtrate to a 15-ml. centrifuge tube, add 3 ml. of digitonin solution, and 1 drop of 10 per cent acetic acid solution. Place a stirring rod in the tube and stir thoroughly. Place the tube, together with the stirring rod, in a pint or quart size preserving jar, cover the jar tightly, and allow to stand at room temperature overnight. In the morning, transfer the tube and rod to a test tube rack and stir gently to free particles of precipitate which may have adhered to the walls of the tube. Remove the rod carefully without touching the upper part of the tube and place it aside carefully so that no adherent precipitate is rubbed off; a wire rack with numbered positions is suggested, so that the rod may be returned to the proper tube later. Centrifuge the tube for about 15 minutes at about 2800 r.p.m. Decant the supernatant and drain in an inverted position for a few minutes, removing the last drop by touching the lip of the tube to a clean towel; or remove the supernatant by gentle suction through a fine capillary pipet, without stirring up the precipitate or touching the sides of the tube. A few particles may float at or near the top of the solution after centrifugation; they are discarded with the supernatant.

102 Reagents Required: Acetone-Alcohol Mixture. Mix 1 volume of absolute ethyl alcohol with 1 volume of redistilled acetone.

Digitonin Solution. Dissolve 400 mg. of digitonin (Hoffman-La Roche, Nutley, N. J., or S. B. Penick and Co., 50 Church St., New York, N. Y.) in 100 ml. of distilled water. Filter or centrifuge just before use if not clear.

10 Per Cent Acetic Acid Solution. Dilute 1 volume of glacial acetic acid to 10 volumes with water, and mix.

Actione-Ether Mixture. To 1 volume of redistilled acetone add 2 volumes of peroxide-free ether and mix. To prepare peroxide-free ether, wash ordinary ether with sodium sulfite, followed by water, and distill from calcium chloride.

Potassium Hydroxide Solution. Dissolve 10 g. of reagent grade potassium hydroxide in 20 ml. of water. Store in a bottle equipped with a medicine dropper carrying a rubber bulb. Phenolphthalein Solution. Dissolve 1 g. of phenolphthalein in 95 per cent alcohol and dilute to 100 ml.

Acetic Acid. Only the highest purity anhydrous product ("glacial") may be used.

Acetic Anhydride-Sulfuric Acid Reagent. Just before needed, place 20 ml. of acetic anhydride (Eastman) in a glass-stoppered cylinder and chill in ice water. When cold, add 1 ml. of concentrated sulfuric acid, a little at a time, with mixing and cooling during the addition. Stopper the cylinder, shake the contents vigorously for a few moments and return to the ice bath. Keep cold during use, and do not use any reagent more than 1 hour old. More or less of the reagent may be prepared as needed, using the same proportions.

Stock Cholesterol Standard. Dissolve 100 mg. of pure dry cholesterol in about 50 ml. of glacial acetic acid by warming on an electric hot plate and stirring. Transfer with rinsings to a 100-ml. glass stoppered volumetric flask, dilute to 100 ml. with acetic acid, and mix. This solution contains 1 mg. of cholesterol per ml. and is quite stable in the cold. It must be warmed to room temperature before using. Dilute standard. Transfer 5 ml. of stock standard, containing 5 mg. of cholesterol, to a 50-ml. glass-stoppered volumetric flask, dilute to the mark with acetic acid, and mix well. This solution contains 0.2 mg. of cholesterol in 2 ml.

Replace the stirring rod in the tube and wash down the walls of the tube and the rod with 1.5 to 2 ml. of acetone-ether mixture added from a dropping pipet with attached rubber bulb. Stir the precipitate up theroughly, replace the rod on the rack, and centrifuge the tube for five minutes. Remove the supernatant as above, and repeat the washing twice more, using ether instead of acetone-ether. Replace the rod in the tube and set aside until ready for color development.

Saponification and Precipitation of Total Cholesterol: Add 3 drops of potassium hydroxide solution to a 15-ml, graduated centrifuge tube, and add 3 ml. of the acetone-alcohol filtrate. Insert a stirring rod and stir vigorously until no droplets of alkali can be seen in the solution. Leave the rod in the tube, and place tube and rod in a preserving jar containing a layer of sand about 3 cm. deep which has been previously heated in a water bath until the temperature of the sand is about 45°. The sand acts as a heat reservoir. Close the jar tightly and place in an incubator (37° to 40°) for 30 minutes. Remove the tube to a rack, allow it to cool to room temperature, raise the rod, and add alcohol-acetone mixture to the 6-ml. mark. Add 1 drop of phenolphthalein solution, followed by 10 per cent acetic acid, drop by drop with stirring, until the red color disappears. Add 1 drop in excess, followed by 3 ml. of digitonin solution. Stir thoroughly, place the tube and rod in a preserving jar, cover tightly, and allow to stand at room temperature for at least three hours, and preferably overnight. Separate and wash the precipitate exactly as described above for the precipitation of free cholesterol, except that only one ether washing instead of two is necessary.

Development and Reading of Color: Place a layer of sand about 3 cm. deep in a shallow pan and heat to 110° to 115° in an oven. Place the tubes containing the precipitated and washed cholesterol digitonide in the pan and return the pan to the oven. 103 After 30 minutes, remove the pan, and, while the tubes are still in the hot sand, from a buret add 2 ml. of acetic acid in such a way that the acid washes down the wall of the tube and the rod. Stir well with the rod, allow to remain in the sand for about two minutes (not longer), remove and cool to room temperature, with the rod still in the tube. Undissolved material at this stage is neglected.

When the tubes are ready for color development, place them in a water bath at 25° C. from which light is excluded 104 and allow to come to temperature equilibrium. Note the time, and add 4 ml. of the cold acetic anhydride-sulfuric acid reagent, mix well with the rod, and return to the bath. Allow to stand 27 minutes, then transfer to colorimeter or photometer containers and read within the next 10 minutes. If possible, it is better to have the time of standing before reading constant at about 30–31 minutes.

A standard suitable for both colorimetric and photometric measurement is prepared as follows: Transfer 2 ml. of a standard solution of cholesterol in acetic acid, containing 0.2 mg. of cholesterol, to a suitable tube containing a stirring rod. Place in the water bath at 25° and allow to come to temperature equilibrium. When ready, add 4 ml. of the acetic anhydride-sulfuric acid reagent, mix, return to the bath, and allow to stand 27 minutes. Use within the next 10 minutes. 104 For photometric measurement, a blank is prepared similarly, except that 2 ml. of acetic acid alone are used instead of the standard cholesterol solution.

For colorimetric measurement, the colorimeter must be equipped with microcups and the eyepiece of the colorimeter must be provided with a red

¹⁰³ This heating is to ensure complete removal of water from the hygroscopic digitonide precipitate.

¹⁰⁴ A large pan of water containing metal racks and placed in an enclosed box fitted with a door, or in a closet, is satisfactory. Insert a thermometer in the water and keep at 25° by adding hot or cold water as required.

¹⁰⁵ Because the standard appears to fade rapidly while it is in the colorimeter cup. Fits (loc. cit.) suggests the preparation of a larger volume of standard, fresh portions of which are used at intervals during the 27 to 37 minute period of color development.

filter (Wratten No. 71A, supplied by Eastman Kodak Co. or by the manufacturer of the colorimeter). Arrange the time of color development so that the standard is ready first, and the unknowns reach the 27-minute stage at short intervals thereafter, depending upon the rapidity with which the color comparisons can be made. Adjust the standard against itself at 20 mm., and as each unknown becomes ready, rinse cup and plunger with a small portion and read against the standard. Do not use the standard after 37 minutes have elapsed from the start of color development; if more unknowns are present than can be read in this time, have a second standard suitably timed and ready for use. 106

For photometric measurement, transfer the colored solutions to suitable containers and determine the density in the photometer, at 625 my. Adjust the photometer to zero density against water, and determine the densities of the blank, the standard, and the unknowns at 30 to 31 minutes after adding the acetic anhydride-sulfuric acid reagent. Subtract the density of the blank from those of the standard and unknowns, to obtain the true densities.

Calculation. For colorimetric measurement: Since the amounts of filtrate taken for the free and total cholesterol determinations represent 0.24 and 0.12 ml. of original sample respectively, the calculations are as follows:

Free Cholesterol.

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{100}{0.24} = \text{mg. of free cholesterol per 100 ml.}$$

Total Cholesterol.

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{100}{0.12} = \text{mg. of total cholesterol per 100 ml.}$$

For photometric measurement:

Free Cholesterol.

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.2 \times \frac{100}{0.24} = \text{mg. of free cholesterol per 100 ml.}$$

Total Cholesterol.

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.2 \times \frac{100}{0.12} = \text{mg. of total cholesterol per 100 ml.}$$

At 625 m μ , and in a 1-cm. cuvette, the density of the standard is approximately 0.100^{107} (Fig. 169). Under the conditions described, from 40 to 200 mg. per cent free cholesterol and 80 to 400 mg. per cent total cholesterol may be accurately determined. For higher levels, repeat the analysis using less sample in the alcohol-acetone precipitation; or use less filtrate in the digitonin precipitation, with other reagents in proportion

107 Color developed for 30 to 33 minutes at 21°.

¹⁰⁶ Because of the instability of the standard, it has been suggested that when a number of analyses are being run colorimetrically, an artificial standard be used which is standardised each day against a cholesterol standard. Shapiro, Lerner and Posen (Proc. Soc. Exptl. Biol. Med., 32, 1300 (1935)) proposed a permanent artificial standard made from Carter's Midnight Black Ink. Sperry and Brand (J. Biol. Chem., 156, 351 (1943)) describe in detail the use of dilute naphthol green B solution as an artificial standard.

except for the final solution in acetic acid and color development; and correct the calculations accordingly.

Because of the sensitivity of the cholesterol color to bleaching by light, photometric measurements should be made as rapidly as possible, to avoid prolonged exposure to the light beam in the photometer.

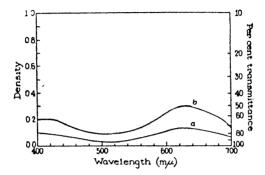

Fig. 169. Absorption spectra of colored solutions obtained by Schoenheimer-Sperry method for cholesterol, for standards containing (a) 0.2 mg., and (b) 0.4 mg. of cholesterol. Solution depth, 1 cm.

Interpretation. Normal blood cholesterol appears to be maintained at a constitutional level which is characteristic for each individual, and from which large deviations do not ordinarily occur for that particular individual. Considerable variation, however, is found among different individuals, the "normal range" being from about 110 to 390 mg. per 100 ml. of serum or plasma. Of this, about one-third is present as free cholesterol (on the basis of digitonin precipitation, which is generally accepted as standard) and the remainder is esterified. Although many of the data in the literature are in terms of total cholesterol, the distribution of cholesterol between the free and the ester forms is attracting more attention, particularly in the diagnosis of liver disease. According to Sperry, routine determination of whole blood cholesterol should be abandoned, since the cells contain only free cholesterol and in quite constant amount, no changes in pathological conditions having been noted. Serum cholesterol is increased, and the determination has clinical value, in nephrosis, lipemia, diabetes mellitus, hypothyroidism, and biliary obstruction due to calculi or other causes. Increases are also found in pregnancy and after a high lipid diet. Decreased serum cholesterol is found in hyperthyroidism, pernicious anemia, and certain types of liver disease. In the latter condition, the proportion of ester cholesterol to total cholesterol may be sufficiently lowered to be of diagnostic significance. A low cholesterol diet leads to lowered serum cholesterol; since there is ample evidence that cholesterol is synthesized within the body, changes in blood level due to diet presumably represent merely the net result of the various factors concerned.

3. Reinhold and Shiels' Modification of the Myers-Wardell Method: 108 Principle. The serum or plasma is dried on anhydrous sodium sulfate and extracted with chloroform. The total cholesterol of the extract is determined colorimetrically by the Liebermann-Burchard reaction with acetic anhydride and sulfuric acid. In the original method of Myers and Wardell, plaster of paris was used instead of sodium sulfate. Leiboff 109 describes a procedure in which the sample is dried on a small piece of absorbent paper which is then extracted in a specially designed flask. In the Bloor, Pelkan, and Allen 110 procedure, no special apparatus is necessary; proteins are precipitated with alcohol-ether mixture, an aliquot of the filtrate is dried in a beaker, and extracted with successive small portions of hot chloroform. In all of these procedures, low results will be obtained if the extraction is incomplete.

Procedure: 111 Transfer 1 ml. of plasma or serum to a small mortar containing about 8 g. of anhydrous sodium sulfate. Mix uniformly, dry in an oven at 100° for 10 minutes, cool in a desiccator, pulverize, and transfer completely to a paper extraction shell which is then inserted into a Soxhlet extraction tube (see Fig. 170) suspended from the condensing coil of the extraction apparatus. (If the extraction apparatus illustrated in Fig. 170 is not available, Myers' arrangement shown in Fig. 171 may be used, in which the extraction tube is a perforated glass tube (2.5 by 7 cm.) and is connected to a reflux condenser as illustrated.) Place 20 to 25 ml. of redistilled chloroform in the extraction flask, place on an electric hot plate, and extract for 90 minutes, during which time cold water flows through the condenser or coil. Allow the extract to cool and transfer with rinsings to a 25-ml. volumetric flask. Make up to volume with chloroform, mix well, and filter through a dry filter if necessary.

Transfer 10 ml. of the chloroform extract to a dry test tube and add 2 ml. of the freshly prepared acetic anhydride-sulfuric acid reagent. Treat 10 ml. of a standard solution of cholesterol in chloroform, containing 0.8 mg. of cholesterol, in the same way, and for photometric measurement prepare a blank by treating similarly a 10-ml. portion of chloroform alone. After mixing, keep in a dark place at 25° for exactly 30 minutes, 104 then transfer to colorimeter or photometer containers and read.

For colorimetric measurement, compare the unknown against the standard in the usual way. The colorimeter may be equipped with a light filter

111 Reagents Required: Anhydrous sodium sulfate, reagent grade.

Chloroform. Commercial chloroform should be washed with water, dried over anhydrous potassium carbonate, and distilled. Dry the distillate over phosphorus pentoxide and again distil. Keep protected from light. Present-day reagent grade chloroform (such as Merck's) may be satisfactory without the necessity of further treatment.

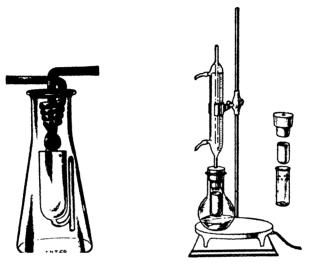

Acetic Anhydride-Sulfuric Acid Reagent. Just before use, add 1 volume of concentrated sulfuric acid slowly with shaking to 10 volumes of acetic anhydride. Prepare only enough

reagent for a particular series of analyses, and discard the unused portion.

Cholesterol Standard. Stock Standard. Dissolve 160 mg. of pure dry cholesterol in chloroform and transfer with washings of chloroform to a 100-ml. flask. Make up to volume with chloroform and mix. This solution contains 8 mg. of cholesterol in 5 ml. Keep cold and away from light. To prepare the dilute working standard, transfer 5 ml. of stock standard to a 100-ml. volumetric flask, dilute to the mark with chloroform, and mix. This solution contains 0.8 mg. of cholesterol in 10 ml. It is stable for some days if kept cold and away from light.

over the eyepiece (Wratten No. 71A or its equivalent, supplied by Eastman Kodak Co. or by the manufacturer of the colorimeter) although this is not essential. Since the standard color fades rapidly, if more than two or three unknowns are to be read, a number of standards must be prepared, suitably timed with respect to the unknowns, or the standard may be used to standardize an artificial standard (see previous method) against which the properly timed unknowns are read.

For photometric measurement, determine the densities of the blank, standard, and unknown at exactly 30 minutes after adding the acetic

Figs. 170 and 171. Extraction apparatus for cholesterol determination. (Fig. 171 after Myers: "Practical Chemical Analysis of Blood," C. V. Mosby Co., 2d ed., St. Louis.)

anhydride-sulfuric acid reagent, in a photometer at 660 my. Set the photometer to zero density with water. Subtract the density of the blank from the other values to obtain their true densities.

Calculation. For colorimetric measurement: Since the 10 ml. of extract used correspond to 0.4 ml. of original sample, the calculation is as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.8 \times \frac{100}{0.4} = \text{mg. of cholesterol per 100 ml.}$$

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.8 \times \frac{100}{0.4} = \text{mg. of cholesterol in 100 ml.}$$

Under the conditions specified, and in a 1-cm. cuvette, the density of the standard is approximately 0.700. Since the standard corresponds to a serum with 200 mg. per cent cholesterol, the limit of accurate measurement under these conditions is about 300 mg. per cent. It is suggested for

photometric measurement that smaller aliquots, such as 2 ml. or 5 ml., of the chloroform extract be taken, diluted to 10 ml. with chloroform, and the color then developed as described. Using the above calculation formula, results must then be multiplied by 5 or 2 respectively. In this way a much wider range of cholesterol concentration may be accurately covered.

Discussion. The final color in the above procedure is due to both free cholesterol and cholesterol esters. Since free cholesterol and ester cholesterol give different amounts of color per milligram, and the color develops at different rates, interpretation of results may be obscure if an abnormal distribution of cholesterol between free and ester forms is present. Reinhold¹¹² utilizes the difference in velocity of the Liebermann-Burchard reaction with cholesterol esters and free cholesterol as a basis for determination of cholesterol partition. Sperry and Brand¹¹³ describe a procedure for total cholesterol after saponification of the ester fraction, thus eliminating errors due to variation in ester content.

The Liebermann-Burchard reaction with cholesterol gives much more color in chloroform than in the glacial acetic acid used in the previous method. To offset this advantage, the reaction in chloroform is, according to Schoenheimer and Sperry, more sensitive to the effect of such analytical variables as time, temperature, etc., so that more careful technical control is necessary. The spectrophotometric characteristics of the color in chloroform are somewhat similar to that in acetic acid (see Fig. 169) except that peak light absorption in the red end of the spectrum is at 660 mμ instead of at 625 mμ. 114 The high light absorption at 420 mμ permits use of this range as well as the 660 mu range. Although the color intensity here slowly increases rather than waxing and waning as at 625 mu, and is a function of the extent of exposure to light during color development. neverthless Summerson and Robinson¹¹⁵ found this range to be in some respects more satisfactory than at 660 mµ. Sunderman and Razek¹¹⁴ have shown that measurement at 530 m_{\mu} is also satisfactory; although the optical density is low here, the agreement with Beer's law is excellent.

Interpretation. See under previous method.

4. Other Methods. Other methods for the determination of serum cholesterol usually employ isolation as the digitonide, followed either by weighing on a microbalance, 116 or oxidation with chromic acid. In the oxidation procedures, either titrimetric 117 or gasometric 118 methods may be employed. For details, see the original papers.

DETERMINATION OF FATTY ACIDS

- 1. Introduction. The fatty acids of blood are present largely as esters in the form of (a) neutral fat, (b) phospholipids, (c) cholesterol esters;
 - Reinhold: Proc. Soc. Exptl. Biol. Med., 32, 614 (1935).
 Sperry and Brand: J. Biol. Chem., 150, 351 (1943).
 - 114 Sunderman and Razek: J. Biol. Chem., 118, 379 (1937).
 - 115 Unpublished.
 - 116 Mueller: J. Biol. Chem., 25, 549 (1916); Ewert: Biochem. Z., 263, 159 (1933).
- 117 Okey: Proc. Soc. Exptl. Biol. Med., 26, 518 (1929); Turner, J. Biol. Chem., 92, 495 (1931).
 - 118 Kirk, Page, and Van Slyke: J. Biol. Chem., 196, 203 (1934).

there may be a small amount of free fatty acid (i.e., soaps) also present. The total fatty acids of whole blood are distributed approximately evenly between cells and plasma; this even distribution apparently simply reflects the fact that while phospholipids for example are much more abundant in the cells than in the plasma, the reverse is true for esterified cholesterol, which is apparently absent from the cells. Total fatty acid content is usually determined by saponification and titration of the liberated fatty acids.

2. Method of Stoddard and Drury: 119 Principle. The blood is extracted with alcohol-ether, the extract saponified, the fatty acids separated, filtered, washed, dissolved in alcohol, and titrated with phenol blue as indicator.

Procedure: Extraction: Five ml. of whole blood, plasma, or serum, are introduced gradually into a 100-ml. volumetric flask containing about 75 ml. of a mixture of 95 per cent alcohol and redistilled ether (3:1). The flask is immersed in boiling water and rotated frequently and vigorously (to prevent superheating) until boiling begins, then cooled to room temperature, made up to volume with alcohol-ether, mixed, and filtered through fat-free filter paper.

Saponification: To a 100-ml. beaker containing a few grains of coarse sand (previously boiled with acid, washed, dried, and extracted with ether) add gradually, while evaporating on a water bath, 75 ml. of the filtrate. The temperature should be low enough to avoid perceptible boiling but may be raised after the ether has evaporated. Evaporate to a volume of about 30 ml. Add 0.1 ml. of saturated CO₂-free NaOH, 120 mix, add a few grains more of sand, cover with a watch glass, and boil gently for 20 to 30 minutes (to saponify).

Separation and Washing: Remove the watch glass, drop in a small piece of litmus paper, make acid with 30 per cent HCl; then run back to alkalinity with 10 per cent NaOH (in order to avoid an excess of alkali on evaporating to dryness). Evaporate to dryness (in order to get rid of all alcohol). Add 15 ml. of water, heat on the steam bath, and stir to dissolve the soaps. While hot, add a drop of thymol blue indicator and make acid (faint pink) with 30 per cent HCl. Set the beaker for 10 minutes in cold water, then swirl almost continuously for five minutes to produce a better separation of the

fatty acids.

Filters are previously prepared as follows: Use a Gooch crucible, smallest size (top 28 mm., bottom 18 mm. in diameter). Set the crucible in a rubber holder which fits over a 500-ml. suction flask. A paper pulp suspension is made by shaking up a piece of soft filter paper in 300 to 400 ml. of distilled water. Shake vigorously and immediately pour some into the crucible while there is a strong suction on. Repeat until a layer about 1 mm. thick is formed. Tamp the layer down carefully all over with the end of a glass rod. Allow the larger masses of filter pulp fibers in the suspension to settle out, and pour on successive amounts of the thin upper suspension of isolated shreds, keeping a strong suction on and tamping down occasionally, until the filter is dense enough to offer a definite resistance to the suction. Remove the crucible from the rubber holder and dry in an air oven at 110° for 15 minutes. Allow to cool before using.

Place the crucible in its holder in an ordinary funnel and filter some of the fatty acid suspension into a test tube. If the filtrate is not perfectly clear, put it through the crucible again. If the filtration does not start in a

¹¹⁰ Stoddard and Drury: J. Biol. Chem., 84, 741 (1929). This method has been critically evaluated by Man and Gildea: J. Biol. Chem., 99, 61 (1932), ¹²⁰ See Appendix.

few minutes, transfer the crucible and rubber holder to the filter flask and start the suction very gently, with a test tube under the funnel. After filtration has started, continue without suction. After the fatty acid suspension is filtered and drained, wash with 4 ml. of 5 per cent NaCl solution, neutralized to methyl red. Use a pipet and run the salt solution down the walls of the beaker all around, then, tipping the beaker, use a fine bent glass rod to rinse the side of the beaker more thoroughly with the solution, then pour this rinsing into the Gooch crucible, rinsing its side with the aid of the rod. Wash until the filtrate from one washing takes not over 0.05 ml. of 0.02 N NaOH to neutralize it to phenolphthalein. Usually this is true of the third washing. Put the crucible back on the suction flask with a nonprotein nitrogen tube (cut off to a convenient height and calibrated at 1-ml. intervals from 10 to 15 ml.) under the funnel. Wash down the walls of the beaker with 5 ml. of 95 per cent alcohol, heat to boiling, and pour into the crucible. With the glass rod quickly loosen up any fatty acid fragments on the wall of the crucible. Allow to run nearly out, then put on a moderate suction. Rinse out the beaker and crucible twice more with 3 ml. of alcohol each time, heating it to boiling. Then wash off the outside of the crucible and the funnel.

Titration: Add a few grains of sand, boil the filtrate for 1 minute, cool in a beaker of water, note the volume of alcohol, add 3 drops of 0.3 per cent phenol blue in 50 per cent alcohol, titrate with 0.02 N NaOH to a pure blue which stays practically unchanged (no yellow tinge) while shaking for two minutes, keeping a stopper in the mouth of the tube to avoid absorption of CO₂. For a blank boil 10 ml. of alcohol and titrate.

Calculation. Calculate the correction necessary for the amount of alcohol present before titration. Add a correction amounting to 0.005 ml. for each ml. of NaOH used in titration (a simple correction for the volume of solution). Subtract the total correction from the titration. Multiply by the normality factor, thus getting the number of millimoles of fatty acid. Multiply by

$$\frac{100}{\text{ml. of filtrate evaporated}} \times \frac{100}{\text{ml. of blood used}}$$
= millimoles of fatty acid per 100 ml. of blood.

To translate into terms of weight (not a very significant figure), multiply by an average factor for the fatty acids as they usually occur in blood = 277.2. The molecular weights are so nearly alike that a considerable variation in the proportions will not affect the calculated weight by more than about 2 per cent.

Interpretation. Human whole blood has a total fatty acid content ranging from about 9 to 14 millimoles (milliequivalents) per liter. This corresponds to about 250 to 390 mg. of average fatty acids per 100 ml. Some variation is found between different individuals, and in a particular individual at various times. Factors such as diet and disease which influence the blood content of neutral fat, phospholipid, and cholesterol esters will naturally influence the total fatty acid content.

DETERMINATION OF LIPID PHOSPHORUS

1. Introduction. The lipid phosphorus of blood and tissues is found in such compounds as lecithin, cephalin, sphingomyelin, phosphatidyl

serine, etc., which are obtained by the extraction of tissues with certain nonaqueous solvents. In blood plasma, lecithin is the major phospholipid according to Bloor, while in the red cells cephalin and sphingomyelin predominate; the data of Kirk¹²¹ present a somewhat different picture. The simplest procedure for the determination of phospholipid is the analysis of lipid-containing extracts for total phosphorus, as described below; this procedure gives fairly accurate results. Bloor¹²² isolates phospholipids from nonlipid phosphorus by precipitation with acetone and magnesium chloride, and determines the phospholipid titrimetrically after oxidation with chromic acid. Gasometric determination as total carbon by wet combustion is also satisfactory.¹²³ Kirk¹²¹ and Artom¹²¹ have described procedures for the separate microdetermination of certain of the various phospholipids in blood.

2. Method of Youngburg,¹²⁴ Modified: Principle. The extracted lipids are oxidized with sulfuric acid and hydrogen peroxide and the phosphate present determined colorimetrically. The phosphate procedure of Fiske and SubbaRow is applied here; the Youngburgs use the stannous chloride reagent of Kuttner and Cohen (see p. 578) which is applicable to smaller amounts of phosphorus. This latter procedure is described in the Eleventh Edition of this book.

Procedure: Transfer 18 ml. of alcohol-ether mixture¹²⁸ to a wide-mouthed test tube (best 150 by 20 mm.) graduated at 20 ml., and drop in slowly, while shaking, 1 ml. of plasma or serum. Mix, place in a boiling water bath, and heat the contents of the tube to boiling. Remove and allow to cool to room temperature. Make up to the 20-ml. mark with alcohol-ether mixture, mix, and filter.

Transfer 8 ml. of filtrate to a 200 by 25 mm. pyrex test tube, add a silica pebble (from broken silica ware), place in a wire rack containing a wire bottom, over an electric hot plate, and evaporate to dryness.

Add 2.5 ml. of 5 N sulfuric acid to the residue in the tube and digest over the hot plate as in the method for total acid-soluble phosphorus (see p. 581), including oxidation with perhydrol (30 per cent hydrogen peroxide). The remaining procedure is the same as for total acid-soluble phosphorus of blood (see p. 581), with color development at a final volume of 25 ml.; a different standard is however used, containing only half as much inorganic phosphate, i.e., 0.5 ml. of standard phosphate solution, containing 0.04 mg. of inorganic phosphate, instead of the 1 ml. specified on p. 582. The conditions for colorimetric or photometric measurement of the color intensity are the same as for acid-soluble phosphorus.

Calculation. Since the 8 ml. of extract represent 0.4 ml. of original sample, calculation of results is similar to that for acid-soluble phosphorus except that the value 0.04 replaces 0.08 in the calculations, corresponding

¹³¹ Kirk: J. Biol. Chem., 123, 623, 637 (1938). See, however, Sinclair and Dolan: J. Biol. Chem., 142, 659 (1942); Artom: ibid., 157, 595 (1945).

¹²² Bloor: J. Biol. Chem., 82, 273 (1929). For an adaptation of this method, see Ellis and Maynard: J. Biol. Chem., 118, 701 (1937). McCoy and Schultze (J. Biol. Chem., 156, 479 (1944)) describe a photometric adaptation of the chromic acid oxidation procedure, suitable for small amounts of lipids.

123 Kirk, Page, and Van Slyke: J. Biol. Chem., 106, 203 (1934); Van Slyke and Folch: ibid., 136, 509 (1940).

124 Youngburg and Youngburg: J. Lab. Clin. Med., 16, 158 (1930).

¹³⁶ Alcohol-Ether Mixture: Three volumes of 95 per cent redistilled alcohol and 1 volume of redistilled ether, Mix,

to the use of half as strong a standard. Or calculate as for acid-soluble phosphorus and divide the result by 2, to obtain mg. of lipid phosphorus per 100 ml. of original sample.

Interpretation. Plasma or serum contains about 9 to 10 mg. of lipid phosphorus per 100 ml., whole blood slightly more, averaging about 12 mg. per cent. These values may be expressed as lecithin by multiplying by 25, since lecithin contains approximately 4 per cent phosphorus; it is known, however, that only part of the total blood phospholipids is represented by lecithin. Artom (loc. cit.) gives the following distribution of phospholipids for a sample of human plasma: lecithin, 55 per cent of the total phospholipids; phosphatidyl ethanolamine (cephalin), 21 per cent; sphingomyelins, 12 per cent; phosphatidyl serine, 7 per cent. Little is known concerning the pathological significance of variation in this distribution. Pathological variation in total phospholipid content is greater for red cells than for plasma. In diabetes and nephritis, the lipid phosphorus follows roughly the degree of lipemia. Increases in lecithin are also noted in pregnancy and in certain hepatic conditions. The existence of a constant ratio between cholesterol (which is antihemolytic) and lecithin (hemolytic) has not been definitely established.

DETERMINATION OF BILE PIGMENT IN SERUM

1. Icteric Index (Meulengracht): Principle. The intensity of yellow pigmentation of serum is compared with a standard potassium bichromate solution.

Procedure: 126 Separate the serum from 4 or 5 ml. of freshly drawn unhemolyzed blood. For colorimetric measurement, accurately dilute 1 ml of serum with 5 per cent sodium citrate solution in a small graduated cylinder, according to its color, until an approximate match with the standard potassium bichromate solution is obtained. Transfer to a colorimeter cup and compare against the standard bichromate.

For photometric measurement, 127 dilute 1 ml. of serum to 10 ml. with 5 per cent sodium citrate solution. Determine the density in a photometer at 420 mg, setting the photometer to zero density with the 5 per cent sodium citrate solution alone. Determine the density of the standard potassium bichromate solution at the same wavelength, using water as a blank.

Calculation. For colorimetric measurement:

Reading of Standard Reading of Unknown X Dilution = Icteric Index

For example, if 1 ml. of serum is diluted to 6 ml., the dilution is 6, and if

126 Reagents Required: 5 Per Cent Sodium Citrate Solution. Dissolve 50 g. of U.S.P. or C.P. sodium citrate in water and dilute to 1 liter. If turbid, allow to stand several days and filter. Add a little chloroform as a preservative. Saline solution (0.9 per cent sodium chloride) may also be used as a diluent in the colorimetric procedure, but citrate gives clearer solutions.

Standard Potassium Bichromate (0.01 Per Cent). Dissolve exactly 0.1 g. of reagent-grade potassium bichromate in water, transfer with rinsings to a 1-liter volumetric flask, add two to three drops of concentrated sulfuric acid, dilute with water to the mark, and mix. Keep in a brown glass bottle. The icteric index of this solution is arbitrarily defined as equal to 1.

137 As developed by Prof. W. H. Summerson for use at the New York Hospital.

the unknown exactly matches the standard in the colorimeter, the icteric index is 6.0.

For photometric measurement: Since the standard bichromate solution has an equivalent icteric index of 10 under the conditions of the procedure, the calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 10 = \text{Icteric Index}$$

In a 1-cm. cuvette at 420 m μ , an icteric index of 10 gives a density reading of approximately 0.200, at a 1:10 dilution of the serum. Under these conditions, the limit of accurate measurement corresponds to an icteric index of approximately 50. For higher values, the determination is repeated at a greater dilution of the serum, the new dilution value replacing the 10 in the above calculation formula. Since the standard is a stable colored solution, its density should be constant. Therefore, once the density of the standard has been established for a given photometer and wavelength or filter, this value may be used in the future without the necessity of repeating the reading of the standard in every series of analyses.

Interpretation. The normal icteric index ranges between 4 and 6. The zone of latent jaundice (i.e., hyperbilirubinemia without clinical signs of jaundice) is between 6 and 15. Above this value icteric symptoms may be observed. The yellow color is considered to be due chiefly to the presence of bilirubin, an icteric index of 5 corresponding roughly to 0.1 to 0.2 mg. of bilirubin per 100 ml. of serum. The presence of certain other pigments will lead to errors; hemolysis in particular is to be avoided. This may be done by using a dry syringe and needle for collecting the blood, allowing the blood to clot protected from light, and centrifuging sharply to obtain a clear serum. Blood should be drawn before breakfast to avoid chyle; lipemic sera cannot be used because of interfering turbidity. The carotinemia which follows ingestion of carrots will lead to a high apparent icteric index and false interpretation; carrots should not be eaten the day before the test. Further aspects of the significance of serum bilirubin are discussed below.

2. Van den Bergh Test: 128 Principle. Plasma or serum is treated with Ehrlich's reagent (diazotized sulfanilic acid). Bilirubin present reacts with the reagent to form a colored compound known as azorubin or azobilirubin. Qualitatively, the color may develop immediately ("direct reaction") or on standing ("indirect reaction"). Occasionally an atypical color develops almost immediately ("biphasic reaction"). Quantitatively, the color may be used as a measure of the bilirubin content of the serum or plasma (see Section 3).

Procedure: 130 Obtain unhemolyzed plasma or serum as described above. Jaundiced serum must be diluted 1:5 or, if highly colored, 1:10, with water. To

¹²⁸ Van den Bergh: Presse méd., 29, 441 (1921); Sepulveda and Osterberg: J. Lab. Clin. Med., 28, 1359 (1943).

¹³⁹ Reagents Required: Diaso Reagent—Solution A. To 1 g. of sulfanilic acid add 15 ml. of concentrated hydrochloric acid. Add water, stir to dissolve, and dilute to 1 liter with water. Solution B. Dissolve 0.5 g. of sodium nitrite in water and dilute to 100 ml. Just before the

1 ml. of serum (generally diluted), add 2 ml. of freshly prepared Ehrlich's diazo reagent. ¹³⁰ Direct reaction: a pink to purple color develops immediately, reaching maximum intensity in a minute or so. Indirect reaction: no color change is noted during the first two minutes. Within 10 minutes a golden color forms, changing over a period of an hour or more through brown to pink. ¹³¹ Biphasic reaction: a color appears during the first two minutes, but it is brownish-red rather than the typical pink or purple of the direct reaction.

Interpretation. The chemical and clinical significance of the three types of Van den Bergh reaction have been the object of considerable investigation. Van den Bergh believed that the different reactions were dependent upon the path by which the pigment entered the serum. For example, the direct reaction is usually found in the condition of obstructive jaundice, i.e., when the biliary passages are blocked, preventing the excretion of bile pigment which has already been secreted by the liver cells. The indirect reaction is usually found when the jaundice is of hemolytic or extrahepatic origin, and the biphasic reaction is thought to represent a combination of both types. Further study has not justified the belief that the various types of jaundice may be distinguished in terms of the qualitative Van den Bergh test. 132 While normal sera and sera from cases of hemolytic jaundice usually show no direct-reacting bilirubin, in most other types of jaundice it is usually possible to demonstrate the presence of both direct-reacting and indirect-reacting bilirubin. It appears probable that there are two distinct types of serum bilirubin; for instance, indirect-reacting bilirubin may be removed from serum by extraction with chloroform, while direct-reacting bilirubin is not soluble in this solvent. Griffiths¹³³ has reported the isolation from human bladder bile of a pigment called "cholebilirubin" which gives the direct reaction, is distinct chemically from bilirubin, and appears to have the properties of the direct-reacting bilirubin of serum. It has been proposed that the terms "cholebilirubin" and "hemobilirubin" be used for the directreacting and indirect-reacting bilirubin respectively; these terms carry the unfortunate implication of origin, which has not been conclusively established. Other interpretations of the Van den Bergh reaction which have been proposed include the theory that variations are due to concentration differences, 134 or that the bilirubin of plasma is bound to protein, with a portion capable of dissociating to give an immediate reaction ("direct-reacting") while the remainder ("indirect-reacting") can react

test, prepare the diazo reagent by mixing 25 ml. of solution A with 0.75 ml. of solution B. This mixed solution keeps only a short time at room temperature.

¹³⁰ Better results are sometimes obtained by adding the diazo reagent slowly down the side of the test tube containing the serum so that a layer is formed over the serum. Observe the color at the interface between serum and reagent.

isi The indirect test is frequently carried out by adding three to four volumes of alcohol to the mixture of serum and reagent after 10 minutes. The indirect color appears immediately after mixing.

only slowly or after the addition of alcohol. 185 No single theory has apparently found universal acceptance.

3. Quantitative Determination of Serum Bilirubin: Method of Malloy and Evelyn: 136 Principle. The principle is the same as that used in the qualitative Van den Bergh reactions described above. The azobilirubin formed is determined by photometric measurement.

Procedure: 137 Dilute 1 ml. of unhemolyzed plasma or serum to 10 ml. with water, and mix. Blank: Place 5 ml. of absolute methyl alcohol in a test tube. Add 1 ml. of the blank hydrochloric acid solution, mix by tapping, and add 4 ml. of the 1:10 diluted serum or plasma. Mix gently by inversion. Unknown: Place 5 ml. of absolute methyl alcohol in a second test tube. Add 1 ml. of freshly prepared diazo reagent, mix by tapping, and add 4 ml. of the 1:10 diluted serum or plasma. Mix gently by inversion. Care must be taken to handle both blank and unknown tubes in the same manner, so that any turbidity which may form will be the same in both tubes. Allow to stand 30 minutes for color development, then transfer to suitable containers and read in the photometer at 540 my. Set the photometer to zero density with the blank. This compensates for any extraneous color or turbidity present in the unknown.

Calculation:

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{amount of bilirubin in standard} \times \frac{10}{4} \times 100$ = mg. of bilirubin per 100 ml. of serum or plasma

The density of the standard is established as follows: Transfer 4 ml. of dilute standard alcoholic solution of bilirubin, containing 0.04 mg. of bilirubin, to a test tube, and add 5 ml. of methyl alcohol, followed by 1 ml. of diazo reagent. Mix by inversion and allow to stand 30 minutes for color development. At the same time, prepare a blank tube containing 9 ml. of methyl alcohol and 1 ml. of diazo reagent. Mix. After 30 minutes, set the photometer to zero density at 540 m μ with the blank tube and determine the density of the standard.

Under the conditions specified, and in a 1-cm. cuvette, the standard has a density of approximately 0.300 (see Fig. 172). Since this standard corresponds in an analysis to a serum bilirubin content of 10 mg. per cent, up to about 30 mg. per cent of bilirubin may be accurately determined. If the value is above this, dilute the contents of both blank and unknown

- 125 Coolidge: J. Biol. Chem., 132, 119 (1940).
- 136 Malloy and Evelyn: J. Biol. Chem., 117, 481 (1937).
- 127 Reagents Required: Absolute Methyl Alcohol.

Diazo Reagent: Solution A. To 1 g. of sulfanilic acid add 15 ml. of concentrated hydrochloric acid, dissolve and dilute with water to 1 liter. Stable indefinitely. Solution B. Dissolve 0.5 g. of sodium nitrite in water and dilute to 100 ml. Keep away from light, and discard when it turns yellow. Diazo Reagent. Mix 10 ml. of Solution A with 0.3 ml. of Solution B. Must be prepared fresh before using.

Blank Hydrochloric Acid Solution. Dilute 15 ml. of concentrated hydrochloric acid to 1 liter with water. Stable indefinitely.

Standard Bilirubin Solution: Stock Standard. Place 10 mg, of bilirubin (obtainable from Eastman Kodak Co., Rochester, N.Y., or Hoffmann-La Roche, Nutley, N.J.) in a 100-ml. volumetric flask, add chloroform to dissolve, and dilute to 100 ml. with chloroform. Keep in a dark bottle in the cold. Dilute standard. Transfer 10 ml. of stock standard to a 100-ml. volumetric flask and dilute to the mark with methyl alcohol. Mix. This standard contains 0.01 mg, of bilirubin per ml. Prepare just before using.

tubes with an equal volume of 50 per cent methyl alcohol, read immediately, and multiply the results by 2.

The color developed in this procedure is quite stable and reproducible. Since bilirubin is expensive and the standards do not keep very well, it is feasible to determine the standard density once carefully for a given photometer and wavelength setting or filter, and to use this value in future analyses, without the necessity of repeating the reading of the standard each time.

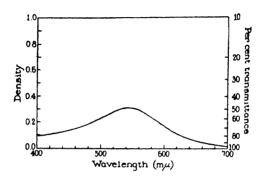

Fig. 172. Absorption spectrum of azobilirubin, as obtained in Malloy-Evelyn bilirubin method.

If a photometer is not available, the unknown may be compared in a colorimeter against the standard in the usual manner. A green filter over the eyepiece of the colorimeter will aid in color matching. An artificial standard containing cobalt sulfate has been suggested for visual colorimetry, ¹³⁸ to replace the bilirubin standard. The colorimetric method of Gibson and Goodrich ¹³⁹ is described in the Eleventh Edition of this book.

Interpretation. Normal plasma or serum contains 0.1 to 0.25 mg. of bilirubin per 100 ml. Bilirubin content is sometimes expressed in "units," 1 unit corresponding to 0.5 mg. per cent, thus normal plasma contains 0.2 to 0.5 unit. The zone of latent jaundice is represented by the range of 0.25 to 1.0 mg. per cent. Hyperbilirubinemia may occur in diseases of the liver or biliary tract, and also in extrahepatic conditions of a hemolytic nature, such as those accompanying infectious diseases, pernicious anemia, hemolytic anemia, hemorrhage, etc. Low values for bilirubin may be found in secondary anemia. The determination may therefore be of importance in the differential diagnosis of anemias. The renal threshold for bilirubin is 3.5 to 4.0 units (1.7 to 2.0 mg. per cent) in the plasma.

DETERMINATION OF PLASMA PROTEINS

1. Introduction. The standard method for the determination of protein is by the Kjeldahl type of digestion and oxidation, converting the nitrogen present to the form of ammonia, which is then determined. If the

¹⁸⁸ White: Brit. J. Exptl. Path., 13, 76 (1932).

¹³⁰ Gibson and Goodrich: Proc. Soc. Exptl. Biol. Med., 31, 413 (1934).

material contains nonprotein nitrogen, this is determined in a separate analysis and subtracted from the total nitrogen value to give the protein nitrogen. This is then multiplied by 6.25 to give the protein value, since the average protein contains 16 per cent nitrogen. If sufficient material is available the most accurate version of this procedure is a macro-Kjeldahl method similar to that described in Chapter 32 for the determination of the total nitrogen of the urine. For blood analysis with its inherent limitation in the amount of material available, this is replaced by the various micro-Kjeldahl methods, and the procedures become similar to the determination of nonprotein nitrogen already described (p. 495).

To obtain satisfactory results more rapidly and simply than is possible by micro-Kjeldahl methods, various direct colorimetric, turbidimetric and specific gravity procedures have been developed. The colorimetric procedures are usually based on color reactions specific for protein or constituent amino acids and are standardized accordingly. Turbidimetric methods rely on the comparison of the turbidity produced by precipitating reagents on proteins in dilute solution with the turbidity produced similarly on a standard protein solution. The specific gravity methods are based on the fact that protein is by far the most abundant solid constituent of blood, and hence the specific gravity should be determined largely by the protein content.

Fractionation of the plasma proteins prior to separate analysis is based almost entirely on the classical methods using concentrated salt solutions, and the bulk of clinical literature is in terms of such fractions. Fractionation by electrophoretic mobility has not yet reached the stage of routine practicality, except possibly in a few of the larger institutions. For a further discussion of the various methods of fractionating the plasma proteins, see Chapter 22. The determination of blood hemoglobin content will be considered in a separate section.

2. Micro-Kjeldahl Method: Principle. Total proteins are determined in serum or plasma by a micro-Kjeldahl method employing direct nesslerization, making the appropriate correction for nonprotein nitrogen. Fibrinogen in plasma is determined by isolation as fibrin, followed by digestion and direct nesslerization. Albumin is determined by analysis of the fluid remaining after precipitating the globulin fraction with 23 per cent sodium sulfate solution. Globulin in serum is estimated by subtract-

¹⁴⁰ This method is a combined adaptation of the procedures of various authors. The direct nesslerization micro-Kjeldahl procedure of Wong (J. Biol. Chem., 55, 427 (1923)), employing persulfate for oxidation, is recommended because of its superiority when protein is present. Fractionation of the proteins with sodium sulfate solution follows the procedure of Howe (J. Biol. Chem., 49, 109 (1921)); this method is significantly improved by the use of ether to aid in separating the albumin and globulin fractions, as suggested by Kingsley (J. Biol. Chem., 133, 731 (1940)). Isolation of fibrinogen as fibrin is essentially according to Cullen and Van Slyke (J. Biol. Chem., 41, 587 (1920)). These latter authors point out the desirability of using a uniform amount of anticoagulant such as oxalate in comparative studies on plasma proteins, because of the effect of oxalate on water distribution between cells and plasma. They use 5-mg. of potassium oxalate per ml. of blood. For other methods of digestion and fractionation see Campbell and Hanna: J. Biol. Chem., 119, 1, 9, 15 (1937); Pillemer and Hutchinson: ibid., 158, 299 (1945). These latter authors use cold methyl alcohol for fractionation and claim their fractions agree closely with those obtained by electrophoretic separation.

ing the albumin from the total protein content; in plasma by subtracting albumin and fibrinogen from total protein.

Procedure: 141 Total Proteins (Albumin + Globulin + Fibrinogen): Dilute exactly 1 ml. of the serum or plasma to 50 ml. in a volumetric flask with 0.9 per cent sodium chloride solution. (If serum is used, the "total protein" will represent only albumin + globulin.) Using 1 ml. of this diluted mixture, proceed as directed below under "Digestion."

Fibrinogen: To 1 ml. of plasma in a small cylinder add 30 ml. of 0.9 per cent sodium chloride solution, followed by 1 ml. of 2.5 per cent calcium chloride solution. Mix with a slender pointed glass rod, leaving the rod in the mixture. Allow to stand for 30 minutes or until a solid clot has formed. Carefully rotate the rod in the jelly, squeezing out the water by pressing the clot against the side of the cylinder at the same time. All the fibrin should stick to the rod and appear ultimately as a thin white sheath over the rod. If any bits of clot escape this process, pour the cylinder contents onto a dry filter, and when the fluid has drained pick up the remaining clots with the tip of the rod and squeeze out the excess fluid by pressing against the side of the funnel. Transfer the rod and adhering fibrin to a piece of dry filter paper and dry as thoroughly as possible by rolling against the filter paper. Transfer the rod and dried fibrin to a centrifuge tube graduated at 10 ml. and containing 4 ml. of 1 per cent sodium hydroxide solution. Place tube and contents in a boiling water bath until the fibrin has dissolved and only a turbid suspension of calcium oxalate remains. This should require but a few minutes. Remove from the water bath, remove the rod, washing it down with a few ml. of water, and make up the contents of the tube to 10 ml. with water. Mix and centrifuge. Pipet a 5-ml. portion of the clear supernatant fluid to a digestion tube and proceed as described below under "Digestion." Albumin: To 1 ml. of serum or plasma in a 50-ml. centrifuge tube add ex-

actly 30 ml. of 23 per cent sodium sulfate solution. Stopper and mix by inversion. Add about 5 to 10 ml. of ether, again stopper, and shake vigorously. Centrifuge for about 10 minutes, capping the tube to prevent loss of ether. After centrifuging, the precipitated globulins should form a compact layer below the ether and above the clear albumin solution. Slant the tube and insert a pipet of narrow bore, and with the mouthpiece closed by the finger, along the side of the tube past the packed globulin layer into the clear fluid below. Fill the pipet with the fluid and transfer to a dry test tube, wiping off any precipitate adhering to the outside of the pipet before discharging its contents. Use 1 ml. of this for digestion as described below.

141 Reagents Required: 0.9 Per Cent Sodium Chloride Solution. Dissolve 9 g. of reagent-grade low-nitrogen sodium chloride in water, dilute to 1 liter, and mix. Stable indefinitely.

2.5 Per Cent Calcium Chloride Solution. Dissolve 25 g. of anhydrous reagent-grade calcium chloride in water, dilute to 1 liter, and mix. Stable indefinitely.

23 Per Cent Sodium Sulfate Solution. Dissolve 230 g. of anhydrous reagent-grade sodium sulfate in 600-700 ml. of water by warming and stirring. While still warm transfer to a 1-liter volumetric flask, dilute with water to the mark, and mix. Transfer to a clean bottle and place in the incubator or water bath at 37°. Keep at this temperature at all times, stoppered to prevent evaporation, since some of the salt will crystallize out if kept at room temperature.

1:1 Sulfuric Acid. Pour slowly and with stirring 1 volume of concentrated sulfuric acid into 1 volume of water. Cool, and keep stoppered to prevent absorption of ammonia from the air.

Persulfate Solution. Shake about 8 g. of reagent-grade nitrogen-free potassium persulfate in a glass-stoppered bottle with about 100 ml. of water. The undissolved excess settles to the bottom and helps keep the solution saturated even though there is gradual decomposition. Keep in the refrigerator, shake briefly and allow to settle before using, and prepare fresh every few weeks.

Standard Nitrogen Solution and Nessler Reagent. See p. 495.

145 On cold days some of the sodium sulfate may crystallize out during the centrifuging. If this happens, warm the tube and contents in the incubator at 37° until the crystals have redissolved, add more ether, shake, and again centrifuge as described.

If a centrifuge is not available, the mixture may be poured onto a retentive filter (such as Whatman No. 50) and covered with a watch glass to prevent evaporation. If the first portions of filtrate are not clear, return to the filter. Use 1 ml. of the clear filtrate.

Digestion: Into a pyrex test tube graduated at 35 and 50 ml. (see method for nonprotein nitrogen, p. 495) place 1 ml. (or 5 ml. in the case of fibrinogen) of the solution to be analyzed. Add 1 ml. of 1:1 sulfuric acid and a quartz chip or a few glass beads. Digest over a microburner as described for the determination of nonprotein nitrogen until excess water has been driven off, the solution darkens, and white fumes appear. When the tube is nearly full of dense fumes, cover the mouth of the tube with a watch glass and reduce the flame or raise the tube so that the mixture boils gently. Continue boiling for three minutes. Remove the burner and allow to cool for one minute. Add to the tube contents, drop by drop, 0.5 ml. of persulfate solution. Replace the burner, tap the tube to start boiling if necessary, and continue boiling until clear. Cool, dilute with water, and proceed with the direct nesslerization and colorimetric or photometric measurement exactly as described on p. 496 for the determination of nonprotein nitrogen. The same standard is used, containing 0.15 mg. of nitrogen, in the presence of 1 ml. of the 1:1 sulfuric acid and 0.5 ml. of persulfate solution, to balance the amounts present in the unknown. For photometric measurement the blank tube contains water, acid, and persulfate as described for the standard.

Calculation. For colorimetric measurement. Total Protein and Albumin are calculated directly, as follows:

$$\left[\left(\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.15 \times \frac{100}{\text{V}} \right) - \text{NPN} \right] \times \frac{6.25}{1000}$$
= grams of protein per 100 ml., (or per cent protein)

where V represents the actual volume of serum or plasma used in the determination; NPN represents the nonprotein nitrogen content in mg. per cent, as determined in a separate analysis. For total protein, V = 0.02; for albumin, V = 0.0323 (i.e., $\frac{1}{31}$).

Fibrinogen is calculated as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.15 \times 2 \times 100 \times \frac{6.25}{1000}$$

= grams of fibrinogen per 100 ml. of plasma

Globulin = Total Protein - (Albumin + Fibrinogen) in the case of plasma; for serum, Globulin = Total Protein - Albumin.

For photometric measurement, calculations are the same except that

the expression $\frac{\text{Density of Unknown}}{\text{Density of Standard}}$ replaces the expression

Reading of Standard Reading of Unknown

used in the colorimetric calculations. The limits of accurate colorimetric or photometric measurement are the same as those specified for the determination of nonprotein nitrogen on p. 497. If an analysis falls outside of

these limits, the digestion is repeated, using a smaller or larger aliquot as the case may be, and the calculations are corrected accordingly.

Interpretation. Normal values for plasma (or serum) proteins, in g. per 100 ml. of plasma or serum, are as follows: albumin, 4.6-6.7; globulin, 1.2-2.3; fibrinogen, 0.3-0.6. A major function of the plasma proteins (see Chapter 22) is to aid in the normal distribution of water between the blood and tissues, albumin being approximately twice as effective as globulin in this respect, gram for gram. Edema almost invariably occurs when the total plasma proteins fall below the critical level of 5.3 g, per 100 ml. Increased plasma protein levels are noted in dehydration, due to diminished fluid intake or pathologic loss of fluid from the body (diarrhea, vomiting, surgical or traumatic shock, excessive burns, Addison's disease); or when there is an absolute increase in globulin content, as in various anaphylactic conditions, malignancy, liver cirrhosis, and certain chronic infections. Decreased plasma protein is found after loss of plasma by extravasation or renal excretion (albuminuria) or when protein synthesis is impaired due to malnutrition, vitamin deficiencies, or diseases involving the digestive organs or liver. Fibrinogen values are increased in pneumonia and other infections accompanied by leukocytosis or suppuration, but are low in acute yellow atrophy of the liver, poisoning due to chloroform or phosphorus, and typhoid fever. High sedimentation rate of red blood cells is associated with increased fibringen values in plasma.

3. Method of Kingsley: 143 Principle. The diluted plasma or serum is treated with a special biuret reagent. The color developed is compared with that of a standard protein solution treated similarly. By suitable fractionation of serum before treatment with the biuret reagent, albumin may be determined separately. From the total serum protein and albumin contents, globulin is determined by difference. The method as described has been slightly modified to permit the determination of total protein, albumin, and globulin on the same sample of serum. 144

Procedure: 145 Transfer 0.5 ml. of unhemolyzed serum to a graduated centrifuge tube, or small (13 by 125 mm.) test tube graduated at 10 ml. Add

¹⁴² Kingsley: J. Lab. Clin. Med., 27, 840 (1942). See also Robinson and Hogden: J. Biol. Chem., 135, 707, 727 (1940); Mehl: ibid., 157, 173 (1945).

144 Modified by Prof. W. H. Summerson for use at the New York Hospital.

146 Reagents Required: 23 Per Cent Sodium Sulfate Solution. Dissolve 230 g. of anhydrous reagent-grade sodium sulfate in 600 to 700 ml. of water in a beaker by heating and stirring. While still warm transfer to a 1-liter volumetric flask, dilute with water to the mark, and mix. Transfer to a clean bottle, and place in the incubator or water bath at 37°. Keep at this temperature at all times, stoppered to prevent evaporation, since some of the salt will crystallize out if kept at room temperature.

Special Biuret Reagent. Prepare a saturated solution of sodium hydroxide which is carbonate-free (see Appendix). This saturated solution should contain about 75 g. of sodium hydroxide per 100 ml. after preparation. This may be checked by titration of a diluted portion. Measure 92 ml. of the carbonate-free saturated solution of sodium hydroxide, containing 69 g. of sodium hydroxide, into a 500-ml graduated cylinder, and add water to the 300-ml. mark. Add 100 ml. of a 1 per cent solution of crystalline copper sulfate, and stir to mix. Transfer to a clean bottle fitted with a rubber stopper. This reagent is stable for months at room temperature. The formation of a slight sediment does not appear to impair its usefulness, particularly in photometric measurements run with a blank and standard as described in the text.

Standard Protein Solution. Obtain a pooled lot of normal human serum (10-15 ml. will be

23 per cent sodium sulfate solution to the 10-ml. mark. Mix well by repeated inversion (but do not shake), and immediately pipet out a 2-ml. portion of the uniform suspension and place in a separate small test tube, which need not be graduated. This is tube "1," which will be used for the determination of total protein. To the remainder of the suspension in the centrifuge tube add about 3 ml. of ether, stopper, and shake vigorously. Centrifuge for about five minutes, capping the tube to prevent loss of the ether. After centrifuging, hold the tube in a slanting position and insert the tip of a 2-ml. transfer pipet of narrow bore along the side of the tube past the white layer of packed globulin precipitate and into the clear fluid below. Remove a 2-ml. portion of the clear fluid with the pipet, wipe off any precipitate adhering to the outside of the pipet, and transfer to a second test tube (tube "2"). This will be used for the albumin determination. For photometric measurement, place 2 ml. of the standard protein solution in a third tube, and 2 ml. of water alone in a fourth tube as a blank. For colorimetric measurement these latter two tubes are unnecessary since the unknown is compared against standards which have already been prepared (see below and footnote 145). To each tube add 4 ml. of the special bluret reagent, followed by 2 to 3 ml. of ether. Stopper, shake vigorously, and centrifuge for five minutes. By means of a pipet, transfer the solution under the ether layer to colorimeter cups or photometer cuvettes146 and read within the next 10 to 20 minutes, preferably as soon as possible, since on prolonged standing a slight turbidity may develop which requires further treatment with ether and centrifugation. For photometric measurement, set the photometer to zero density with the blank, at 520 mu.

If the total protein content alone is desired, the fractionation with sodium sulfate solution is omitted. Dilute 0.5 ml. of serum to 10 ml. with 0.9 per cent sodium chloride solution, mix, transfer a 2-ml. portion to a small test tube, and continue as described for "1" above. Alternatively, 0.1 ml. of serum, measured in a pipet calibrated "+ contain," may be pipetted into 1.9 ml. of 0.9 per cent sodium chloride solution in a test tube, the pipet being rinsed several times with the diluting fluid, and this 2-ml. portion treated with biuret reagent as described above.

Calculation. For colorimetric measurement, use a green filter (with maximal transmission at 520 m μ) over the eyepiece, set the unknown at 10 mm., and read against those two of the three standards described in

needed). Determine the total protein content of a portion by micro-Kjeldahl or macro-Kjeldahl analysis (see p. 495). Dilute 5 ml. of the remainder to 100 ml. in a volumetric flask with 15 per cent sodium chloride solution, and mix. Label with the total protein content, in grams per 100 ml., of the original serum, since this value is used in the calculations. This solution is usable for about a month if kept in the refrigerator at all times. A new solution may be standardized by colorimetric comparison with the previous standard if deterioration of the latter has not occurred. If this procedure is followed, check occasionally by the Kjeldahl method to avoid the possibility of error. Since with a particular photometer the density of a given standard is quite constant if the analysis is properly carried out, this is as good an index as any of possible changes in the standard.

For colorimetric measurement, three colored standards are prepared, representing the biuret reaction on sera at a level of approximately 3, 6, and 9 g. per cent total protein respectively. These standards are stable for at least one month if stored in the refrigerator. Standard I. To 1 ml. of serum of known protein content add 39 ml. of water and 80 ml. of the biuret reagent. Standard II. To 2 ml. of the serum add 38 ml. of water and 80 ml. of biuret reagent. Standard III. To 3 ml. of serum add 37 ml. of water and 80 ml. of biuret reagent. The equivalent protein values for these standards, used in the calculation, are as follows: Standard I, C/2; Standard II, C; Standard III, 3C/2; where C is the total protein content of the serum used, in grams per 100 ml.

146 If the photometer is equipped for use with small test tubes which can be centrifuged, these may be used for color development and subsequent reading, without the necessity for transfer.

footnote 145 which appear on inspection to be lower and higher respectively than the unknown. Calculate results as follows:

$$\frac{A \times \frac{R_L}{10} + B \times \frac{R_H}{10}}{2} = \text{grams of protein per 100 ml.}$$

where A and B represent the equivalent protein concentrations of lower and higher standards respectively, in grams per 100 ml. of serum, and $R_{\rm L}$ and $R_{\rm H}$ are the respective standard readings. If the unknown reading is within 10 or 15 per cent of either standard, the comparison with the other standard may be omitted, in which case the calculation becomes:

$$\frac{\text{Reading of Standard}}{10} \times C \times f = \text{grams of protein per 100 ml. of serum}$$

where C is the total protein concentration of the standard serum used, in grams per cent, and f is 0.5, 1.0, or 1.5 depending upon whether Standard I, II, or III is used.

Calculations for tubes "1" and "2" are the same, the value for "1" giving total protein in grams per cent, and the value for "2" giving albumin in grams per cent. Globulin = Total protein - Albumin.

For photometric measurement:

Total Protein.

 $\frac{\text{Density of "1"}}{\text{Density of Standard}} \times C = \text{grams of total protein per 100 ml. of serum}$ Albumin.

Density of "2" $\times C = \text{grams of albumin per 100 ml. of serum } Globulin.$

Total protein - albumin = grams of globulin per 100 ml. of serum

C is the total protein content of the (undiluted) standard serum, in grams per cent. At 520 m μ , and in a 1-cm. cuvette, a serum containing 7 g. per cent of total protein has a density of approximately 0.400, when corrected for the density of the blank (Fig. 173). Up to 11 g. per cent of total protein may be determined accurately under the conditions described. For higher values, or with deeper cuvettes, use 1-ml. portions instead of 2 in tubes "1" and "2," plus 1 ml. of water, and multiply the results by 2.

Interpretation. Values for most normal and pathological sera by this method show good agreement with micro-Kjeldahl determinations. Discrepancies have been noted under certain conditions, but it is not known whether this is due to alteration in nitrogen content or in biuret-reacting power. The method is known to give satisfactory clinical results. For further interpretation, see the preceding method.

4. Determination of Plasma or Serum Protein, Hemoglobin, and Cell Volume (Hematocrit) by the Copper Sulfate-Specific Gravity Method: 147 Principle. The specific gravity of whole blood, plasma, or serum is established by allowing small drops of the material to fall into a series of copper sulfate solutions of known and varying specific gravity and noting whether the drops rise, fall, or remain sus-

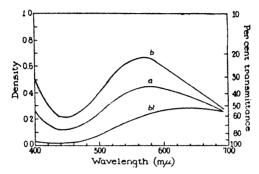

Fig. 173. Absorption spectra of colored solutions obtained in Kingsley method for protein, for biuret reagent alone (bl), and for biuret reagent in presence of serum containing 3.5 g. per cent total protein (a), and 7 g. per cent total protein (b). Solution depth, 1 cm.

pended under the defined conditions. From the specific gravity thus established, the plasma or serum protein, hemoglobin, and hematocrit values are obtained on the basis of an experimentally established relationship between these various quantities. If the plasma or serum protein content alone is to be determined, only plasma or serum is needed. Approximate hemoglobin and hematocrit values (within about 10 per cent) may be obtained with a few drops of whole blood alone. Accurate hemoglobin and hematocrit values are obtained by determining the specific gravity of both whole blood and its plasma.

Procedure: Venous blood is collected with a minimal amount of stasis (tourniquet applied for not over one minute). Capillary (finger tip) blood may be used, except in shock, for the approximate hemoglobin and hematocrit determination. To obtain plasma, transfer the blood immediately after drawing to a container having either a dried film of heparin sufficient to provide approximately 0.2 mg. for each ml. of blood expected, or a dried film of the Heller and Paul oxalate mixture¹⁴⁸ sufficient to provide not over 1 mg. per ml. of blood expected. Mix to dissolve, and centrifuge. If both whole blood and plasma are wanted, save a portion of the well-mixed blood

¹⁴⁷ As developed by Phillips, Van Slyke, Dole, Emerson, Hamilton, and Archibald, at the Hospital of The Rockefeller Institute for Medical Research, New York, N.Y. For a "gradient tube" method, based on a similar principle but using nonaqueous solvents in a single tube, and suitable for very small amounts of serum, see Lowry and Hunter: J. Biol. Chem., 159, 465 (1945).

149 Dissolve 3 g. of ammonium oxalate and 2 g. of potassium oxalate in water and dilute to 250 ml. Pipet 0.05 ml. of this solution for each ml. of blood to be received in a container (small test tube or bottle), spread in a film and dry in an incubator at 37° or in a vacuum desiccator. See Heller and Paul: J. Lab. Clin. Med., 19, 777 (1934).

for the whole blood determination and centrifuge the remainder to obtain the plasma. For serum protein determination, serum from ordinary clotted blood is used.

Prepare a series of standard copper sulfate solutions of known and varying specific gravity. 149 For the most accurate work, the series should be graded at intervals of 0.001 in specific gravity; for rougher work, intervals

of 0.004 suffice. For plasma and serum, the range of specific gravity covered should be 1.015 to 1.035; for whole blood 1.035 to 1.075.

fresh drop on solutions of higher or lower specific

gravity as the case may be, until a solution is

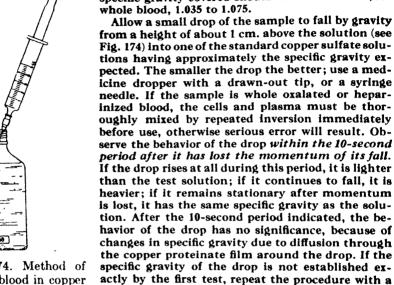

Fig. 174. Method of dropping blood in copper sulfate—gravity procedure.

found in which the drop either remains stationary, which gives the specific gravity of the sample, or there are two adjacent standards in one of which the drop rises, and in the other it falls. In this case interpolation between the values of the two standards is used; by noting the relative rate of rise and fall in the two solutions, it should be possible to interpolate to one-quarter of the difference in specific gravities between them. Thus by experience one should be able to tell whether the specific gravity of the drop is halfway between the two standards, or nearer to one than to the other.

If oxalated whole blood and plasma is used, correct the observed values for the oxalate by subtracting 0.0004 for each mg. of oxalate mixture present per ml. of blood, applying the correction to both whole blood and plasma results. Heparinized blood or serum requires no correction. Use the corrected values in obtaining results.

Calculation. From the determined specific gravities, results are obtained by reference to the line chart shown in Fig. 175. For approximate hemoglobin and hematocrit determination using whole blood alone, the blood is assumed to have a normal plasma specific gravity of 1.0264, and a line from this point on the left-hand scale of the chart is drawn across the chart to the determined whole blood specific gravity as measured on the right-hand scale. The hemoglobin content and hematocrit value is read from the interception of this line with the middle scale. Where both

plasma and whole blood specific gravities have been determined, the line is drawn connecting the two measured values on their respective scales, and the hemoglobin and hematocrit values read from the intercept on the middle scale. For plasma protein content, in grams per 100 ml., the left-hand scale is used. If serum is used instead of plasma, the same scale is used, the results then being in terms of grams of protein per 100 ml. of serum.

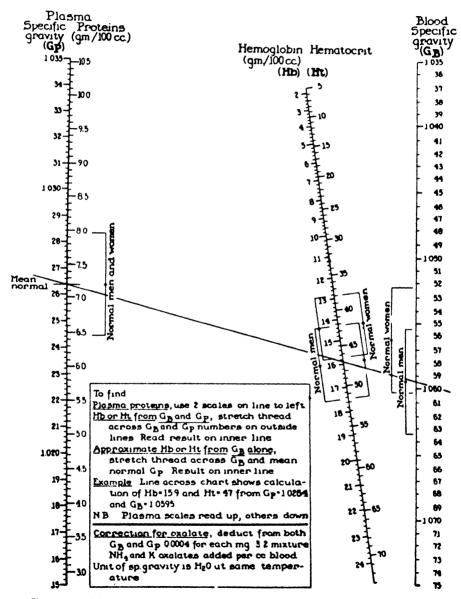

Fig. 175. Line chart for calculating plasma proteins, hemoglobin, and hematocrit from gravities of plasma and blood.

The copper sulfate solutions are permanent if kept stoppered to prevent evaporation. A given standard may be used over and over again, until one-fortieth its volume of blood, plasma, or serum has been added, i.e., one small drop per ml. Thus a 100-ml. portion serves for about 100 tests. For routine work, it is good practice to keep a record of the number of drops added to a given standard, and to discard it when the indicated limit has been reached. The solutions are self-cleaning, precipitated material ordinarily settling to the bottom. If any material should stick in the surface film, either during or after an analysis, it should be dislodged by tapping or removed with a wooden applicator stick before further use. The hemoglobin of whole blood will impart a greenish color to used standards; this does not impair their effectiveness. Temperature control is necessary only in the preparation of the standards, as described in the Appendix; once the standards are prepared, further temperature control is ordinarily unnecessary.

Interpretation. See previous methods.

5. Other Methods. The micro-Kjeldahl method may be made more accurate by distillation followed by nesslerization or titration; gasometric determination of the ammonia may also be used. See discussion of non-protein nitrogen determination on p. 498. The colorimetric method of Greenberg¹⁵⁰ is described in the Eleventh Edition of this book. The determination of the specific gravity is the basis of the "falling drop" method of Barbour and Hamilton,¹⁵¹ which has found considerable clinical application. For a turbidimetric method, see Looney and Walsh.¹⁵²

DETERMINATION OF HEMOGLOBIN

1. Introduction. In spite of the great clinical importance of hemoglobin determinations, as a rule they are the most poorly conducted of all blood chemical analyses. The majority of so-called office instruments in the hands of the average worker are known to give errors as high as 20 per cent. The very fact that a method is adapted for small amounts of blood should presuppose accurate calibration and use of pipets, careful dilution and color match, and frequent checking of both instrument and technician on blood of known hemoglobin content.

The standard method for the determination of hemoglobin, and the one upon which almost all others are ultimately based, is the determination by gasometric methods of the oxygen-binding power (oxygen capacity) of the blood. This method is described in detail in Chapter 24. An advantage of this method is that when properly carried out the results represent the functional hemoglobin of the blood, or that portion which is capable of carrying oxygen, 153 and do not include such nonfunctional pigment as methemoglobin, carbon monoxide hemoglobin, etc., as is the case with most of the other common methods. Results by the oxygen capacity

¹⁶⁰ Greenberg: J. Biol. Chem., 82, 545 (1929).

 ¹⁶¹ Barbour and Hamilton: J. Biol. Chem., 69, 625 (1926).
 ¹⁸² Looney and Walsh: J. Biol. Chem., 130, 635 (1939).

¹⁵³ The desirability of this distinction may be limited under certain conditions, as for example in methemoglobinemia. See also Rimington: Ann. Rev. Biochem., 12, 430 (1943).

method may be expressed directly in terms of oxygen, as volumes per cent, i.e., ml. of bound oxygen per 100 ml. of blood, or they may be converted to grams of hemoglobin by making use of the empirically established fact that 1 g. of hemoglobin is capable of combining with 1.36 ml. of oxygen under optimal conditions. Thus an oxygen capacity of 20 volumes

per cent corresponds to a hemoglobin content of 20/1.36, or 14.7 g. per 100 ml.

Another method for the determination of hemoglobin which is also suitable for standardization purposes. particularly in laboratories where gasometric equipment is not available, is to determine the total iron content of the blood. The iron content of hemoglobin has been accurately established at 0.340 per cent, 154 and the hemoglobin iron ordinarily represents 98 per cent or more of the total blood iron. Thus if the iron content is determined, the hemoglobin content may be accurately established. A simple and reliable colorimetric procedure for this purpose, developed by Wong, is described elsewhere in this section.

Direct colorimetric procedures for hemoglobin determination range from the most simple to the most

Fig. 176. Rieker-Dare hemoglobinometer.

complex, with a corresponding range in accuracy. They utilize either the color of the blood itself (diluted or undiluted as the case may be) or the color produced by treating blood with various reagents. The color is compared with, or measured in terms of, a standard color obtained from or representing a blood of known hemoglobin content. These procedures are best used in conjunction with the ordinary laboratory colorimeter or photometer as described below. For clinical purposes, a number of special "hemoglobinometers" of various types have been designed. The Dare hemoglobinometer (Fig. 176), one of the simplest of the more accurate clinical instruments, is based on comparison of a film of undiluted blood of uniform depth with a red glass plate of graduated intensity which has been suitably standardized. The widely used Sahli type of clinical hemoglobinometer (Fig. 177), is based on treatment of the blood with dilute acid to produce the brown "acid hematin" color, followed by dilution until the color exactly matches a standard brown glass plate. From the dilution required, the hemoglobin content is readily obtained. This instrument is frequently very carelessly used; with care, however, it is capable of giving results accurate to within

¹⁶⁴ Bernhart and Skeggs: J. Biol. Chem., 147, 19 (1948).

5 per cent or so. The development of the photoelectric cell has produced hemoglobinometers of which the Fisher "electrohemometer" is an example (Fig. 178). This is essentially a one-purpose desk-model photoelectric photometer; the blood sample, appropriately diluted in the glass tube, is placed in the instrument and the hemoglobin content read directly

from the scale, which is calibrated by the manufacturers.

For all hemoglobinometers supplied with a ready-made calibration, regardless of type or source, the desirability

Fig. 177. Sahli hemoglobinometer. (Courtesy, Klett Manufacturing Co.)

Fig. 178. Fisher Electro-hemometer. (Courtesy, Fisher Scientific Co.)

of checking the calibration at intervals with blood of known hemoglobin content cannot be overemphasized. Manufacturers do not use these instruments, they merely make them, and the conditions of calibration and use may vary from time to time and differ from laboratory to laboratory. Only by careful checking under the conditions of actual use is it possible to eliminate errors from this source.

It has been the custom among clinicians to express hemoglobin values in terms of per cent of some arbitrarily established normal. Unfortunately, there is no general agreement as to what the "normal" value should be, for the very good reason that the hemoglobin content of the blood of a normal individual depends upon such factors as age, sex, occupation, climate, altitude, and other environmental circumstances, etc., and is obviously also influenced by the red cell count of the blood and factors which cause normal variation in this respect. The confusion attendant to the use of "per cent of normal" is illustrated by the fact that a blood hemoglobin content of say 14.5 g. per 100 ml., which is an exact value, becomes "105 per cent of normal" on the Haldane scale, where 13.8 g. per cent is considered normal, and "84 per cent of normal" on the original Sahli scale, which considered 17.3 g. per cent as normal. The logical way to avoid this confusion, and one which is finding increasing clinical favor, is to express blood hemoglobin content in terms of grams of hemoglobin

per 100 ml. of blood, or volumes per cent oxygen capacity, whichever is preferred, without reference to any arbitrary "normal," interpreting the result if desired in terms of values obtained under similar circumstances from normal individuals of the same age and sex.

It is perhaps even more desirable to adjust the hemoglobin content to an arbitrary standard red cell count, usually 5,000,000. To illustrate, in their standardization of the copper sulfate-specific gravity method for hemoglobin and other blood proteins (p. 553), Phillips, Van Slyke, et al., found the average oxygen capacity of 20 normal adult men to be 21.6 vols. per cent, corresponding to a hemoglobin content of 15.9 g. per cent. If the average red cell count under these conditions is 5.4 million, an acceptable value, the hemoglobin content on the basis of 5.0 million red cells will be $15.9 \times 5.0/5.4$, or 14.7 g. per cent. ¹⁵⁵ In this connection, it is further of interest to note that while adult females have an apparent average hemoglobin content lower by about 1.0 g. per cent than adult males, this difference largely disappears if results are corrected for the variation in red cell count as described above. ¹⁵⁶

2. "Acid Hematin" Method of Cohen and Smith: 157 Principle. Blood is treated with dilute hydrochloric acid to produce a brown color ("acid hematin"). This is then compared with the color produced by similar treatment of a blood of known hemoglobin content.

Procedure: 158 Measure 0.05 ml. of blood from a freely flowing source into an accurate micropipet, calibrated "to contain." If the blood appears to be low in hemoglobin, it is advisable to use a double sample. Wipe off excess blood from the outside of the pipet, and blow the blood from the pipet into 10 ml. of dilute hydrochloric acid. Rinse the pipet thoroughly by sucking up the acid and blowing back several times. Allow to stand at room temperature for at least one hour to complete color development, or, if speed is essential, place in hot tap water (50 to 55°) for 10 minutes. 159 Read in the

156 Haden: loc. cit.

157 Cohen and Smith: J. Biol. Chem., 39, 489 (1919).

158 Reagents Required: Dilute Hydrochloric Acid. Dilute 10 ml. of concentrated hydrochloric acid to 1 liter with water and mix. This solution is approximately 0.1 normal; it need not be standardized.

Standard "Acid Hematin" Solution. Obtain a large sample of normal human blood and determine its hemoglobin content by either gasometric methods (Chapter 24) or the iron method of Wong (p. 564). On the basis of the hemoglobin content, dilute the blood with 0.1 N hydrochloric acid in a volumetric flask so that the resultant hemoglobin concentration is

3 per cent. Thus if the hemoglobin content is 14.2 g. per cent, dilute 21.1 ml.
$$\left(i.e., \frac{100 \times 3}{14.2}\right)$$

to 100 ml. with 0.1 N acid. Mix well and store in the refrigerator. This stock standard will keep for three months if kept cold and away from light. It must be well-mixed just before using, because the brown color is due to a colloidal suspension of hemin, which will settle out on standing. From the stock solution, the dilute standard is prepared fresh every week by diluting 5 ml. to 200 ml. in a volumetric flask with 0.1 N acid. Keep cold and away from light, and mix well before using. This dilute standard is an "acid hematin" solution equivalent to 0.075 g. per cent hemoglobin (i.e., to 15 g. per cent blood hemoglobin at a 1:200 dilution), For a method of preparing standard "acid hematin" solutions from crystalline hemin, see Elvehjem: J. Biol. Chem., 93, 203 (1931).

15 If both unknown and standard are treated with one-tenth volume of 10 per cent sodium hydroxide at this point, after color development and prior to reading, the pro-

¹⁸⁵ Haden's value on a 5.0 million red cell basis is 15.6 g. per cent (*J. Am. Med. Assoc.*, 79, 1496 (1922)). Dr. Ralph G. Stillman (personal communication) has summarized literature reports relative to 11 large cities throughout the world and finds an average value of 14.7 g. per cent computed in terms of a 5.0 million red cell count.

colorimeter or photometer against the standard "acid hematin" solution. For photometric measurement, set the photometer to zero density with water or dilute acid as a blank, at 520 my.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.075 \times \frac{100}{0.05} \times \frac{10}{100}$$

= grams of hemoglobin per 100 ml. of blood

In this calculation, the 0.075 represents the hemoglobin content of the standard, in g. per 100 ml.; the 0.05 is the volume of blood taken, and the 10 (more exactly 10.05) represents the volume to which the blood is diluted. If smaller or larger amounts of blood are used, at the same or different dilution volumes, change the calculation accordingly. A blue glass or gelatin filter over the eyepiece of the colorimeter improves the precision of color match.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.075 \times \frac{100}{0.05} \times \frac{10}{100}$$

= grams of hemoglobin per 100 ml. of blood

The "acid hematin" color, which is really a colloidal suspension of hemin (see Chapter 22), has no characteristic peak light absorption in the visible spectrum (Fig. 179). The choice of filter depends largely upon the sensitivity desired. At 520 m μ , and in a 1-cm. cuvette, the standard (equivalent to 15 g. per cent hemoglobin at a dilution of 1:200) has a density of approximately 0.500, and agreement with Beer's law is excellent over the entire range of hemoglobin content apt to be encountered.

This method has the advantage of a relatively permanent standard, in terms of which each unknown may be measured. It will probably be found that for a given photometer and filter or wavelength setting the density of the standard will be constant and reproducible from day to day if mechanical or other changes do not occur in the photometer and if measurements are made under uniform conditions. In this event, the established density of the standard may be used in the photometric calculations without the necessity of reading the standard at each analysis. To eliminate error due to any changes in calibration, however, it is advisable to check the standard reading at intervals.

Interpretation. The hemoglobin content as determined by either the "acid hematin" or "alkali hematin" methods represents total hemoglobin, i.e., the methods do not distinguish between hemoglobin itself and such nonfunctional derivatives as methemoglobin, carbon monoxide hemoglobin, etc. Thus the results are apt to be slightly high as compared to

cedure becomes the "alkali hematin" method of Wu (J. Biochemistry (Japan), 2, 173 (1922)), claimed to be superior to the "acid hematin" method. See, however, Ponder: J. Biol. Chem., 144, 339 (1942). Conditions of color measurement and calculations are the same as for the procedure described in the text.

oxygen capacity measurements, particularly in the case of city dwellers and chronic tobacco smokers, whose blood may contain up to 5 per cent of its total hemoglobin as carbon monoxide hemoglobin. The "acid hematin" method as described is not applicable to the blood of species possessing nucleated erythrocytes (i.e., birds) because of the turbidity caused by the nuclei; the "alkali hematin" method does not have this disadvantage.

In normal individuals, at birth the blood hemoglobin content may be over 21 g. per 100 ml. of blood, dropping to about half this value, of

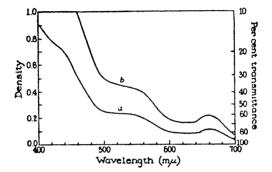

Fig. 179. Absorption spectra of colored solutions obtained in "acid hematin" method for hemoglobin, for (a) 7.5 g. per cent hemoglobin, and (b) 15 g. per cent hemoglobin, each at a 1: 200 dilution. Solution depth, 1 cm.

around 11 to 12 g. per cent, during the first six months after birth, and remaining at approximately this level up to about three years of age, after which there is a gradual increase until the age of 16 or so is reached. At this point, the hemoglobin content reaches a level which tends to be maintained throughout life; for males this level lies between roughly 14.5 and 16.0 g. per cent; for females, 13.5 and 15.0 g. per cent. As indicated on p. 559, the sex difference is due largely to differences in red cell count. This factor does not appear to explain the effect of age on hemoglobin content.

Aside from age and sex, other factors which influence the normal hemoglobin content include climate, altitude, exercise, menstruation, diurnal variation, and in general any factor which influences the red cell count or plasma volume. A decreased hemoglobin content is found in the various anemias, in pregnancy, after moderately severe or chronic hemorrhage, and following the excessive intake of fluids. An increased hemoglobin content, usually accompanied by an increase in red cell count (polycythemia) is found in hemoconcentration due to either shock or dehydration, in anoxia caused by either low oxygen pressure (high altitudes) or

¹⁶⁰ For adaptation of the "acid hematin" method to use with chicken blood, see Schultze and Elvehjem: J. Biol. Chem., 105, 253 (1934).

failure to properly oxygenate blood because of cardiac or pulmonary involvement, and experimentally after the administration of cobalt salts.

3. Method of Newcomer: 181 Principle. The blood is treated with dilute hydrochloric acid to produce the brown "acid hematin" color described for the previous procedure. This is then matched in a colorimeter against a brown glass plate which has been spectrophotometrically standardized to correspond to the color obtained from a known amount of hemoglobin.

Procedure: Measure out 0.01 (or 0.02) ml. of blood in an accurate micropipet calibrated "to contain." Transfer to 5 ml. of dilute (0.1 N) hydrochloric acid and allow the color to develop exactly as described in the previous procedure. While waiting for color development to become complete, fill each cup of the colorimeter with water, set the cups at 15 mm., and adjust the light so that both fields are of equal intensity. Insert the standard Newcomer plate in the left-hand light path; there is usually a slit above the plunger or a holder beneath the cup for this purpose; in some instruments the plunger is unscrewed and the mounted plate placed therein. When the unknown is ready, rinse the right hand cup with a portion (or dry the cup thoroughly before filling with unknown) and match against the plate in the usual way.

Calculation. For a plate exactly 1 mm. thick, Newcomer gives the following formula:

Reading of Unknown × Dilution = grams of hemoglobin per 100 ml.

of blood (per cent hemoglobin)

If 0.01 ml. of blood is used, the dilution is 501; for 0.02 ml., the dilution is 251. The factor 0.38 (plate factor) must be corrected if the thickness varies from 1 mm., by referring to correction tables of Newcomer in the article cited (1919). If some other factor has been established for a particular plate by the manufacturer, it should be used instead of the value given in the formula. The best procedure, however, is to calibrate one's own plate by running an analysis on blood of known hemoglobin content, or by matching against a standard "acid hematin" solution (see footnote 158, p. 559) in which case the plate factor becomes the only unknown in the above equation and is readily obtained. It is particularly to be noted that if a blue glass filter is used over the eyepiece of the colorimeter to improve color match, as is done in some laboratories, a different factor will be required than if the filter is not used. The correct factor must be known, or established by calibration.

Interpretation. See previous procedure.

4. Direct Photometric Method: Principle. Blood is diluted in weakly alkaline solution. The color intensity is then measured in a photometer at 540 m μ , and the hemoglobin content estimated from the established reading of a blood of known hemoglobin content under similar conditions. In the procedure described here, very dilute ammonia solution is used for diluting the blood; 0.1 per cent sodium carbonate solution

¹⁶¹ Newcomer: J. Biol. Chem., 37, 465 (1919); 55, 569 (1923).

has also been proposed for this purpose.¹⁶² If the diluted blood is treated before reading with a source of carbon monoxide gas, such as ordinary illuminating gas, the procedure becomes the more exact carbon monoxide hemoglobin method of Palmer.¹⁶³

Procedure: Collect 0.02 ml. of blood in an accurate micropipet calibrated "to contain." Wipe off excess blood from the outside of the pipet, and transfer the blood to 5 ml. of dilute ammonium hydroxide solution. In a test tube. Rinse the pipet with the solution by filling and emptying several times. Mix, transfer to a suitable container if necessary, and read in the photometer at 540 my. Set the photometer to zero density with a blank of the dilute ammonia solution alone. For the Palmer procedure, bubble illuminating gas through the solution (in the hood) for about 30 seconds before reading in the photometer at 540 my.

Calculation.

Density of Unknown $\times F$ = grams of hemoglobin per 100 ml. of blood

F is a factor established by running the above-described procedure on a blood of known hemoglobin content. Obtain a sample of normal human blood and determine its hemoglobin content by either the gasometric method (Chapter 24) or, if gasometric equipment is not available, by the method of Wong described on p. 564. Treat duplicate or triplicate portions of this standard blood by the procedure described above. From the determined density and the hemoglobin content, calculate F as follows:

$$F = \frac{\text{Hemoglobin content, in g. per cent}}{\text{Density}}$$

Once established for a given photometer and filter or wavelength setting, the value of F will ordinarily be constant unless mechanical or other changes occur in the photometer. Checking the calibration at intervals will eliminate errors due to change in the value of F. In general, the calibration factor for one instrument and filter is not applicable to another instrument or filter, even of the same make.

At 540 m μ , and in a 1-cm. cuvette, a blood with 15.0 g. per cent hemoglobin has a density of approximately 0.500 when simply diluted as described; after carbon monoxide treatment, the density is approximately 0.550. For spectrophotometric data, see Fig. 131, p. 427. Beer's law is valid over the entire range of hemoglobin content apt to be encountered. For measurement using deeper cuvettes, measure the blood into 10 ml. of ammonia solution instead of 5 ml., establishing F on the same basis.

Interpretation. In the absence of significant amounts of abnormal blood pigments, both the simple dilution procedure and the Palmer method are known to give satisfactory results. The Palmer method is more accurate, since it is free from any error due to the presence of carbon monoxide hemoglobin in the blood as drawn. The chief disadvantage of the Palmer method in the past has been the difficulties associated with

¹⁶² Sanford, Sheard, and Osterberg: Am. J. Clin. Path., 3, 405 (1933).

¹⁴¹ Palmer: J. Biol. Chem., 33, 119 (1918).

¹⁶⁴ Dilute 4 ml. of concentrated ammonium hydroxide to 1 liter with water and mix. Stable indefinitely.

the preparation and maintenance of a suitable standard; this is eliminated by photometric calibration. The illuminating gas must of course be free from substances other than carbon monoxide which are capable of reacting with hemoglobin. If the blood contains significant amounts of methemoglobin, results will be in error. For the photometric determination of methemoglobin and total hemoglobin in the presence of methemoglobin, see the method of Evelyn and Malloy (p. 566). For other aspects of interpretation, see previous methods.

5. Method of Wong: 165 Principle. The iron is detached from the hemoglobin molecule by treatment with concentrated sulfuric acid in the presence of potassium persulfate, without heating. After removal of the proteins by tungstic acid, the iron in the filtrate is determined colorimetrically. From the total iron content, the hemoglobin content is readily obtained, since hemoglobin contains 0.34 per cent of iron, and only about 1 to 2 per cent or less of the total blood iron is nonhemoglobin iron.

Procedure: 166 With an Ostwald or micropipet, accurately transfer 0.5 ml. of well-mixed oxalated whole blood to a 50-ml. volumetric flask. Add 2 ml. of iron-free concentrated sulfuric acid. Mix by whirling one to two minutes. Add 2 ml. of saturated potassium persulfate solution. Mix and dilute to about 25 ml. with water. Add 2 ml. of 10 per cent sodium tungstate solution. Mix. Cool to room temperature under the tap, and dilute to volume with water. Stopper and mix by inversion. Filter through a dry paper, collecting the filtrate in a dry flask. Prepare a standard in a second 50-ml. volumetric flask by adding to about 25 ml. of water in the flask the following: 2 ml. of concentrated sulfuric acid, 2 ml. of saturated potassium persulfate solution, and 2.5 ml. of standard iron solution containing 0.1 mg. of ferric iron per ml. Cool to room temperature, dilute with water to the mark, and mix. For photometric measurement, prepare a blank similar to the standard except that the standard iron solution is omitted.

Measure 10 ml. of unknown filtrate, standard, and blank if necessary, into separate test tubes. To each add 0.5 ml. of saturated persulfate solu-

¹⁶⁵ Wong: J. Biol. Chem., 77, 409 (1928). Hanzal (Proc. Soc. Exptl. Biol. Med., 30, 846 (1933)) uses sulfuric acid and hydrogen peroxide to effect complete oxidation of organic matter, followed by the thioglycollic acid colorimetric procedure described as an alternate method in the text. For a modification of the Wong method, claimed to be superior, see Ponder: J. Biol. Chem., 144, 333 (1942).

166 Reagents Required: Concentrated Sulfuric Acid, iron-free.

Saturated Polassium Persulfate Solution. Shake 7 to 8 g. of reagent-grade iron-free potassium persulfate with 100 ml. of water in a glass-stoppered bottle. The undissolved excess settles to the bottom and compensates for loss by decomposition. Shake briefly before using. Keep in the refrigerator.

10 Per Cent Sodium Tungstate Solution. Dissolve 100 g. of reagent-grade iron-free sodium tungstate in water and dilute to 1 liter. Of the various reagents, it is most important that the tungstate be iron-free, since it is the only reagent whose iron content is not corrected for in photometric measurement by the use of a blank as described in the text.

Standard Iron Solution. Dissolve 0.702 g. of reagent-grade crystalline ferrous ammonlum sulfate ("Mohr's salt") in 100 ml. of water. Add 5 ml. of concentrated sulfuric acid, warm slightly, and add concentrated potassium permanganate solution drop by drop until 1 drop produces a permanent color. Transfer to a 1-liter volumetric flask with rinsings, dilute to the mark, and mix. This solution contains 0.1 mg. of ferric iron per ml., and is stable indefinitely.

3 N Potassium Thiocyanate Solution. Dissolve 146 g. of reagent-grade potassium thiocyanate in water and dilute to 500 ml. Filter if turbid. Add 20 ml. of pure acetone to improve the keeping quality. Deterioration will be evidenced by the rapid formation of a yellow color in the blank test described in the procedure.

Thioglycollic Acid. Obtainable from Eastman Kodak Co., Rochester, New York. Concentrated Ammonium Hydroxide, iron-free.

tion followed by 2 ml. of 3 N potassium thiocyanate solution. Mix by inversion and read in the colorimeter or photometer within the next 30 minutes. For photometric measurement, set the photometer to zero density with the blank, at 480 my.

An alternate procedure for color development using thioglycollic acid is as follows: to the 10-ml. portions in small flasks or test tubes as described above, add 0.1 ml. of thioglycollic acid, 167 and 2 ml. of concentrated ammonium hydroxide. Mix well, cool to room temperature by placing in cold water, and read in the colorimeter or photometer at any time within the next hour. Just before reading, shake again; the color may fade on pro-

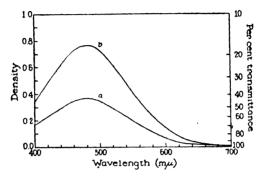

Fig. 180. Absorption spectra of colored solutions obtained in Wong method for iron and hemoglobin, for standards containing (a) 1.25 mg., and (b) 2.5 mg. of iron in 50 ml. Solution depth, 1 cm.

longed standing but it can be immediately restored by shaking in air. For photometric measurement, set the photometer to zero density with the blank, at 540 m $_{\rm H}$.

Calculation. For colorimetric measurement, using either the thiocyanate or thioglycollic acid procedure:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.25 \times \frac{100}{0.5} \times \frac{1}{3.4}$$
= grams of hemoglobin per 100 ml. of blood

The value 1/3.4 represents the fact that 1 g. of hemoglobin contains 3.4 mg. of iron. If this factor is omitted in the calculations, the result gives mg. of total iron per 100 ml. of blood. Under ordinary circumstances, less than 2 per cent of the total blood iron is from sources other than hemoglobin; this nonhemoglobin iron is therefore neglected in the calculation of hemoglobin content, or a suitable correction may be made.

For photometric measurement, using either procedure:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.25 \times \frac{100}{0.5} \times \frac{1}{3.4}$$

= grams of hemoglobin per 100 ml. of blood

The thiocyanate color has maximum absorption at about 480 mµ. (Fig. ¹⁶⁷ Burmester (J. Biol. Chem., 105, 189 (1934)) adds sodium sulfite solution prior to adding the thioglycollic acid, to reduce the persulfate. This does not appear to be necessary.

180). At this wavelength, and in a 1-cm. cuvette, the density of the standard described is approximately 0.750. Since the standard corresponds to a blood iron content of 50 mg. per cent, equivalent to 14.7 g. per cent hemoglobin, all values of hemoglobin ordinarily encountered may be satisfactorily determined under these conditions. With deeper cuvettes, use a 5-ml. aliquot of filtrate instead of 10 ml., add 5 ml. of the reagent blank solution used to set the photometer to zero density, develop and read the color as described, and multiply the results by 2. If a filter at 480 m μ is not available, equally satisfactory results at about 40 per cent lower scale reading may be obtained at 420 or 520 m μ .

The thioglycollic acid color has maximum absorption at 540 m μ . As compared to the thiocyanate color, the density of the standard under similar conditions is considerably less, being approximately 0.240 at peak absorption. This is not too low for accurate photometric measurement, however, and the color is superior in many respects to the thiocyanate color for analytical purposes. Excellent agreement with Beer's law is found up to double the standard concentration at almost any wavelength between 400 to 580 m μ . The only disadvantage appears to be a tendency of the color to fade on standing; as already mentioned, restoration to the original value is easily accomplished by brief shaking in air.

Interpretation. This method is recommended for standardization of other hemoglobin procedures in the absence of facilities for determining oxygen capacity. For other aspects of interpretation, see previous methods.

6. Photometric Determination of Methemoglobin and Total Hemoglobin: Method of Evelyn and Malloy: Principle. Methemoglobin has a characteristic light absorption at 635 m μ (see Fig. 131, p. 427); this absorption is abolished in the presence of cyanide, which converts methemoglobin to cyanmethemoglobin. The difference in light absorption at 635 m μ before and after adding cyanide is a measure of the methemoglobin present. Total hemoglobin is determined by converting all the hemoglobin present to cyanmethemoglobin and measuring the light absorption at 540 m μ . Evelyn and Malloy also describe a procedure for measuring sulfhemoglobin with the same sample; this is omitted here because of the uncertainty associated with standardization. For details, see original article.

Procedure: 169 Transfer 0.1 ml. of capillary or well-mixed oxalated venous blood to a test tube containing 10 ml. of M/60 phosphate buffer at pH 6.6. Mix and allow to stand five minutes.

¹⁶⁸ Evelyn and Malloy: J. Biol. Chem., 126, 655 (1938).

¹⁶⁰ Reagents Required: M/15 Phosphate Buffer, pH 6.6. Dissolve 9 g. of Na₂HPO₄·12H₂O and 5.7 g. of anhydrous KH₂PO₄ in water and dilute to 1 liter.

M/60 Phosphate Buffer, pH 6.6. To 1 volume of M/15 phosphate buffer, pH 6.6, add 3 volumes of water, and mix.

²⁰ Per Cent Potassium Ferricyanide. Dissolve 20 g. of reagent-grade potassium ferricyanide in water with the aid of heat, cool, and dilute to 100 ml. Dispense from a dropper bottle which delivers about 25 drops per ml. To prepare the 5 per cent solution, dilute 1 volume of the 20 per cent solution with 3 volumes of water.

¹⁰ Per Cent Sodium Cyanide. (Poisonous!) To 5 g. of reagent-grade sodium cyanide in a beaker, add 50 ml. of water, and stir to dissolve. Transfer to a dropping bottle for dispensing, as above.

- (a) Methemoglobin. Determine the density of the solution in a photometer at 635 my, setting the photometer to zero density with water. This is reading D₁. Add 1 drop of neutralized sodium cyanide to the entire 10-ml. sample, mix, allow to stand two minutes, and make a second reading, D₂, under the same conditions as the first reading. The difference between D₁ and D₂ is the measure of the methemoglobin content which is calculated as described below. Any slight turbidity present is immaterial, since it is the same in both readings.
- (b) Total Hemoglobin. Use either the sample treated with cyanide as just described, or the original 1:101 dilution of the blood if total hemoglobin alone is to be determined. Add 1 drop of concentrated ammonium hydroxide to the entire 10-ml. sample to clear it, mix, and transfer a 2-ml. portion to a test tube containing 8 ml. of M/15 phosphate buffer at pH 6.6 and 1 drop of 20 per cent potassium ferricyanide. Mix and allow to stand two minutes to convert hemoglobin to methemoglobin. Add 1 drop of 10 per cent sodium cyanide, mix, and again allow to stand two minutes for the formation of cyanmethemoglobin. Determine the density in the photometer at 540 my, setting the photometer to zero density with a blank consisting of 10 ml. of M/15 phosphate buffer plus 1 drop each of the ferricyanide and the sodium cyanide solutions. Let this reading be D₁.

Calculation. (a) Methemoglobin.

 $(D_1 - D_2) \times F_M = \text{grams of methemoglobin per 100 ml. of blood}$

where F_M is a factor expressing the relationship between a known amount of methemoglobin and the change in density at 635 m μ after adding cyanide. This factor is established as described below.

(b) Total Hemoglobin.

 $D_3 \times F_T = \text{grams of total hemoglobin per 100 ml. of blood}$

where F_T is the calibration factor for hemoglobin as cyanmethemoglobin, determined as described below.

Determination of Calibration Factors.¹⁷⁰ Obtain a sample of normal human blood and determine its hemoglobin content by either the gasometric method (Chapter 24) or the iron method of Wong (p. 564). Of the well-mixed blood, transfer 0.1 ml. to a tube containing 9.9 ml. of M/60 phosphate buffer at pH 6.6 and 0.1 ml. of 5 per cent potassium ferrievanide solution. Mix, allow to stand two minutes, and then determine the density (= D_1) in the photometer at 635 m μ , setting to zero density with a blank consisting of 10 ml. of the phosphate buffer plus 0.1 ml. of the ferricyanide. After the reading has been made, add 1 drop of neutralized sodium cyanide solution to both the entire sample and blank, mix, and allow to stand two-minutes, and again determine the density

Neutralized Sodium Cyanide. (Poisonous!) Mix 1 volume of 10 per cent sodium cyanide solution and 1 volume of 12 per cent acetic acid (12 ml. of glacial acetic acid diluted to 100 ml. with water). Add the acid to the cyanide (not the reverse) quickly with mixing, in the hood. Make only as much as will be used up within an hour, transferring it to a small dropping bottle for dispensing. Avoid exposure to vapors from the solution.

Concentrated Ammonium Hydroxide, in a dropping bottle as above.

176 Evelyn and Malloy do not describe the obtaining of calibration factors, but give instead the numerical values for the various factors as established by them for the Evelyn photoelectric colorimeter. The factors given by Evelyn and Malloy may be employed under their conditions, but independent verification is suggested.

 $(= D_2)$ against the blank, at the same wavelength. The factor F_M is calculated as follows:

$$\frac{\text{Hemoglobin content of blood, in g. per cent}}{(D_1 - D_2)} = F_M$$

To illustrate: in a 1-cm. cuvette under the conditions described, a blood of 15.2 g. per cent hemoglobin content gave a D₁ reading of 0.357 and a D₂ reading of 0.055. The factor is therefore

$$\frac{15.2}{(0.357 - 0.055)} = \frac{15.2}{0.302} = 50.4$$

To obtain F_{τ} , dilute a 2-ml. portion of both the ferricyanide-cyanide treated standard and blank to 10 ml. with water and mix. Set the photometer to zero density at 540 m μ with the blank, and determine the density of the standard (= D₃).

$$F_T = \frac{\text{Hemoglobin content of standard, in g. per cent}}{D_3}$$

To illustrate: the D₃ reading for the blood containing 15.2 g. per cent hemoglobin was 0.211. Therefore $F_{\tau} = 15.2/0.211 = 72.0$.

Once they have been carefully established for a particular photometer and filter or wavelength setting, these factors should be valid indefinitely unless mechanical or other changes occur in the photometer. Checking at intervals will eliminate errors due to such changes.

Interpretation. The limit of precision of both the methemoglobin and total hemoglobin methods as described here is about 0.1-0.2 g. per cent. Using these methods with a Beckman spectrophotometer, in a study of 14 normal young men daily over a four-day period it was not possible to find even 0.1 g. per cent of methemoglobin in any except three random samples.¹⁷¹ Paul and Kemp, ¹⁷² using a similar procedure but at a lower dilution of blood (and therefore possibly increased sensitivity), claim that small amounts of methemoglobin (0.03 to 0.13 g. per cent) are regularly present in normal blood. Increased methemoglobin content (methemoglobinemia) is associated with the administration of a variety of drugs, such as nitrites, aniline and derivatives, sulfanilamide, acetanilide, etc. When the drug is discontinued, the methemoglobinemia begins to decrease; it is thought that methemoglobin can be converted back to hemoglobin in the red cell, hence any evident methemoglobinemia presumably represents a balance between rate of production and rate of reconversion to hemoglobin. 173

The cyanmethemoglobin method for total hemoglobin is considered to be one of the most accurate of the colorimetric methods. Results will be slightly in error in the few instances where the relatively rare pigment

¹⁷² Paul and Kemp: Proc. Soc. Exptl. Biol. Med., 56, 55 (1944).

¹⁷³ Cox and Wendel: J. Biol. Chem., 143, 331 (1942).

sulfhemoglobin is present; Evelyn and Malloy (loc. cit.) discuss this possibility of error and describe a correction for it. For further aspects of interpretation, see previous methods.

7. Other Methods. Hemoglobin may be quickly and accurately determined, along with the total plasma protein, by the copper sulfate-specific gravity method (p. 553). The use of pyridine hemochromogen has also been advocated as a basis for colorimetric or photometric measurement.¹⁷⁴ Among the advantages claimed is that the method may be accurately standardized using pure hemin. Ultra-micro-methods based on the benzidine color test for blood (see Chapter 22) have been described by Wu¹⁷⁵ and by Bing and Baker.¹⁷⁶ For the colorimetric determination of carbon monoxide hemoglobin, see p. 446. Gasometric procedures for the determination of hemoglobin, carbon monoxide hemoglobin, and methemoglobin are described in Chapter 24.

DETERMINATION OF LACTIC ACID

- 1. Introduction. Blood lactic acid is ordinarily determined by conversion to acetaldehyde which is then measured by titrimetric or colorimetric methods. A gasometric procedure based upon oxidation with permanganate to produce carbon dioxide has also been described.¹⁷⁷ Of the various methods, the colorimetric method described here is by far the most sensitive, being readily applicable to 0.1 ml. or less of blood. In obtaining blood for lactic acid determination, precautions must be observed against the conversion of blood glucose to lactic acid on standing ("glycolysis"). The use of fluoride as anticoagulant (see p. 491) will prevent glycolysis; if oxalate or heparin are used, the protein-free filtrate should be prepared as soon as possible after drawing the blood.¹⁷⁸
- 2. Method of Barker and Summerson:¹⁷⁹ Principle. The glucose and other interfering material of the protein-free blood filtrate is removed by the Van Slyke-Salkowski method of treatment with copper sulfate and calcium hydroxide. An aliquot of the resulting solution is heated with concentrated sulfuric acid to convert lactic acid to acetaldehyde, which is then determined colorimetrically by reaction with p-hydroxydiphenyl in the presence of copper ions.

Procedure: 180 Deproteinize the blood sample (whole blood, plasma) with either tungstic acid (p. 493), trichloroacetic acid (p. 579), or zinc hydroxide (p. 524)

177 Avery and Hastings: J. Biol. Chem., 94, 273 (1931).

178 Friedmann and Haugen (J. Biol. Chem., 144, 67 (1942)) describe a procedure in which the drawn blood is ejected directly from the syringe into the protein-precipitating fluid.

179 Barker and Summerson: J. Biol. Chem., 138, 535 (1941).

100 Reagents Required: 20 Per Cent Copper Sulfate. Dissolve 400 g. of CuSO, 5H:O in about 1 liter of water with the aid of heat, cool, dilute to 2 liters, and mix. Stable indefinitely.

4 Per Cent Copper Sulfate. Dilute 1 volume of 20 per cent copper sulfate solution to 5 volumes with water and mix. Store in a bottle fitted with a stopper carrying a 1-ml. pipet which delivers approximately 20 drops per ml. If this is done, 1 drop may be used instead of the 0.05-ml. portion specified in the text.

Calcium Hydroxide, Powder. Either the U.S.P. or C.P. grades are satisfactory. It is con-

at a 1:10 dilution. Transfer 2 ml. of the protein-free filtrate, representing 0.2 ml. of blood, to a centrifuge tube graduated at 10 ml. In a second similar tube place 5 ml. of standard lactic acid solution, containing 0.01 mg. of lactic acid per ml. In a third tube place a little water; this is a blank, and serves to control the small amount of color yielded by the reagents alone. To each tube add 1 ml. of 20 per cent copper sulfate solution and dilute to the 10-ml. mark with water. Add 1 g. of powdered calcium hydroxide to each tube, stopper, 181 and shake vigorously until the solids are uniformly dispersed. Allow to stand for one-half hour, repeating the shaking at least once in the interim. Centrifuge down the precipitate, and transfer duplicate 1-ml. portions of the supernatant from each tube to thoroughly clean and dry test tubes having an internal diameter of 18 to 23 mm. 182 To each tube add 0.05 ml. of 4 per cent copper sulfate solution, followed by 6 ml. of concentrated sulfuric acid from a buret. The sulfuric acid should be added drop by drop at first, mixing the contents of the tube well during the addition. The tube contents will become hot; it is not necessary to cool the tube. After the acid has been added to all the tubes, place them upright in boiling water for five minutes, then transfer the tubes to cold water (preferably running) and cool to 20° C. or below. When the contents of the tubes are sufficiently cool (but not before) add 0.1 ml. of the p-hydroxydiphenyl reagent, drop by drop, to each tube. The reagent precipitates out on entering the concentrated acid; it is dispersed throughout the solution as quickly and uniformly as possible by lateral shaking. When the reagent has been added, place the tubes in a beaker of water at 30° C. and allow to stand for 30 minutes or longer. Redisperse the precipitated reagent at least once during this period. Finally place the tubes in vigorously boiling water for exactly 90 seconds, remove, and cool in cold water to room temperature.

veniently dispensed with a spoon spatula known to hold approximately 1 g., since exact measurement is unimportant.

Sulfuric Acid, Concentrated. Reagent-grade iron-free sulfuric acid is satisfactory. It is dispensed from a buret, suitably protected against absorption of atmospheric moisture. The buret stopcock is cleaned thoroughly of grease and lubricated with a little of the acid itself. In delivering, precautions should be taken against error due to the slow drainage of the viscous acid. According to Russell (J. Biol. Chem., 156, 463 (1944)), nitrates and nitrites in the acid will interfere; only grades with low nitrate content are selected, and if a particular lot shows poor color development it is discarded.

p-Hydroxydiphenyl Reagent. Dissolve 1.5 g. of p-hydroxydiphenyl (obtainable from the Eastman Kodak Co., Rochester, N.Y.) in 10 ml. of 5 per cent sodium hydroxide solution, plus a little water, by warming and stirring, and dilute to 100 ml. with water. Store in a brown bottle fitted with a stopper and pipet capable of delivering 20 drops per ml. If this is done, 2 drops may be used instead of the 0.1-ml. portion specified in the text. The reagent is stable for many months; deterioration is evidenced by high blank readings.

Standard Lactic Acid Solution. This is prepared preferably from lithium lactate, which is anhydrous. (For the method of preparing pure lithium lactate, see Chapter 32). For the stock standard, dissolve 0.213 g. of pure dry lithium lactate in about 100 ml. of water in a 1-liter volumetric flask, add about 1 ml. of concentrated sulfuric acid, dilute to the mark with water, and mix. This solution contains 1 mg. of lactic acid in 5 ml., and is stable indefinitely if kept in the refrigerator. To prepare the working standard, dilute 5 ml. of stock standard to 100 ml. in a glass-stoppered volumetric flask with water and mix. This solution contains 0.01 mg. of lactic acid per ml., and is best prepared fresh daily.

181 Glass-stoppered tubes may be used, or, if unavailable, cover the mouth of the tube with a small square of "parafilm," fresh surface down, held in place by the finger tip. "Parafilm" may be obtained from laboratory supply houses. In this and other phases of the procedure, contact of the solutions with the skin must be avoided because of the possibility of contamination with lactic acid from the skin surfaces.

182 Wide test tubes are specified to facilitate thorough mixing by lateral shaking; this is more important than usual because of the viscosity of the concentrated acid used as solvent. After use, the tubes are best cleaned by simply rinsing in hot tap water, followed by distilled water, and drying by drainage or in an oven. None of the glassware used in this procedure should be cleaned with chromic acid cleaning mixture. Hot soapy water followed by thorough rinsing with distilled water is adequate.

Transfer the colored solutions to suitable containers and determine the photometric density at 560 m_{μ} , using water for setting the photometer at zero density.

Micro-method for 0.1 ml. of Blood; 182 Transfer 0.1 ml. of blood, accurately measured in a pipet calibrated "to contain," to about 5 ml. of water in a centrifuge tube graduated at 10 ml. Rinse the pipet several times with the diluting water. Add 1 ml. of 20 per cent copper sulfate solution, dilute to 10 ml. with water, and follow with 1 g. of powdered calcium hydroxide, shaking, centrifuging, etc., as described for the regular procedure. For color development, measure duplicate 1-ml. portions of the copper-lime supernatant into wide test tubes, add 1 drop of 4 per cent copper sulfate solution, and evaporate to dryness by placing the tubes upright in a boiling water bath or in a drying oven. All water must be driven completely from the tubes. To the dried residue add 1 ml. of water, followed by 6 ml. of concentrated sulfuric acid with mixing, as described for the regular procedure. Further steps in color development and reading are exactly the same as for the regular procedure, using the same standard, which may be taken to dryness or not as desired since results with the standard are the same either wav.

Calculation. Average the duplicate results on the blank to obtain the blank density. Subtract this value from the averages of standard and unknown to obtain their true densities. Since the 1-ml. portion of copper-lime supernatant used for color development contains 0.005 mg. of lactic acid in the case of the standard, and in the regular procedure represents 0.02 ml. of original blood in the unknown (i.e., a dilution of 50), the calculation in this case is as follows:

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.005 \times 50 \times 100$

= mg. of lactic acid per 100 ml. of blood

In the micro-procedure the dilution is 100, and this value replaces the 50 in the above calculation.

It is recommended that the average blank density be determined separately as described to minimize error due to possible variation in the blank. If desired, a single blank tube may be run and used for setting the photometer to zero density, in which case the average measured densities of standard and unknown are used directly in the calculation. The blank color is ordinarily about 10 per cent of the standard color. In a 1-cm. cuvette, at 560 m μ , the standard described (equivalent to 25 mg. per cent blood lactic acid) has a density of approximately 0.400 (Fig. 181) and up to 60 mg. per cent blood lactic acid may be accurately determined. For higher values, or with deeper cuvettes, use smaller aliquots of filtrate and standard for the copper-lime treatment (or, in the micro-procedure, a smaller volume of blood), but keep the final volume at 10 ml. at this stage, using the same amounts of 20 per cent copper sulfate solution and calcium hydroxide as described. Correct the calculations as necessary.

¹⁸⁸ As developed by Summerson, on the basis of the observation by Summerson and Neuwirth (unpublished) that interference from free acetaldehyde, which is present in red cells and is not removed by the copper-lime treatment alone (see Barker and Summerson: loc. cit.; Barker: J. Biol. Chem. 137, 783 (1941)), is eliminated by evaporating to dryness in the presence of copper as described.

Interpretation. Venous blood of normal individuals in the resting state contains 5 to 20 mg. of lactic acid per 100 ml. ¹⁸⁴ During severe exercise this may rise to well over 100 mg. per cent, decreasing rapidly during recovery. Pathologically, increased blood lactate content is noted in general whenever there is a deficient supply of oxygen to the tissues (pneumonia, heart failure) or the organism is unable to maintain the normal equilibrium between lactate production and utilization, as after the administration of anesthetics and in liver disease. Usually the presence of excessive amounts of blood lactate is at the expense of equivalent amounts of blood bicarbonate, and an acidosis results. This disappears as the lactate is utilized.

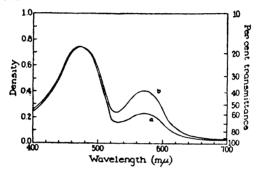

Fig. 181. Absorption spectra of colored solutions obtained in Barker-Summerson lactic acid method, for standards containing (a) 0.002 mg., and (b) 0.004 mg. lactic acid. Solution depth, 1 cm.

3. Method of Friedemann and Graeser:¹⁸⁵ Principle. The glucose of blood filtrates is removed with copper sulfate and calcium hydroxide, the lactic acid converted to acetaldehyde which is then combined with sodium bisulfite. The bound sulfite is determined iodometrically, as in the method for urine (Chapter 32).

Procedure: To 10 ml. of Folin-Wu or Somogyi filtrate representing 1 ml. of blood add 2 ml. of 10 per cent CuSO4 and 2 ml. of 5 per cent suspension of Ca(OH)2. Shake at intervals for one-half hour and centrifuge. Of the filtrate 5-ml. duplicates are taken for analysis as in the method for urine (Chapter 32) using 0.002 N iodine. For the blank treat 10 ml. of 0.1 per cent glucose in the same manner as blood filtrate.

Interpretation. See the previous method.

4. Determination of Lactic Acid in Tissues, Tissue Extracts, Etc. Either of the procedures described above is suitable for the determination of the lactic acid content of various types of biological material. For tissue analysis, precautions must be taken against postmortem changes in lactic acid content, by prompt freezing in solid carbon dioxide ("dry ice") or by adequate treatment with acid to destroy enzyme systems present. Pro-

¹⁸⁴ To convert mg. per cent lactic acid into milliequivalents per liter, divide by 9.0.
185 Friedemann and Graeser: J. Biol. Chem., 100, 291 (1933). See also Wendel: J. Biol. Chem., 102, 47 (1933); Edwards: ibid., 125, 571 (1938).

teins present may be removed by any of the common methods. For the colorimetric procedure, an aliquot of the protein-free fluid containing 0.02 to 0.10 mg. of lactic acid is treated by the copper-lime procedure described at a volume of 10 ml., and 1 ml. of supernatant is analyzed as described for blood. For the iodometric procedure, the aliquot should contain about 0.5 mg. of lactic acid. This is diluted to 10 ml. and treated as described for blood.

DETERMINATION OF CHLORIDES

1. Introduction. The chlorides of whole blood are distributed to the extent of about one-third of the total in the red cells and two-thirds in the plasma. Plasma or serum is therefore ordinarily used for analysis: if whole blood were used, variations in red cell content would affect results out of proportion to their clinical significance. In obtaining plasma, excessive amounts of anticoagulants such as oxalate must be avoided. since they influence water and chloride distribution between cells and plasma; heparin does not have this effect. For precise work, where small changes in chloride content are of significance, blood should be collected under oil to minimize changes in carbon dioxide tension, since this also affects chloride distribution between cells and plasma ("chloride shift," see Chapter 24). This precaution is not necessary in routine clinical practice, but it is important that measurements be made carefully, preferably using volumetric flasks for dilution as in the preparation of protein-free filtrates, because of the high chloride content of plasma or serum and the slight variations which are of significance.

Chloride content is commonly expressed in terms of milligrams of sodium chloride per 100 ml. of sample. It is more exact, and preferable, to express chloride concentration in terms of milliequivalents of chloride per liter, since the major functions of chloride in the body are concerned with osmotic pressure regulation and acid-base balance. One milliequivalent of chloride ion corresponds to 35.5 mg., or 58.5 mg. of sodium chloride. A plasma with a chloride concentration of 585 mg. per cent expressed as sodium chloride therefore contains 100 milliequivalents of chloride per liter. The general relationship between these two methods of expressing chloride content is as follows:

milliequivalents of chloride per liter \times 5.85

= mg. of chloride as sodium chloride per 100 ml.

2. Method of Whitehorn: 186 Principle. The chlorides are precipitated from the blood filtrate by means of silver nitrate in the presence of nitric acid, and the excess of silver titrated with standard thiocyanate solution, using ferric ammonium sulfate as an indicator.

Procedure: 187 Pipet 10 ml. of the Folin-Wu filtrate into a porcelain dish. Add with a pipet 5 ml. of the standard silver nitrate solution and stir thor-

¹⁸⁴ Whitehorn: J. Biol. Chem., 45, 449 (1921).

¹⁸⁷ Reagents Required: Standard Silver Nitrate Solution. Dissolve 2.905 g. of c.p. silver nitrate in distilled water. Transfer this solution to a liter volumetric flask and make up to the mark with distilled water. Mix thoroughly and preserve in a brown bottle. 1 ml. = 1 mg. NaCl. (It is to be noted that the silver nitrate and nitric acid are not added to the protein-

oughly. Add about 5 ml. of concentrated nitric acid (sp. gr. 1.42), mix, and let stand for five minutes, to permit the flocking out of the silver chloride. Then add with a spatula about 0.3 g. of powdered ferric ammonium sulfate and titrate the excess of silver nitrate with the standard thiocyanate solution until the definite salmon-red (not yellow) color of the ferric thiocyanate persists in spite of vigorous shaking for at least 15 seconds. A micro-buret should be used in the titration.

Calculation. Subtract the number of ml. of thiocyanate required from 5.00 (= ml. of silver nitrate added) and multiply the result by 100 to obtain the chloride content expressed as mg. of sodium chloride per 100 ml. To express results in terms of milliequivalents of chloride per liter, calculate as above and divide the result by 5.85.

Interpretation. Plasma or serum normally contains from 570 to 620 mg. per 100 ml., expressed as sodium chloride, or 98 to 106 milliequivalents of chloride per liter. The corresponding figures for whole blood are 450 to 500 mg. per cent, or 77 to 86 milliequivalents per liter. Increased plasma chloride is noted in nephritis, and this determination may aid in deciding whether or not salt should be restricted in the diet. Decreased plasma chloride may occur in gastro-intestinal disturbances associated with vomiting or diarrhea, in pneumonia, and in Addison's disease. Because of the close association between water and chloride, marked disturbances in water distribution (hydration, dehydration) may not necessarily be accompanied by changes from the normal plasma chloride level.

3. Method of Schales and Schales:¹⁸⁸ Principle. The sample is titrated with standard mercuric nitrate solution at the proper acidity in the presence of diphenylcarbazone as indicator. Chlorides present react with the added mercuric ions to form soluble but undissociated mercuric chloride. When an excess of mercuric ion has been added, the indicator turns purple. The end-point is sharp and relatively stable.

Procedure: 189 Transfer 2 ml. of Folin-Wu filtrate of plasma or serum (equivalent to 0.2 ml. of original sample) to a small flask, and add 0.06 ml. (four drops) of diphenylcarbazone indicator solution. Titrate with the standard mercuric nitrate solution, using a micro-buret capable of being read to

free filtrate simultaneously. To do so may result in the mechanical enclosure of silver nitrate solution within the curds, and hence too high results.)

Standard Thiocyanate Solution. Because thiocyanates are hygroscopic, the standard solution should be prepared volumetrically. Dissolve about 1.7 g. of KCNS or 1.4 g. of NH₄CNS in a liter of water. Titrate against standard silver nitrate solution under the conditions specified under "Procedure," and dilute accurately so that 5 ml. are equivalent to 5 ml. of the silver nitrate solution.

Solid ferric alum is used rather than a solution, in order to insure a very high concentration in the mixture to be titrated. It is powdered to facilitate its solution.

188 Schales and Schales: J. Biol. Chem., 146, 879 (1941).

¹⁸⁹ Reagents Required: Diphenylcarbazone Solution. Dissolve 100 mg. of s-diphenylcarbazone (obtainable from Eastman Kodak Co., Rochester, N.Y.) in 95 per cent alcohol, and dilute to 100 ml. Store in a dark bottle in the cold. Equip the bottle with a rubber-bulb medicine dropper whose tip is adjusted so as to deliver 65 to 70 drops of solution per ml. Prepare fresh solution each month.

Standard Sodium Chloride Solution. Dry some reagent-grade sodium chloride in an oven at 110° to 120° overnight. Cool and weigh out 584.5 mg. Dissolve in a little water and transfer with rinsings to a 1-liter volumetric flask. Dilute to the mark with water and mix. This solution is stable indefinitely, and contains 10 milliequivalents of chloride per liter, or

0.01 ml. and delivering small drops. At the end-point, the color of the solution changes from light yellow to deep purple.

The plasma or serum may be titrated directly without previous deproteinization. This procedure eliminates errors in the preparation of the filtrate. Transfer 0.2 ml. of sample to a small flask, add 1.8 ml. of water. 0.06 ml. of indicator, and titrate as above. The color of the solution undergoes several changes during the titration, becoming light yellow just before the end-point is reached, and changing to pale violet at the end-point. Results by the direct titration are slightly higher than when a filtrate is used, possibly because of slight loss of chloride during deproteinization.

Calculation. Results for either the protein-free or direct titration are calculated as follows:

Ml. of mercuric nitrate solution used $\times \frac{100}{\Lambda}$

= milliequivalents of chloride per liter

where A equals the number of ml. of mercuric nitrate solution required for 2 ml. of standard sodium chloride solution. If A equals 2.00, the calculation simplifies to:

Ml. of mercuric nitrate solution used \times 50

= milliequivalents of chloride per liter

If results are desired in terms of mg. of sodium chloride per 100 ml., the calculation is as follows:

Ml. of mercuric nitrate solution used $\times \frac{100}{\Lambda} \times 5.85$

= mg. of NaCl per 100 ml.

Interpretation. See the previous method. This method, while not quite so accurate as the iodometric method described subsequently, is relatively simple and is known to give satisfactory results. It has definite advantages over the Whitehorn method. It may be applied to spinal fluid analyses, ordinarily without deproteinization, but is not applicable to urine. Cf. however Asper, Schales, and Schales: J. Biol. Chem., 168, 779 (1947).

4. Method of Sendroy, Modified by Van Slyke and Hiller:190 **Principle.** The plasma or serum is treated with phosphoric acid containing either tungstic acid or picric acid, which precipitates the proteins. The mixture is then shaken with an excess of solid silver iodate and

58.45 mg. of sodium chloride per 100 ml. It is used to standardize each new lot of standard mercuric nitrate solution.

Standard Mercuric Nitrate Solution. Place a few hundred ml. of water in a 1-liter volumetrio flask and add 20 ml. of 2 N nitric acid. Add 3 g. of reagent-grade mercuric nitrate, dissolve by shaking, dilute to volume with water, and mix. Standardize as follows: transfer 2 ml. of standard sodium chloride solution to a small flask, add 4 drops of diphenylcarbasone solution, and titrate with the mercuric nitrate solution from a micro-buret as described in the text. The number of ml. of mercuric nitrate solution required equals the value A used in the calculations above. If the strength of the mercuric nitrate solution is adjusted so that A equals 2.00, either by adding more mercuric nitrate or by dilution with water containing 20 ml. of 2 N nitric acid per liter, as the case may be, the calculations are simplified (see text). This standard mercuric nitrate solution is stable indefinitely, and need not be protected from light, so that large amounts may be prepared at one time.

100 Sendroy: J. Biol. Chem., 120, 335, 405, 419 (1937); ibid., 130, 605 (1939); ibid., 142, 171

(1942). Van Slyke and Hiller (personal communication).

filtered. Chlorides present react with the insoluble silver iodate to form insoluble silver chloride and soluble iodate, which passes into the filtrate. On the addition of iodide to the filtrate, the iodate reacts to produce free iodine, which is then titrated with standard thiosulfate.

Procedure: 191 Transfer 1 ml. of plasma or serum to a 50 ml. Erlenmeyer flask. Add 25 ml. of phosphoric-tungstic acid or phosphoric-picric acid solution and mix. To the mixture add 0.3 to 0.5 g. of silver iodate (measured with sufficient accuracy from a spoon spatula previously found to contain approximately the right amount). Stopper the flask and shake vigorously for 30 seconds. Pour onto a dry 9-cm. folded filter of loose texture, collecting the filtrate in a dry flask.

Transfer 10 ml. of the water-clear filtrate to a small flask. Add 1 ml. of sodium iodide solution (or 0.5 g. of solid sodium iodide). Mix carefully with

191 Reagents Required: Phosphoric-Tungstic Acid Solution. Transfer 6 g. of reagent-grade chloride-free sodium tungstate to a 1-liter volumetric flask, add water to dissolve, followed by 10 ml. of reagent-grade phosphoric acid, make up to 1 liter with water, and mix. Tungstate may be tested for chloride by dissolving 1 g. in 10 ml. of water, adding 20 ml. of concentrated nitric acid, and filtering into a test tube containing a few ml. of 1 per cent silver nitrate. If the filtrate does not show a precipitate of silver chloride, the tungstate is chloride-free. Tungstate may be freed from chloride by treating a hot concentrated solution with an equal volume of 95 per cent alcohol, filtering off the crystals from the cooled solution, washing with alcohol, and drying in air.

Phosphoric-Picric Acid Solution. This may be used in place of the tungstic acid reagent if chloride-free tungstate is not obtainable; pieric acid is less likely to contain chloride. Place 6 ml. of phosphoric acid and 2 g. of pieric acid in a 1-liter flask, add water to dissolve, dilute to 1 liter and mix.

Silver Iodate. This must be free from more soluble iodates. To test, shake 0.5 g. with 25 ml. of phosphoric-tungstic acid solution for 1 minute, filter, and titrate 10 ml. of filtrate with 0.02308 N thiosulfate, after adding iodide, as described above for plasma filtrates. If more than 0.50 ml. of thiosulfate is required at a temperature of 20°, or 1.00 ml. at 40°, with approximately linear variation at intermediate temperatures, the iodate is not pure enough. To prepare pure silver iodate, dissolve 42.8 g. of potassium iodate in a liter of water and add to it with stirring a liter of silver nitrate solution containing 34 g. of silver nitrate. Filter off the precipitated silver iodate by suction, and wash with water until a 10-ml. portion of the washings when titrated with thiosulfate in the presence of iodide as described above requires no more thiosulfate than corresponds to the solubility of silver iodate as indicated above. Stir up the washed precipitate in 500 ml. of water, suck dry on the Buchner funnel, transfer to a vacuum desiccator to dry thoroughly, and store in a brown bottle.

Sodium Iodide Solution. Dissolve 50 g. of reagent-grade sodium iodide in 50 ml. of water. Store in a brown bottle. This solution must be discarded when a 1-ml. portion added to 10 ml. of phosphoric-tungstic acid solution gives a blue color in the presence of a drop of starch solution. For occasional analyses the dry reagent is more economical. A 0.5-g. portion is used for each analysis. Dispense from a spoon spatula previously found to deliver approximately the right amount.

Standard Sodium Thiosulfate Solution. Prepare a stock thiosulfate solution by dissolving 57.3 g. of crystalline sodium thiosulfate, Na₂S₂O₃-5H₂O, in water, diluting to 250 ml. in a volumetric flask, and mixing. This solution is stable indefinitely. To prepare the thiosulfate solution used in the titration, transfer 25 ml. of stock solution to a 1-liter volumetric flask. add 1 g. of borax as preservative, dilute to volume with water, and mix. This solution should be 0.02308 N. Standardize as follows: prepare a standard 0.1 N iodate solution by dissolving 3.567 g. of pure potassium iodate in water and diluting to 1 liter. This solution is stable indefinitely. Transfer 5 ml. to a small flask, add about 20 ml. of water and 1 ml. of 1 N acid (sulfuric or hydrochloric). Add 1.5 ml. of sodium iodide solution and titrate immediately with the thiosulfate solution, using starch as indicator. If the volume of thiosulfate required is 21.67 ml., the thiosulfate is 0.02308 N and is used without a factor as described in the procedure above. If some other volume of thiosulfate is required, the factor is obtained by dividing 21.67 by the volume of thiosulfate required. Thus, if 22.40 ml. of thiosulfate were used for titrating the 5 ml. of standard iodate, the factor is 21.67/22.40, or 0.967. This factor is then used in the calculations as described in the procedure. The dilute thiosulfate solution undergoes slow deterioration over a period of months. It should be checked at intervals against the standard iodate solution and a new factor obtained if necessary.

one or two swirls, and titrate the liberated iodine immediately with standard sodium thiosulfate solution. Add the thiosulfate in rapid drops, with careful mixing, until the yellow color of the iodine has almost disappeared. Add two drops of starch solution and continue titration until the blue color disappears and the solution is colorless, or, if picric acid was used for deproteinization, only the yellow color of the picric acid remains.

Calculation. In this procedure, 1 equivalent of chloride ion leads to the production of 6 equivalents of iodine, requiring 6 equivalents of thiosulfate for titration. Therefore 1 ml. of N thiosulfate represents ½ milliequivalent of chloride. Since the 10 ml. of filtrate titrated represent 1926 ml. of sample, the formula for calculation of results in terms of milliequivalents of chloride per liter is as follows:

Ml. of thiosulfate \times normality $\times \frac{1}{6} \times \frac{26}{10} \times 1000$ = milliequivalents of chloride per liter

If the normality of the thiosulfate is exactly 0.02308, the calculation simplifies to:

Ml. of thiosulfate \times 10 = milliequivalents of chloride per liter

If the thiosulfate is not exactly 0.02308 N and a factor is used as described under "Standardization," the calculation becomes:

Ml. of thiosulfate \times factor \times 10 = milliequivalents of chloride per liter

To express results on the basis of milligrams of NaCl per 100 ml., since 1 milliequivalent of chloride corresponds to 58.5 mg. of NaCl, the calculations become:

Ml. of 0.02308 N thiosulfate \times 58.5 = mg. of NaCl per 100 ml. or

Ml. of thiosulfate \times factor \times 58.5 = mg. of NaCl per 100 ml.

Interpretation. See under the method of Whitehorn above. This method may be used with Folin-Wu filtrates (10 ml. of filtrate made up to 26 ml. with phosphoric-tungstic reagent, treated with iodate, filtered, and titrated exactly as described above, with the same calculations); it is directly applicable on an unchanged basis to the analysis of spinal fluid, gastric contents, urine, etc., and it may be used on a micro-scale with proportionate decrease in amounts of reagents used, and suitable change in calculations.

5. Determination of Total Chlorides in Blood and Tissues (Van Slyke): Principle. The proteins are oxidized, and the chloride is precipitated, by wet digestion with concentrated nitric acid in the presence of silver nitrate. The excess silver is then titrated with thiocyanate, as described in Whitehorn's method. For details, see the Eleventh Edition of this book.

DETERMINATION OF PHOSPHORUS

1. Partition of Blood Phosphorus. Whole blood contains about 40 mg. of total phosphorus per 100 ml., present chiefly as inorganic phosphate, organic acid-soluble phosphate esters, and lipid phosphorus, with other phosphate-containing compounds possibly present in small amounts. The distribution of phosphorus between cells and plasma is quite uneven: for example, cells contain much more organic and total phosphate than plasma, while the inorganic phosphate of whole blood is practically entirely in the plasma. For the determination of inorganic phosphate and total acid-soluble phosphorus, protein is precipitated with trichloroacetic acid and the filtrate used. For lipid phosphorus determination an alcoholether extract is obtained. In the determination of total acid-soluble, lipid, and total phosphorus, organic matter is destroyed by digestion with sulfuric acid and 30 per cent hydrogen peroxide. The phosphate-containing solutions thus obtained (as well as the trichloroacetic acid filtrate used for the direct determination of inorganic phosphate) are treated with molybdic acid, whereby phosphomolybdic acid is formed from any inorganic phosphate present. On the addition of suitable reducing agents, phosphomolybdic acid is selectively reduced to yield a deep blue color ("molybdenum blue") which is apparently a mixture of lower oxides of molybdenum. This color is used as a measure of the amount of phosphate present.

Bell and Doisy¹⁹³ carried out the reduction with hydroquinone in alkaline solution. Briggs¹⁹⁴ made the color more stable by using an acid solution. Benedict and Theis¹⁹⁵ intensified the color by heating. This procedure is satisfactory where only inorganic phosphate is present, as in serum or plasma filtrates, but cannot be used on whole blood filtrates for example, since any phosphate esters present may be hydrolyzed by the heating in acid and thus lead to high values. Fiske and SubbaRow¹⁹⁶ suggested the use of 1,2,4-aminonaphtholsulfonic acid as reducing agent, at room temperature. This method has been widely used, and is the one described here. Kuttner and Cohen¹⁹⁷ revived the original suggestion of Denigés that stannous chloride be used as reducing agent, and this has likewise found much favor. Stannous chloride has the advantage over aminonaphtholsulfonic acid that the stock reagent is quite stable and the color produced with phosphomolybdate is more intense, thus permitting the estimation of smaller amounts of phosphorus. For example, Shinowara, Jones and Reinhart 198 have described procedures for phosphate determination, using stannous chloride as reducing agent, which require as little as 0.06 ml. of serum. A disadvantage of stannous chloride is that the color intensity changes continuously with time, so that careful control of the time factor is essential, and deviations from Beer's law are

¹⁰⁸ Shinowara, Jones, and Reinhart: J. Biol. Chem., 142, 921 (1942).

found, usually requiring correction factors. In the authors' experience, the method of Fiske and SubbaRow has proved superior to any other method thus far described.

2. Determination of Inorganic Phosphate: 199 Method of Fiske and SubbaRow: 196 Principle. The proteins of blood are precipitated with trichloroacetic acid. The protein-free filtrate is treated with an acid molybdate solution, which forms phosphomolybdic acid from any phosphate present. The phosphomolybdic acid is reduced by the addition of 1,2,4-aminonaphtholsulfonic acid reagent, to produce a blue color whose intensity is proportional to the amount of phosphate present.

Procedure: To 8 ml. of 10 per cent trichloroacetic acid solution in a small flask, add slowly, with mixing, 2 ml. of whole blood, serum, or plasma. Stopper, shake, and filter through a low-ash filter paper. Transfer 5 ml. of filtrate to a cylinder or other container graduated at 10 ml., and add 1 ml. of the Molybdate II reagent. Mix. Add 0.4 ml. of aminonaphtholsulfonic acid reagent, and again mix. Dilute to the mark, mix, and allow to stand five minutes.

For colorimetric measurement, compare in the colorimeter against a standard prepared at the same time, as follows: Transfer 5 ml. of standard phosphate solution, containing 0.4 mg. of phosphorus, to a 100-ml. volumetric flask, and add from a graduate 50 ml. of water. Add 10 ml. of Molybdate I (not Molybdate II), mix, and add 4 ml. of aminonaphtholsulfonic acid reagent. Dilute with water to the 100 ml. mark, mix, and allow to stand five minutes. Compare the standard against itself in the colorimeter before reading the unknown. If the color of the unknown is particularly strong, repeat the reading of the unknown a few minutes later, to be sure that maximal color development has taken place.

For photometric measurement, transfer a portion of the colored solution to a suitable container and read in the photometer at 660 to 720 my (see Fig. 182). Set the photometer to zero density with a blank prepared by

199 Reagents Required: 10 Per Cent Trichloroacetic Acid. Dissolve 10 g. of reagent-grade trichloroacetic acid in water and dilute to 100 ml.

10 N Sulfuric Acid. Carefully add 450 ml. of concentrated sulfuric acid to 1300 ml. of water. To check, dilute 10 ml. of this solution to 100 ml. in a volumetric flask, mix, and titrate a 10-ml. portion with standard 1 N sodium hydroxide. From the titration results, adjust the original solution if necessary to make it exactly 10 N.

Molybdate I. Dissolve 25 g. of reagent-grade ammonium molybdate in about 200 ml. of water. In a 1-liter volumetric flask place 500 ml. of 10 N sulfuric acid. Add the molybdate solution and dilute with washings to 1 liter with water. Mix. Stable indefinitely.

Molybdate II. Dissolve 25 g. of reagent-grade ammonium molybdate in about 200 ml. of water. In a 1-liter volumetric flask place 300 ml. of 10 N sulfuric acid. Add the molybdate solution and dilute with washings to 1 liter with water. Mix. Stable indefinitely.

Aminonaphtholsulfonic Acid Reagent. Place 195 ml. of 15 per cent sodium bisulfite solution (see below) in a glass-stoppered cylinder. Add 0.5 g. of 1,2,4-aminonaphtholsulfonic acid (satisfactory material can be obtained from the Eastman Kodak Co., Rochester, N.Y.). Add 5 ml. of 20 per cent sodium sulfite (see below). Stopper and shake until the powder is dissolved. If solution is not complete, add more sodium sulfite, 1 ml. at a time, with shaking, but avoid an excess. Transfer the solution to a brown-glass bottle and store in the cold. This solution is usable for about four weeks, if kept as described.

15 Per Cent Sodium Bisulfits. To 30 g. of reagent-grade sodium bisulfits in a beaker add 200 ml. of water from a graduated cylinder. Stir to dissolve, and if turbid allow to stand well-stoppered for several days and filter. Keep well-stoppered.

80 Per Cent Sodium Sulfite. Dissolve 20 g. of reagent-grade anhydrous sodium sulfite in water, dilute to 100 ml., and filter if necessary. Keep well-stoppered.

Standard Phosphate Solution. Dissolve exactly 0.351 g. of pure dry monopotassium phosphate in water and transfer quantitatively to a 1-liter volumetric flask. Add 10 ml. of 10 N sulfuric acid, dilute to the mark with water, and mix. This solution contains 0.4 mg. of phosphorus in 5 ml. It is stable indefinitely.

treating 5 ml. of 10 per cent trichloroacetic acid with 1 ml. of Molybdate II and 0.4 ml. of aminonaphtholsulfonic acid reagent, followed by water to a volume of 10 ml. Establish the density of a standard phosphate solution as follows: Transfer 5 ml. of the stock phosphate standard, containing 0.4 mg. of P, to a 50-ml. volumetric flask, make up to volume with 10 per cent trichloroacetic acid, and mix. Transfer 5 ml. of this dilute standard, containing 0.04 mg. of phosphorus, to a suitable container, add 1 ml. of Molybdate

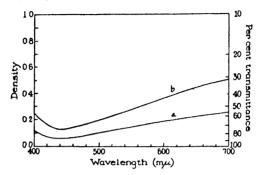

Fig. 182. Absorption spectra of colored solutions obtained in Fiske-SubbaRow phosphate method, for standards containing (a) 0.02 mg., and (b) 0.04 mg. phosphorus. Solution depth, 1 cm.

II and 0.4 ml. of aminonaphtholsulfonic acid reagent, dilute to 10 ml. with water, and mix. Allow to stand five minutes and determine the density in the photometer whose zero is set with a blank as described above.

Calculation. For colorimetric measurement: Since the 5 ml. of filtrate taken represent 1 ml. of original sample, and the standard containing 0.4 mg. of P is in ten times the volume of the unknown, the calculation becomes:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{0.4}{10} \times 100$

= mg. of inorganic P per 100 ml. of whole blood, plasma, or serum

For photometric measurement:

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times 100$

= mg. of inorganic P per 100 ml. of whole blood, plasma, or serum

The density of the standard at 660 m μ in a 1-cm. cuvette is approximately 0.500 (see Fig. 182); at 720 m μ , the peak position of the curve, the density is about 10 per cent greater. Under these conditions the limit of accurate measurement corresponds to an inorganic phosphate content of approximately 7 to 8 mg. per cent, and this range is proportionately reduced with photometric measurement at greater depth of solution. To permit the covering of a greater range of phosphate concentration, the amount of sample taken for protein precipitation may be decreased, e.g.

1 ml. (or 0.5 ml.) of whole blood, serum, or plasma is treated with 10 per cent trichloroacetic acid at a final volume of 10 ml., and 5 ml. of filtrate taken for analysis as described. If this is done, the calculation is the same except that the final result is multiplied by 2 (or 4, if 0.5 ml. of sample was taken). The color obtained in this procedure shows little change between 5 and 20 minutes after adding the aminonaphtholsulfonic acid reagent, and the agreement with Beer's law is excellent, permitting calculation of results in terms of the density of a simultaneously prepared standard and eliminating the necessity for a calibration curve.

Interpretation. The normal inorganic phosphorus content of the blood plasma or serum is about 5 mg, per 100 ml, in infants and children and 3.7 mg, in the adult. In severe nephritis inorganic phosphorus may rise 15 to 20 mg. and may bear a relation to the acidosis found in such cases. Clinically, the most important changes are those in rickets. In the rickets of children or in experimental rickets produced in animals by low phosphorus diets the inorganic phosphorus of the blood may fall to 2 mg. or lower. Treatment with antirachitic vitamin or ultraviolet radiation increases the phosphorus of the blood and leads to recalcification of the rachitic lesions. Occasionally rickets may be accompanied by high inorganic phosphorus of the blood, and the tendency of irradiated ergosterol to restore normal phosphorus values may be independent of its calcifying activity. During the healing period following fracture of a bone, an increase in plasma phosphates is sometimes observed. The phosphate level of the plasma of children rises during the summer and falls during the winter. Rickets has its greatest incidence during the late winter, reaching its peak in March. These findings may be correlated with the degree of exposure to solar ultraviolet rays. Injections of insulin decrease the phosphate of the plasma.

3. Determination of Total Acid-soluble Phosphorus:²⁰⁰ Principle. The organic matter in an aliquot of a trichloroacetic acid filtrate is destroyed by digestion with sulfuric acid and subsequent oxidation with 30 per cent hydrogen peroxide. The phosphate-containing solution is then analyzed for phosphate by the method of Fiske and SubbaRow.

Procedure: Prepare a trichloroacetic acid filtrate of whole blood, plasma, or serum as described for the determination of inorganic phosphate. Transfer 2 ml. of this filtrate to a test tube, 200 by 25 mm., and add 2.5 ml. of 5 N sulfuric acid and a quartz chip to minimize bumping. Place in a slanting position over a micro-burner, with the burner tip about 2 cm. below the bottom of the tube, or suspend in a wire basket about 1.5 inches above an

²⁰⁰ Reagents Required: 10 Per Cent Trichloroacetic Acid Solution, Molybdate I Solution, Aminonaphtholsulfonic Acid Reagent, and Standard Phosphate Solution as described for the determination of Inorganic Phosphate (p. 579), and in addition:

⁵ N Sulfuric Acid. Fill a 250-ml. volumetric flask to the mark with 10 N sulfuric acid solution (see p. 579). Pour the contents of the flask into a 500-ml. volumetric flask, with rinsings, and dilute to the mark with water. Mix. Stable indefinitely.

^{2.5} Per Cent Ammonium Molybdate Solution. Dissolve 2.5 g. of reagent-grade ammonium molybdate in water, transfer to a 100-ml. volumetric flask, fill to the mark, and mix. As soon as any appreciable amount of sediment forms in this solution, it should be discarded.

³⁰ Per Cent Hydrogen Peroxide. Only the highest purity, essentially phosphate-free material may be used. The products of Merck and of J. T. Baker are known to be satisfactory. This reagent is extremely corrosive to the skin and must be handled carefully. Keep in the cold, and use a medicine dropper for dispensing.

electric hot plate. After evaporation is complete and the mixture turns brown or black with no further change, remove the tube, cool slightly, and add 1 drop of 30 per cent hydrogen peroxide, allowing the drop to fall directly into the digestion mixture. Replace the tube and continue heating. The contents of the tube should become colorless; if not, repeat the addition of hydrogen peroxide and heating. When colorless, cool the tube, add a few ml. of water, and heat to boiling momentarily. Cool again and transfer the contents of the tube to a 25-ml. volumetric flask, with washings until the flask is about half full. Add 2.5 ml. of 2.5 per cent ammonium molybdate solution, followed by 1 ml. of aminonaphtholsulfonic acid reagent. Dilute with water to the 25-ml. mark and mix. Allow to stand five minutes, then read in the colorimeter or photometer.

For colorimetric measurement, compare against a standard prepared as described above for the determination of blood inorganic phosphate. For photometric measurement, the most accurate procedure is to run a digested blank and a digested standard along with each series of unknowns. This corrects for any phosphate or other factors in the reagents which may affect the final results. Digested blank: 2 ml. of 10 per cent trichloroacetic acid, treated with sulfuric acid, evaporated, oxidized with hydrogen peroxide, and color reagents added, exactly as described for the unknown. Digested standard: 1 ml. of standard phosphate solution, containing 0.08 mg. of phosphorus, plus 2 ml. of 10 per cent trichloroacetic acid, treated with sulfuric acid, evaporated, oxidized with hydrogen peroxide, and color developed, exactly as described for the unknown. The color of the digested blank and standard is developed at a final volume of 25 ml., as with the unknown. Set the photometer to zero density with the blank, and determine the densities of the standard and the unknown, using the same wavelength as specified for the determination of inorganic phosphate on p. 580.

Calculation. For colorimetric measurement: Since the standard contains 0.4 mg. of P in a final volume of colored solution four times that of the unknown, and the 2 ml. of unknown filtrate represent 0.4 ml. of original sample, the calculation is as follows:

Reading of Standard Reading of Unknown
$$\times \frac{0.4}{4} \times \frac{1}{0.4} \times 100 = \text{mg}$$
, of total acid-soluble phosphorus per 100 ml. of blood, plasma, or serum

If the reagents, particularly the trichloroacetic acid and the hydrogen peroxide, contain significant amounts of phosphorus, the quantity present must be established by a blank digestion and analysis and suitable corrections made.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.08 \times \frac{1}{0.4} \times 100 = \text{mg. of total acid-soluble}$$

$$\text{phosphorus per 100 ml. of blood, plasma, or serum}$$

The conditions for photometric measurement have been presented in connection with the determination of inorganic phosphate.

Interpretation. The acid-soluble phosphorus content of normal blood is approximately 25 to 30 mg. per 100 ml. of whole blood. The total acid-soluble phosphorus includes the inorganic phosphate as well as those organic phosphate esters which are not present as lipid or nucleoprotein material.

Such esters include hexosephosphate, diphosphoglyceric acid,²⁰¹ certain free nucleotides, and other compounds which have not been characterized. In the plasma, the total acid-soluble phosphorus is represented largely by inorganic phosphate. In the cells, the reverse is true, ester phosphate being relatively much more abundant; thus interpretation of total acid-soluble phosphorus values for whole blood must include a consideration of the relative volume of cells to plasma. There is some evidence that the acid-soluble phosphorus of blood is of significance in acid-base balance in the body, since it is found to be considerably depleted during experimental acidosis.

- 4. Determination of Lipid Phosphorus. See p. 540.
- 5. Determination of Total Phosphorus: Dilute 1 ml. of blood, plasma, or serum to 10 ml. with 0.9 per cent sodium chloride solution and mix. Transfer 2 ml. of this diluted solution to a 200 by 25 mm. test tube, add 2.5 ml. of 5 N sulfuric acid and a quartz chip, and heat over a micro-burner or electric hot plate as described for the determination of acid-soluble phosphorus on p. 581. Foaming may be minimized by blowing clean compressed air into the digestion tube through a fine-tipped glass tube. When the water has been driven off and the contents of the tube turn black, continue with the digestion, oxidation, color development, and measurement as described for the determination of acid-soluble phosphorus. Calculation of results is the same except that since the 2 ml. of sample taken for analysis represent 0.2 ml. of original sample instead of 0.4 ml. as in the determination of acid-soluble phosphorus, results are multiplied by 2 to give the total phosphorus, in mg. per 100 ml.
- 6. Determination of Phosphorus in Tissues and Other Biological Material. The colorimetric method described above may be used for tissues and other biological material. Dry ashing may sometimes be necessary. If little organic matter is present, ignition with a small amount of sodium carbonate will suffice. In other cases magnesium nitrate (1 ml. of 10 per cent) is satisfactory. For tissues, carbonate-nitrate fusion mixtures are perhaps best. Porcelain dishes may generally be used but blanks should be run on them. Some silica will not interfere. If platinum is used, dissolve most of the ash with water before adding acid to remove the last of the material as nitrous acid attacks platinum. Evaporate the total solution to dryness in a beaker or porcelain dish (covered with a watch glass as long as carbon dioxide is evolved). Dissolve the residue in water, make to volume, and determine as usual.

DETERMINATION OF SERUM PHOSPHATASE ACTIVITY

1. Introduction. Normal blood serum contains several enzymes or groups of enzymes which catalyze the liberation of inorganic phosphate from phosphate esters such as glycerophosphate, phenylphosphate, etc. The most active phosphatase, and the one longest recognized, has an optimum pH of approximately 9, and is now known as "alkaline" phosphatase to distinguish it from a second or "acid" phosphatase which is of limited activity in normal serum but whose activity is of significance in certain pathological conditions and which has an optimum pH of approximately 5. Neither type of enzyme has any significant activity at the

³⁰¹ Greenwald: J. Biol. Chem., 63, 339 (1925).

optimum pH of the other, although both are active at the pH of normal blood. The enzymatic activity of serum or plasma with respect to either or both enzymes is established in terms of the rate of hydrolysis of suitable phosphate ester substrates buffered to the proper pH.

Various methods have been proposed for the determination of phosphatase activity of serum. For "alkaline" phosphatase, the method of Bodansky²⁰² has perhaps found the widest application. In this method. the phosphate liberated on incubation of serum with buffered glycerophosphate at pH 8.6 is used as an index of phosphatase activity, one Bodansky unit corresponding to the liberation of 1 mg. of inorganic phosphate per 100 ml. of serum during a one-hour period of incubation under these conditions. In the Bodansky method, the liberated phosphate is determined with stannous chloride as reducing agent, and various corrections for the influence of protein precipitant and substrate on the phosphate determination are necessary; these have been established by the author. Shinowara, Jones, and Reinhart²⁰³ claim that these correction factors become unnecessary under the proper conditions and likewise feel that "alkaline" phosphatase activity should be determined at pH 9.3, the optimum pH for this enzyme. They have described procedures for the determination of inorganic phosphate, "alkaline" phosphatase, and "acid" phosphatase on as little as 0.06 ml. of serum. King and Armstrong²⁰⁴ proposed the determination of "alkaline" phosphatase activity in terms of the phenol liberated on incubation with buffered phenylphosphate, and Gutman and Gutman²⁰⁵ have applied this procedure to the determination of "acid" phosphatase. A disadvantage of the King and Armstrong procedure is that the serum inorganic phosphate content, which is usually of importance along with phosphatase activity, must be determined separately with an entirely different set of reagents. In the procedures described here, the incubation procedure of the Bodansky method is used for "alkaline" phosphatase determination, with modification to permit the use of the method of Fiske and SubbaRow (see p. 579) for the determination of phosphate liberated; for "acid" phosphatase. the conditions prescribed by Shinowara, Jones, and Reinhart are followed. likewise modified to permit the use of the Fiske and SubbaRow phosphate method.

2. Determination of "Alkaline" Phosphatase:206

Procedure: Collect about 5 ml. of whole blood in a centrifuge tube, allow to clot at room temperature, remove clot, then centrifuge (twice if neces-

²⁰² Bodansky: J. Biol. Chem., 99, 197 (1932); 101, 93 (1933). This method is described in the Eleventh Edition of this book.

²⁰² Shinowara, Jones, and Reinhart: J. Biol. Chem., 142, 921 (1942).

²⁰⁴ King and Armstrong: Can. Med. Assoc. J., 31, 376 (1934).

²⁰⁵ Gutman and Gutman: J. Biol. Chem., 136, 201 (1940).

²⁰⁶ Reagents Required: "Alkaline Phosphate" Substrate. Into a 100-ml. volumetric flask introduce successively 3 ml. of petroleum ether (B.P. 20° to 40° C., J. T. Baker Analyzed Special), about 80 ml. of distilled water, 0.5 g. of sodium \(\theta\)-glycerophesphate (Eastman), 0.424 g. of sodium diethyl barbiturate (Merck), and water to volume (read at interface between petroleum ether and aqueous solution). Empty (out of doors) into a 100-ml. glass stoppered pyrex bottle containing an inch layer of petroleum ether. Keep in the refrigerator. When multiples of 100 ml. are prepared, it is advisable to distribute the substrate into small

³⁰ Per Cent Trichloroacetic Acid. Dissolve 30 g. of reagent-grade trichloroacetic acid in

sary). The separated serum may be kept for several hours in the refrigerator, or for several days if frozen.

- a. Incubated Sample: Measure 9 ml. of "alkaline phosphate" substrate into a glass-stoppered cylinder²⁰⁷ and place in an incubator or water bath at 37° until the fluid reaches incubator temperature. Add 1 ml. of serum, mix, note the time, and incubate for exactly one hour. Remove, cool in ice water for several minutes, and add 2 ml. of 30 per cent trichloroacetic acid. Mix, let stand a few minutes, and filter through a low-ash filter paper.
- b. Control Sample: At or near the end of the incubation period, prepare a control sample as follows: Measure 9 ml. of substrate into a glass-stoppered cylinder and add 2 ml. of 30 per cent trichloroacetic acid. With mixing add 1 ml. of serum, stopper, shake, and filter as above.

When both filtrates are ready, transfer 8 ml. of each to cylinders or test tubes graduated at 10 ml. In a third similar container place 8 ml. of standard phosphate solution, containing 0.04 mg. of phosphorus. For photometric measurement, a fourth or blank tube is necessary. This contains 8 ml. of 5 per cent trichloroacetic acid alone. When all the tubes are ready, add to each 1 ml. of Molybdate II reagent, and mix. Add 0.4 ml. of aminonaphtholsulfonic acid reagent to each, dilute immediately to 10 ml. with water, and mix. Allow to stand five minutes for color development.

For colorimetric measurement, compare both control and incubated unknowns against the standard. Since the 8 ml. of filtrate represent twothirds of the total sample, the calculation is as follows:

Reading of Standard Reading of Unknown
$$\times$$
 0.04 \times $\frac{3}{2}$ \times 100 = mg. of inorganic phosphate per 100 ml. of serum (control or incubated).

For photometric measurement, read the unknowns and standard in a photometer which is set to zero density with the blank, using the same conditions as for the determination of inorganic phosphate described on p. 579. The calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times \frac{3}{2} \times 100 = \text{mg. of inorganic phosphate per 100}$$
ml. of serum (control or incubated)

The phosphatase activity is the difference between the inorganic phosphate content of the incubated and control samples, expressed in mg. of phosphorus per 100 ml. Thus, if the control result is 4.0 mg. per cent, and the incubated result is 8.5 mg. per cent, the phosphatase activity is 8.5 - 4.0 = 4.5 Bodansky units per 100 ml. of serum.

In colorimetric measurement, with the standard set at 20 mm., the control tube usually reads approximately 30 mm., and a phosphatase activity up to about 8 units may be accurately determined. In photometric measurement in a 1-cm cuvette, the limit is about 12 units. For activities greater than this, the phosphate analysis is repeated on a smaller portion of filtrate from the incubated serum, making up to 8 ml. volume with

water and dilute to 100 ml. Stable indefinitely. To prepare a 10 per cent solution from this, dilute 1 volume with 2 volumes of water. To prepare a 5 per cent solution, dilute 1 volume with 5 volumes of water.

Standard Phosphate Solution. Place 6.25 ml. of the standard phosphate solution used for the determination of inorganic phosphate (see p. 579), containing 0.5 mg. of phosphorus, in a 100-ml. volumetric flask. Add 16.7 ml. of 30 per cent trichloroacetic acid solution, dilute to 100 ml. with water, and mix. This solution contains 0.04 mg. of phosphorus in 8 ml., in 5 per cent trichloroacetic acid. It should be stable indefinitely if stored in the cold.

Molybdate II, Aminonaphtholsulfonic Acid Reagent. See p. 579.

107 Ordinary test tubes and clean rubber stoppers may be used.

5 per cent trichloroacetic acid, and correcting the calculations accordingly. If the liberated phosphate is 60 mg. per cent or higher, inhibition of hydrolysis occurs and the incubation is repeated with the time shortened to 30 or 15 minutes, in which case results are multiplied by 1.8 or 3.3 respectively. The result on the control sample is essentially an analysis for serum inorganic phosphate, but includes any effect of glycerophosphate on color development. This effect is frequently very low or negligible, in which case the results on the control serum may be accepted as the measure of the serum inorganic phosphate, and reported as such along with the phosphatase values.

Interpretation. The serum "alkaline" phosphatase activity in normal adults ranges from 1.5 to 4.0 units per 100 ml. (average 2.7) and in normal children 5 to 12 units (average 8.0). These values are greatly exceeded in polyostotic Paget's disease (up to 50 times), rickets (up to 20 times), hyperparathyroidism (10 times). Smaller increases are observed in a number of other diseases of osseous origin. High serum phosphatase is a manifestation of processes that cause rapid growth of bone in the normal young, of new bone (repair), and of calcified and uncalcified pathological bone. Among nonosseous conditions in which increased phosphatase activity is observed are acute catarrhal jaundice and other cases of liver involvement. Under certain conditions the serum phosphatase activity may be used in the differential diagnosis of liver disease.

3. Determination of "Acid" Phosphatase:208 The procedure is exactly the same as for "alkaline" phosphatase, except that the buffered "acid phosphate" substrate of Shinowara, Jones, and Reinhart is used for the incubation and for the control sample. Calculation of results is the same as for "alkaline" phosphatase, the unit of "acid" phosphatase activity being defined as equivalent to the liberation of 1 mg. per cent of inorganic phosphate during one hour incubation at pH 5.0.

Interpretation. In terms of the unit above defined, normal serum contains from 0.0 to 1.1 units of acid phosphatase activity, with no significant elevation observed except in cases of carcinoma of the prostate with metastases, when values as high as 30 units or more have been observed. It should be pointed out here that the King and Armstrong unit as used by Gutman and Gutman²⁰⁵ is defined in terms of the liberation of 1 mg. per cent of phenol, and is approximately double the value of the phosphate unit here described. Results by the method described here will therefore tend to be about half as high as those obtained by the use of phenylphosphate as substrate.

²⁰⁸ Reagents Required: "Acid Phosphate" Substrate. This is identical with the "alkaline phosphate" substrate already described except that sufficient acetic acid is incorporated to bring the pH to 5.0. Into a 100-ml. volumetric flask introduce successively 3 ml. of petroleum ether, about 80 ml. of water, 0.5 g. of sodium β -glycerophosphate, 0.424 g. of sodium diethylbarbiturate, and 5 ml. of 1 N acetic acid. Dissolve by mixing, and add water to bring the aqueous meniscus to the 100-ml. mark. Keep in the refrigerator. The pH of the final solution should be checked, and if it is not 5.0, adjusted to that value by the addition of dilute acid or alkali as necessary.

Other reagents required are those described for the determination of "alkaline" phosphatase, with the exception of the substrate.

DETERMINATION OF SULFUR

- 1. Introduction. Of the total sulfur of whole blood, a portion is present as the inorganic sulfate ion, another portion is in the form of various nonprotein organic compounds which may be present (glutathione, ergothionine, etc.), most of which are found chiefly in the red cells, and the remainder is represented by the sulfur-containing amino acids of the proteins present. In the analysis of serum or plasma, inorganic sulfate is ordinarily determined by isolation as the benzidine salt, followed by colorimetric²⁰⁹ or titrimetric²¹⁰ estimation of the benzidine component. Nephelometric²¹¹ and gasometric²¹² methods for inorganic sulfate have also been described. Ethereal or conjugated sulfate (i.e., the increment in inorganic sulfate produced by acid hydrolysis of the protein-free sample) appears to be present, if at all, in such small amount in human plasma as to come within the limits of error in the two analyses necessary for its estimation. Significant values may be found for the plasma of species other than man. Total sulfur is determined by complete oxidation of organic matter, followed by estimation of inorganic sulfate present.
- 2. Determination of Inorganic Sulfate in Serum: Method of Letonoff and Reinhold:²¹³ Principle. Serum is deproteinized with uranium acetate. The sulfate in the filtrate is precipitated as benzidine sulfate, then washed, dissolved, and determined colorimetrically after treatment with sodium β -naphthoguinone-4-sulfonate.

Procedure: Six ml. of 0.4 per cent uranium acetate solution are measured into a 15-ml. centrifuge tube, 2 ml. of nonhemolyzed serum are added slowly, and, after mixing by inverting four times, the mixture is centrifuged for 10 minutes. Four ml. of clear centrifugate are measured into another centrifuge tube (selected so that the tip will retain precipitates). One ml. of glacial acetic acid and 9 ml. of benzidine solution²¹⁴ are added. The tube is capped, placed in ice water for at least a half hour, then centrifuged for 15 minutes at 3000 r.p.m. The supernatant fluid is decanted and discarded. and the tube permitted to drain in an inverted position for three minutes. Fourteen ml. of acetone are added. The precipitate is suspended in the acetone, then again centrifuged for 15 minutes at high speed. The acetone is decanted and the tube allowed to drain five minutes. After the mouth of the tube has been wiped, 1 ml. of a 1 per cent solution of sodium borate in 0.1 N sodium hydroxide is added and the precipitate dissolved by stirring. (The tube may be placed in warm water at 60° if solution is slow.) Finally, 10 ml. of water and 1 ml. of the color reagent 215 are added. The solutions are

²⁰⁰ For a colorimetric method different from the one described in the text, see Cuthbertson and Tompsett: Biochem. J., 25, 1237 (1931); Pirie: Biochem. J., 23, 1063 (1934).

110 Power and Wakefield: J. Biol. Chem., 123, 665 (1938).

²¹¹ Denis and Reed: J. Biol. Chem., 71, 191 (1926).

²¹² Van Slyke, Hiller, and Berthelsen: J. Biol. Chem., 74, 659 (1927).

²¹³ Letonoff and Reinhold: J. Biol. Chem., 114, 147 (1936). This method is said to give lower results than other methods because of the absence of the hydrolytic effect of acid protein precipitants.

²¹⁴ One per cent benzidine in acetone, filtered and stored in a brown bottle in the refrigerator. It should be discarded when it becomes highly colored.

²¹⁶ Color Reagent. 0.15 g. of pure sodium \$\beta\$-naphthoquinone-4-sulfonate is dissolved in 100 ml. of distilled water. The solution will keep about two weeks in the cold. Each sample of this reagent should be tested by treating 2 ml. and 4 ml. of the working standard solution of benzidine hydrochloride with the color reagent, borate, water, and acetone as described below. Acceptable preparations do not deviate from the theoretical Beer's law relationship by more than 5 per cent.

mixed and allowed to stand five minutes, then 2 ml. of acetone are added. At the same time, two standards are prepared by measuring 2 and 5 ml. of benzidine hydrochloride solution²¹⁶ into two test tubes. One ml. of borate solution is added to each, followed by 8 ml. and 5 ml. of water respectively. One ml. of color reagent is added and the development of color carried out as described. The unknown solutions are compared with standards in the colorimeter.

Calculation. When colorimetric comparison is made with the 2-ml. benzidine standard:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{1}$$
= mg. of sulfate sulfur per 100 ml. of serum

For the stronger standard, replace 0.02 in the above equation by 0.05.

Precise photometric data for this color are not available. Since the reagent and reaction resemble that for the amino-acid determination (p. 517), satisfactory photometric measurement should be possible at 490 m μ , against a blank prepared by treating 10 ml. of water with 1 ml. of borate, 1 ml. of color reagent, and 2 ml. of acetone.

Interpretation. Normal human blood serum contains approximately 1 mg. of inorganic sulfate (as S) per 100 ml. In nephritis with retention, the inorganic sulfate values are increased. High values have also been reported in pyloric or intestinal obstruction, in leukemia, and in diabetes.

3. Determination of Total Sulfur in Biological Material: Method of Stockholm and Koch:²¹⁷ Principle. The complete oxidation of biological material for the sulfur determination is often a difficult procedure. The following method in which strong hydrogen peroxide and nitric acid are used is believed to be the most effective.

Procedure: Into a 100-ml. nickel crucible (50 by 70 mm.) containing 10 ml. of 25 per cent sodium hydroxide solution, introduce 0.5 to 2.0 g. of the substance. The covered crucible is then heated on the steam bath until the mass is almost dry. This requires several hours, but causes considerable decomposition of the complex substances present, so that the sulfur in particular can later be easily oxidized. In case the evaporation has proceeded too rapidly, it is best to add again 10 ml. of water and to repeat the slow evaporation. To the slightly moist material 5 ml. of 30 per cent $\mathrm{H}_2\mathrm{O}_2^{218}$ are added very gradually. In some cases it is necessary to stir the mass with a

²¹⁶ Standard Benzidine Hydrochloride Solution. 0.1606 g. of benzidine hydrochloride, purified as described below, is transferred to a 200-ml. volumetric flask, dissolved in water previously warmed to about 50°, cooled, and diluted to volume. The solution should be stored in the cold. Ten ml. are equivalent to 1.0 mg. of sulfur. For a working standard, 10 ml. of this solution are diluted to 100 ml. with water. One ml. contains benzidine equivalent to 0.01 mg. of sulfur. The solution should be stored in the cold.

The benzidine hydrochloride is purified as follows: 5 g. of benzidine hydrochloride are dissolved in 200 ml. of 5 per cent hydrochloric acid by warming to about 50°. Any insoluble residue is filtered. Twenty ml. of concentrated hydrochloric acid are added with continuous stirring. The solution is cooled in ice water for about 30 minutes, when the crystals that have formed are collected on a Buchner funnel. The material is washed with cold diluted hydrochloric acid (15 ml. of concentrated acid to 100 ml. of water). After removing the hydrochloric acid by suction, the crystals are washed with two 25 ml. portions of cold ethyl alcohol and four portions of ether. After all traces of ether are removed, the dry crystals are transferred to a brown bottle.

²¹⁷ Stockholm and Koch: J. Am. Chem. Soc., 45. 1053 (1923).

^{*18} Merck's Superoxel.

glass rod or to add a few drops of water so as to distribute the reagent properly. During this treatment the heating is continued on the steam bath.

The material thus partially oxidized is next transferred to a 300-ml. Kjeldahl flask, acidified with nitric acid, and concentrated over a free flame until salts begin to separate. This concentrated solution is then oxidized, while boiling, by the gradual addition of fuming nitric acid and bromine until 10 ml. of acid and 40 to 50 drops of bromine have been used. With material low in, or free from, fat this treatment is usually sufficient to bring about complete oxidation of the organic matter. The solution is next evaporated almost to dryness and after water has again been added evaporation is repeated to remove most of the nitric acid. When the water solution of this material is not absolutely clear it is filtered and after it has been neutralized with sodium hydroxide and diluted to about 600 ml. it is acidified by the addition of 10 ml. of concentrated hydrochloric acid. 10 ml. of 0.1 N sulfuric acid are added, the mixture heated to boiling and 10 ml. of a 10 per cent barium chloride solution added, drop by drop. The boiling is continued for 10 to 15 minutes and then the mixture is heated for 10 to 12 hours before it is filtered and washed as usual. The filter paper and precipitate are cautiously burned and weighed. Blank estimations are made in exactly the same way.

DETERMINATION OF CALCIUM

ď.

1. Introduction. The calcium of blood is found entirely in the plasma. red cells apparently being devoid of calcium. Since most of the common anticoagulants for blood act by reaction with calcium, serum from clotted blood is ordinarily used for analysis; heparinized plasma may also be used. Of the total serum calcium, about half appears to be combined with protein in some way, and little is known of its physiological significance. The remainder is dialyzable, and, according to McLean and Hastings, largely in the ionic form. The symptoms of hypo- and hypercalcemia appear to be associated chiefly with variations in this diffusible fraction. Serum calcium is usually determined by precipitation as an insoluble calcium salt. such as oxalate or phosphate, for which specific analytical methods are available. Clark-Collip Modification of the Kramer-Tisdall Method:219 Principle. Calcium is precipitated directly from the serum as oxalate and the latter is titrated with potassium permanganate. Sendroy²²⁰ has shown that direct precipitation as oxalate from diluted serum gives accurate results, and that preliminary removal of protein is not necessary.

Procedure: Introduce into a graduated 15-ml. centrifuge tube 2 ml. of clear serum, 2 ml. of distilled water, and 1 ml. of 4 per cent ammonium oxalate solution. Mix thoroughly. Mixing is aided by holding the tube at the mouth and giving it a circular motion by tapping the lower end. The centrifuge tube should have an outside diameter of 6 to 7 mm. at the 0.1 ml. mark. Let stand for 30 minutes or longer. Again mix the contents. Centrifuge for about 5 minutes at 1500 revolutions per minute. Carefully pour off the supernatant liquid and while the tube is still inverted let it drain in a rack for five minutes, resting the mouth of the tube on a pad of filter paper. Wipe the mouth of the tube dry with a soft cloth. Stir up the precipitate

²¹⁹ Clark and Collip: J. Biol. Chem., 63, 461 (1925); Tisdall: J. Biol. Chem., 56, 439 (1923); Kramer and Tisdall: J. Biol. Chem., 47, 475 (1921); Clark: J. Biol. Chem., 49, 487 (1921). ²²⁰ Sendroy: J. Biol. Chem., 152, 539 (1944).

³²¹ Overnight standing is preferred, otherwise precipitation is sometimes incomplete.

²²² To insure uniform drainage the tubes should always be cleaned thoroughly by heating at approximately 100° for a few minutes in a cleaning mixture made by adding 1500 ml. of concentrated sulfuric acid to a solution of 200 g. of sodium dichromate in 100 ml. of water.

and wash the sides of the tube with 3 ml. of dilute ammonia (2 ml. of concentrated ammonia to 98 ml. of water)²²³ directed in a very fine stream, from a wash bottle. Centrifuge the suspension and drain again as before. Add 2 ml. of approximately normal sulfuric acid (28 ml. of concentrated acid to a liter) by blowing it from a pipet directly upon the precipitate so as to break up the mat and facilitate solution. Place the tube in a boiling water bath for about one minute. Titrate with 0.01 normal potassium permanganate²²⁴ to a definite pink color which persists for at least one minute. If necessary during the course of the titration warm the tube by placing in a water bath kept at 70° to 75°. A micro-buret graduated in 0.02 ml. should be used.

Calculation. One ml. of 0.01 N KMnO₄ is equivalent to 0.2 mg. of Ca.

$$(x - b) \times 0.2 \times \frac{100}{2}$$
 = mg. of Ca per 100 ml. serum

where x equals the number of ml. of permanganate required in the titration, and b is the blank, i.e., the number of ml. of permanganate required to titrate 2 ml. of the sulfuric acid solution to the usual end-point.

Interpretation. Normal human blood serum contains from 9 to 11 mg. of calcium per 100 ml. corresponding to 4.5–5.7 milliequivalents per liter. Values for children are slightly higher than for adults. A slight decrease may be observed during the late months of pregnancy. After parathyroidectomy the blood calcium falls to a low level and the injection of parathyroid extract results in a considerable increase. In infantile tetany values of 3.5 to 7.0 mg. have been observed. In severe nephritis the calcium content may decrease to 7.0 mg. or less. There is apparently a reasonably close relationship between serum calcium, phosphate, and protein. Except in children and in cases where the calcium metabolism per se is abnormal, this relationship may be expressed by the following empirical equation:²²⁵

Ca (in mg. per cent) = 7 - 0.255 P (in mg. per cent) + 0.566 protein (in grams per cent)

²²³ Wang (J. Biol. Chem., 111, 443 (1935)) recommends as the washing solution, 2 per cent ammonia in equal parts of alcohol, ether, and water, to avoid flotation of the precipitate. Stanford and Wheatley (Biochem. J., 19, 710 (1925)) wash twice with a thoroughly filtered, saturated aqueous solution of calcium oxalate, 15 ml. of which, upon acidifying and titrating with 0.01 N KMnO₄, should require not more than 0.25 ml.

²²⁴ 0.01 N KMnO₄. (Halverson and Bergeim: J. Ind. Eng. Chem., 10, 119 (1918)). Dissolve 0.4 g. of pure potassium permanganate in 1 liter of redistilled water in a thoroughly clean Florence flask. Insert a funnel covered with a watch glass as a condenser and digest for several hours at near the boiling point. Cool, let stand overnight, and filter with gentle suction through a 3-inch Buchner funnel lined with ignited asbestos. Transfer to a perfectly clean glass stoppered bottle and keep in a dark place. (Permanganate solution prepared by dilution of 0.1 N solution must be standardized immediately before use as it deteriorates rapidly and comes to a constant value only after several days.) The 0.01 N permanganate is standardized against 0.01 N sodium oxalate which should keep for several months. Dry highest purity sodium oxalate in an oven at 100° to 105° for 12 hours. Dissolve exactly 0.67 g. of the oxalate in redistilled water, add 5 ml. of concentrated H2SO4, and dilute to 1 liter. Mix well. Transfer exactly 25 ml. of this solution to a 100-ml. Erlenmeyer flask, add 1 ml. of concentrated H2SO4, warm to about 70°, and titrate with the KMnO4 solution. The permanganate solution should be frequently restandardized although after the first few days, if carefully prepared and kept, it should not deteriorate more than 0.1 per cent per week.

²²⁶ Peters and Eiserson: J. Biol. Chem., 84, 155 (1929); Oberst and Plass: J. Biol. Chem., 92, xiii (1931). See, however, Stearns and Knowlton: J. Biol. Chem., 92, xii (1931).

Thus interpretation of pathological variations in serum calcium should be based upon knowledge of the serum phosphate and protein values, unless these are known to be normal.

3. Method of Roe and Kahn:²²⁶ Principle. Calcium is precipitated from the protein-free serum filtrate as tricalcium phosphate, which is then determined colorimetrically by a procedure similar to that used for the determination of blood inorganic phosphate (p. 579). Kuttner and Cohen have described a micro-modification using this principle, in connection with their method for phosphorus determination.

Procedure:227 To 8 ml. of 10 per cent trichloroacetic acid in a small flask, add 2 ml. of serum. Mix well by shaking. Filter through a Ca-free filter paper (Whatman No. 42 is satisfactory). Transfer 5 ml. of filtrate to a 15-ml. conical graduated centrifuge tube, add 1 ml. of 25 per cent Ca-free sodium hydroxide solution, mix by tapping, and let stand five minutes. Add 1 ml. of 5 per cent trisodium phosphate solution, mix thoroughly by tapping, and set aside for one hour. Centrifuge for two minutes. Decant supernatant liquid, place tube in an inverted position in a small beaker containing a mat of clean gauze or filter paper, and allow to drain two minutes. Wipe mouth of tube dry with a clean cloth. Add from a bulb pipet with a fine tip 5 ml. of alkaline-alcoholic wash reagent, forcing the wash fluid in at first so as to break up the mat of tricalcium phosphate, and then washing down the sides of the tube. If necessary, use a stirring rod to break up the precipitate, rinsing down the rod with a little of the wash fluid. Centrifuge two minutes, decant, drain, and wipe the mouth of the tube as before. Repeat the washing procedure,228 centrifuging, etc., with a second 5-ml. portion of wash reagent, centrifuging, decanting, draining, and wiping off excess fluid as above. To the residue in the centrifuge tube add 1 ml. of acid molybdate reagent and tap against the palm of the hand to effect complete disintegration and solution of the precipitate. When dissolved, add 10 ml. of water, mix by tapping, and set aside. Prepare a standard by transferring 10 ml. of the standard phosphate solution, containing phosphate equivalent to 0.1 mg. of calcium, to a second similar graduated tube, add 1 ml. of the acid molybdate reagent, and mix. For photometric measurement, prepare a blank tube containing 10 ml. of water and 1 ml. of acid molybdate. When all the tubes are ready, add to each 0.5 ml. of amino-

²²⁶ Roe and Kahn: J. Biol. Chem., 81, 1 (1929). Kuttner and Cohen: J. Biol. Chem., 75, 517 (1927). The latter procedure as applied to the Roe and Kahn method is described in the Eleventh Edition of this book.

²²⁷ Reagents Required: The trichloroacetic acid, sodium hydroxide, and trisodium phosphate (Na₂PO₄·12 H₂O) solutions are prepared on the indicated basis from reagent-grade chemicals. The two alkaline solutions should be decanted occasionally from any sediment which forms and which might lead to errors if included in the analysis.

Alkaline-Alcoholic Wash Reagent. Mix 58 ml. of ethyl alcohol with 10 ml. of amyl alcohol and dilute to 100 ml. with water. Add 2 drops of 1 per cent phenolphthalein and 5 per cent Ca-free NaOH a drop at a time to a distinct pink (usually two to three drops).

Acid Molybdate Reagent. Dissolve 12.5 g. of reagent-grade ammonium molybdate in 400 ml. of water in a 500-ml. volumetric flask. Add slowly with shaking 100 ml. of concentrated sulfuric acid. Stable indefinitely.

Aminonaphtholsulfonic Acid Reagent. The same as described on p. 579 for the determination of inorganic phosphate.

Standard Phosphate Solution. Dissolve 2.265 g. of pure dry monopotassium phosphate in water, dilute to 1 liter in a volumetric flask, and mix. Add a little chloroform as a preservative. This stock solution contains 0.517 mg. of P per ml., equivalent to 1 mg. of Ca as calcium phosphate. The working standard is prepared by diluting 1 ml. of stock solution to 100 ml. with water. This standard should be prepared fresh daily. 10 ml. contain phosphate equivalent to 0.1 mg. of Ca.

238 Roe and Kahn state that only one washing is necessary. Two washings provide a greater margin of safety.

naphtholsulfonic acid reagent, followed by water to the 15-ml. mark, and mix immediately by inversion. Allow to stand 10 minutes before reading in the colorimeter or photometer. For photometric measurement, set the photometer to zero density at $660~m_{\rm p}$ with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.1 \times \frac{100}{1} = \text{mg. of Ca per 100 ml. of serum}$$

The standard corresponds to 10 mg. per cent serum calcium, and will be satisfactory for practically all values encountered in analyses. For very low values (below 5 mg. per cent) dilute the unknown after color development to 12 ml. instead of 15 ml., and correct the calculations accordingly. For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.1 \times \frac{100}{1} = \text{mg. of Ca per 100 ml. of serum}$$

The characteristics of the color and the conditions of photometric measurement are the same as those described for the determination of inorganic phosphate (p. 580). At 660 m μ , in a 1-cm. cuvette, the standard has a density of approximately 0.400, and all values of serum calcium may be accurately determined under these conditions.

The photometric blank will correct for any phosphate present in the color-producing reagents, but not for contamination by calcium in the earlier stages of the procedure. Since it is very difficult to obtain absolutely Ca-free reagents or filter paper, for precise work a correction for calcium already present should be made. This is best done by running a standard calcium solution229 through the entire procedure (treatment with trichloroacetic acid, filtering, etc.) and comparing the value obtained with that expected. Thus if a standard equivalent to 10 mg. per cent calcium gives on analysis a value of 10.5 mg. per cent, the correction to be subtracted from serum results is 0.5 mg. per cent. It is sometimes suggested that using such a calcium standard, instead of a phosphate standard as described, will include the calcium present in the reagents and hence serve as a correction. This is only true if the unknown and standard should happen to contain exactly the same amounts of calcium; otherwise it is in error, since the constant calcium correction becomes a variable and unknown fraction of the total calcium present in the unknown.

Interpretation. See previous method.

4. Other Methods. Numerous other methods have been proposed for the determination of serum calcium, some of which require only very small quantities of serum. Instead of titrating the oxalate directly, Fiske and Adams²³⁰ redissolve the washed oxalate in nitric acid, dry, add oxalic acid, dry again, ignite, and titrate the residue as calcium oxide. Kuttner

²²⁶ Suspend 0.250 g. of pure dry calcium carbonate in a little water in a 1-liter volumetric flask, add dilute (1:10) HCl to dissolve, add a few ml. of acid in excess, dilute to 1 liter with water, and mix. This solution is stable indefinitely and contains 0.1 mg. of Ca per ml. It corresponds therefore to a serum with a Ca content of 10 mg. per cent.

²²⁰ Fiske and Adams: J. Am. Chem. Soc., 53, 2498 (1931).

and Cohen (loc. cit.), in a method applicable to 0.1 ml. of serum, ash the material, precipitate the calcium as phosphate, and analyze for phosphate colorimetrically. Gasometric methods include measurement of the carbon dioxide evolved in the reaction between oxalate and permanganate²³¹ or ceric sulfate,²³² or in the combustion of calcium picrolonate;²³³ this latter procedure is applicable to as little as 0.02 ml. of serum. Sendroy²³⁴ has described photometric methods likewise applicable to 0.02 ml. of serum.

5. Determination of Calcium in Tissues and Other Biological Materials. Where the amount of organic matter to be destroyed is small, the material may be ashed in silica or platinum crucibles with the aid of a few drops of nitric acid to destroy the last carbon. Feces, milk, and bone may usually be handled in this way. Tissues low in calcium present a more difficult problem and Corley and Denis have suggested autoclaving such materials with alkali. ²³⁵ By using a micro-calcium determination the amount of organic matter necessary to be destroyed is greatly decreased.

DETERMINATION OF MAGNESIUM

- 1. Introduction. Magnesium is found constantly in small amount in blood, being distributed about equally between cells and plasma. Plasma or serum is ordinarily used for analysis, usually after the calcium has been precipitated to prevent interference in the analysis. Most methods proposed depend upon the precipitation of magnesium as phosphate, followed by colorimetric phosphate analysis. Precipitation of magnesium with 8-hydroxyquinoline has also been used.²³⁶ Hirschfelder and Serles²³⁷ have described a colorimetric method based upon the color formed in alkaline solution in the presence of certain dyes. The clinical significance of blood magnesium is relatively unknown; in tissues (such as muscle) the magnesium ion has been shown to play an important part in certain enzyme systems associated with intermediary metabolism (see Chapter 34).
- 2. Method of Denis²³⁸ Modified: Principle. After removal of calcium as oxalate the magnesium is precipitated as magnesium ammonium phosphate and the latter is estimated by a colorimetric phosphate determination. In the method here described, the Fiske-SubbaRow phosphate method is used. For a procedure based on Youngburg's adaptation of Kuttner's colorimetric phosphate method, see the Eleventh Edition of this book.

Procedure: Precipitate the calcium from 2 ml. of serum as in the procedure for calcium in serum (see p. 589). After centrifuging, pipet 3 ml. of the supernatant fluid into a 15-ml. graduated centrifuge tube and add with stirring 0.5 ml. of a 5 per cent solution of ammonium phosphate containing 5 ml. of concentrated NH₄OH per liter, followed by 2 drops of concentrated

²³⁸ Denis: J. Biol. Chem., 52, 411 (1922). See also Briggs: J. Biol. Chem., 52, 349 (1922).

NH₄OH. Let stand overnight. Centrifuge. Siphon off the supernatant fluid and wash the tube with 5 ml. of a mixture of 1 part of concentrated NH₄OH (sp. gr. 0.9) and 2 parts of water. Centrifuge and siphon off wash liquid. Repeat the washing a second and third time and then wash finally with 5 ml. of 75 per cent alcohol containing 10 ml. of concentrated NH₄OH per liter. Siphon off again and let stand in a warm place until the ammonia has evaporated.

To the residue in the centrifuge tube add 1 ml. of the Molybdate I reagent used in the Fiske-SubbaRow phosphate method (p. 579), and tap to dissolve. When dissolved, add 5 ml. of water and set aside. Prepare a standard by placing 1 ml. of the Molybdate I reagent in a second graduated tube and adding 3 ml. of the standard phosphate solution (equivalent to 0.03 mg. of magnesium)²³⁹ plus 2 ml. of water. For photometric measurement prepare a blank by placing 1 ml. of Molybdate I reagent plus 5 ml. of water in a third graduated tube. When all the tubes are ready, add to each 0.4 ml. of aminonaphtholsulfonic acid reagent, followed immediately by water to the 10-ml. mark. Mix and allow to stand five minutes before reading in the colorimeter or photometer. For photometric measurement, set the photometer to zero density at 660 my with the blank.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{100}{1.2} = \text{mg. of Mg per 100 ml. of serum}$$

The value 1.2 represents the fact that 3 ml. of supernatant obtained from 2 ml. of serum, after precipitating the Ca as oxalate, correspond to 1.2 ml. of the original serum.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{100}{1.2} = \text{mg. of Mg per 100 ml. of serum}$$

The characteristics of the color and the conditions of photometric measurement are the same as for the determination of inorganic phosphate (p. 579). At 660 m μ , the standard has a density of approximately 0.500 in a 1-cm. cuvette. Since this standard corresponds to a serum Mg content of 2.5 mg. per cent, up to 5 mg. per cent may be accurately determined under these conditions. For higher values, or for photometric measurement at a greater depth of solution, add 2 ml. of molybdate reagent to unknown, blank, and standard instead of the 1 ml. specified (use the same 3-ml. portion of standard) followed by water in each case to about 12 ml., then add 0.8 ml. of aminonaphtholsulfonic acid reagent and water to a 20-ml. final volume. There is no change in the calculations. Color development at a greater dilution is recommended rather than the analysis of a smaller portion of serum because it is not known whether or not precipitation of magnesium in this procedure will be quantitative at conditions other than those specified.

Interpretation. Normally about 1 to 3 mg. of Mg are found in 100 ml. of serum and about 1.6 mg. per 100 ml. of blood. No characteristic changes have been observed in pathological conditions.

DETERMINATION OF SODIUM

- 1. Introduction. The sodium of whole blood appears to be present entirely in the form of the sodium ion, with over 90 per cent of the total blood sodium present in the plasma. Plasma or serum is therefore ordinarily used for analysis, and for precise work precautions should be taken against the transfer of water and electrolytes between cells and plasma brought about by changes in the blood gas content. Sodium is commonly determined by precipitation in the form of uranyl zinc sodium acetate. which, while soluble in water, is relatively insoluble in alcohol or acetone. Prior to isolation of the sodium as the triple salt indicated, the proteins are precipitated²⁴⁰ or the sample is ashed;²⁴¹ electrodialysis may also be used for separation of the sodium from interfering material.²⁴² The triple salt may be determined by gravimetric, 241 titrimetric, 240 or colorimetric 243 methods. Another reagent which has been proposed for the determination of sodium is pyroantimonate.²⁴⁴ In the analysis of serum sodium, precision is essential because of the relatively small variations which are of clinical significance. The determination of sodium in tissues is similar to the procedures used for blood.²⁴⁵ The "flame photometer" (p. 482) appears to promise a basis for the simple, rapid, and accurate determination of sodium.
- 2. Method of Weinbach:²⁴⁰ Principle. After deproteinization, the sodium in the filtrate is precipitated in alcoholic medium as the triple salt, uranyl zinc sodium acetate, which is washed, dissolved in water, and titrated with standard sodium hydroxide. It is claimed that phosphates present do not interfere. For a similar method in which phosphates are first removed, see Dregus.²⁴⁰

Procedure: 246 To 1 volume of whole blood or cells (or 2 volumes of serum or plasma) in a small flask, add 7 (or 6) volumes of water, shake, and let stand

²⁴⁷ Butler and Tuthill: J. Biol. Chem., 93, 171 (1931); Barber and Kolthoff: J. Am. Chem. Soc., 50, 1625 (1928); 51, 3233 (1939).

²⁴² Keys: J. Biol. Chem., 114, 449 (1936); Consolazio and Talbott: *ibid.*, 132, 753 (1940); Sobel, Kraus, and Kramer: *ibid.*, 140, 501 (1941).

²⁴³ McCance and Shipp: Biochem. J., 25, 449 (1931); Salit: J. Biol. Chem., 96, 659 (1932); Hoffman and Osgood: ibid., 124, 347 (1938). This latter is a photometric procedure.

244 Kramer and Tisdall: J. Biol. Chem., 46, 467 (1921); Kramer and Gittleman: ibid., 62, 353 (1924).

²⁴⁵ For a micro-procedure applicable to small amounts of tissues and blood, see Clark, Levitan, Gleason and Greenberg: J. Biol. Chem., 145, 85 (1942).

²⁴⁶ Reagents Required: Uranyl Zinc Acetate Reagent. Solution A: 77 g. uranyl acetate, UO₂(CH₂COO)₂·2H₂O, and 14 ml. of glacial acetic acid are dissolved in about 400 ml. of water by stirring and heating on a steam bath, and diluted to 500 ml. in a volumetric flask. Solution B: 231 g. of sinc acetate (3H₂O) and 7 ml. of glacial acetic acid are likewise dissolved and made up to 500 ml. The two solutions are mixed while hot, allowed to stand at least 24 hours, and filtered.

Acetone Wash Reagent. A small amount of the triple salt, uranyl zine sodium acetate, is prepared by adding 15 ml. of the uranyl zine acetate reagent to 1 ml. of approximately 5 per cent NaCl with subsequent addition of about 5 ml. of 95 per cent alcohol in small portions. Filter with suction and wash the precipitate with four or five small portions of 95 per cent alcohol and then with four or five small portions of ether, sucking dry after each addition of alcohol or ether. Add this amount of triple salt to a liter of acetone, shake, let stand overnight, and filter.

Standard Sodium Solution. Exactly 1 g. of c.p. sodium chloride is dissolved in water and

until hemolysis is complete. Add rapidly, with shaking, 2 volumes of 20 per cent trichloroacetic acid, making a total of 10 volumes. (This deproteinization may be done with as little as 0.1 to 0.2 ml. of material.) Mix, let stand 10 minutes, and filter through ashless filter paper (or centrifuge if the sample is small). Transfer 1 ml. of the whole blood filtrate (or 0.5 ml. of the serum filtrate) to a 15-ml. centrifuge tube and add 5 ml. of the uranyl zinc acetate reagent. From a 1-ml. graduated pipet add 0.3 ml. of 95 per cent alcohol and let stand for five minutes. Again add 0.3 ml. of alcohol and let stand for a few minutes. This procedure is repeated, without greatly disturbing the precipitate, until 2.1 ml. of alcohol have been added, the entire process of precipitation taking about 1/2 hour. Centrifuge, decant, drain by inversion on a pad of filter paper, and wipe the mouth of the tube with a cloth. Wash the precipitate once by blowing in 10 ml. of acetone wash reagent; centrifuge, decant, drain on filter paper, and wipe the mouth of the tube. The precipitate, which is readily soluble in water, is then transferred quantitatively to a 100-ml. Erlenmeyer flask by blowing in three or four 5-ml. portions of water, which has been recently boiled and cooled, to drive off dissolved carbon dioxide. Add approximately 50 ml. of water free from carbon dioxide and 0.5 ml. of 1 per cent phenolphthalein solution and titrate with 0.02 N NaOH to a just barely perceptible pink, with a microburet graduated in 0.02 ml. A blank should be run to determine the amount of 0.02 N NaOH which will just give the end-point with distilled water. Determine sodium on 0.5 ml. of standard sodium solution to standardize the procedure (see footnote 246, p. 595) and to facilitate determining the end-point.

Calculation. According to Weinbach, the equation for the titration reaction is:

$$(UO_2)_3ZnNa(CH_3COO)_9 + 8NaOH \rightarrow 3(UO_2)(OH)_2 + Zn(OH)_2 + 9CH_3COONa$$

Hence 8 moles of NaOH are required for each mole of Na.²⁴⁷ Each ml. of 0.02 N NaOH is thus equivalent to $(0.02 \times 23)/8 = 0.0575$ mg. of Na in the sample. If 1 ml. of a 1:10 filtrate is used,

(Titration – Blank)
$$\times$$
 0.0575 \times 100/0.1
= mg. of Na per 100 ml. of blood (or serum)

To convert mg. per cent sodium into milliequivalents per liter, divide by 2.3.

Interpretation. Normally, the range of serum or plasma sodium content is approximately 300 to 330 mg. per 100 ml., or 130 to 143 milliequivalents per liter.²⁴⁸ The sodium content of red cells is much less, ranging from 4 to 16 milliequivalents per liter.²⁴⁹ Whole blood sodium determinations have little clinical value. Sodium is the chief base of the plasma; its function there appears to be primarily physicochemical, in connection

made up to a liter in a volumetric flask. Each ml. of this solution contains 0.393 mg. of sodium.

²⁴⁷ According to Dregus, the titration yields sodium uranate, Na₂U₂O₇, zinc acetate, and sodium acetate at the end-point, and 9 moles of NaOH are required instead of 8 for each mole of sodium present. To eliminate uncertainty, the best procedure is to determine the sodium equivalent of the sodium hydroxide by analysis of a standard sodium solution, and to use this factor in the calculations.

Values are about 10 per cent higher if expressed in terms of a liter of plasma water.
 Snyder and Katzenelbogen: J. Biol. Chem., 143, 223 (1942).

with the maintenance of osmotic pressure and acid-base balance. The organism has such a strong tendency to maintain a constant level of total base content that only slight changes are ordinarily found, even under pathological conditions, hence the need for precision in analyses. Significant decreases in plasma sodium content have been noted in pregnancy, in obstruction of the pylorus and other parts of the gastro-intestinal tract, in pneumonia, in severe nephritis, and in Addison's disease. In the latter case, the decrease in the blood sodium level brought about by withdrawal of salt from the diet is of diagnostic significance.

DETERMINATION OF POTASSIUM

- 1. Introduction. Potassium, like sodium, is found in blood entirely in the form of the potassium ion. The distribution of blood potassium between cells and plasma is just opposite to that of sodium, potassium being much more abundant in the cells. Whole blood potassium determinations have relatively little clinical significance, plasma or serum ordinarily being used for analysis. In obtaining plasma or serum, hemolysis must be avoided and separation from the cells should be carried out as soon as possible to minimize error due to diffusion of potassium from cells to surrounding fluid. Weichselbaum, Somogvi, and Rusk²⁵⁰ advise that a syringe be dispensed with in obtaining blood, and allow the blood to flow directly from the needle in the vein into a small test tube, followed by standing for not over 20 minutes to permit clotting, and centrifuging to obtain the serum. The determination of potassium is usually based upon precipitation as the insoluble chloroplatinate²⁵¹ or silver cobaltinitrite, 252 followed by titrimetric or colorimetric estimation. Titrimetric and gravimetric methods based upon precipitation as the insoluble phospho-12-tungstate salt have also been described. 253 The "flame photometer" (p. 482) appears to promise a satisfactory basis for the rapid and accurate determination of potassium.
- 2. Method of Looney and Dyer:254 Principle. Potassium is precipitated from the protein-free, chloride-free serum filtrate as the insoluble potassium silver cobaltinitrite of the Breh and Gaebler procedure. The washed precipitate is decomposed by alkali to liberate the nitrite, which is then determined colorimetrically by an application of the Bratton-Marshall sulfonamide method (see p. 603). The method has the advantage of not requiring a preliminary ashing of the sample, and yields a stable color.

²⁵⁰ Weichselbaum, Somogyi, and Rusk: J. Biol. Chem., 132, 343 (1940).
²⁵¹ Shohl and Bennett: J. Biol. Chem., 78, 643 (1928). The chloroplatinate methods usually require a preliminary ashing; for the use of electrodialysis to avoid ashing, see Sobel, Hanok, and Kramer: J. Biol. Chem., 144, 363 (1942), and other references cited for the determination of sodium by electrodialysis (p. 595). Micro-methods include those of Cunningham, Kirk, and Brooks: J. Biol. Chem., 139, 21 (1941), and Clark, Levitan, Gleason, and Greenberg: ibid., 145, 85 (1942). These methods are applicable to small amounts of

²⁵² Breh and Gaebler: J. Biol. Chem., 87, 81 (1930). This method is described in the Eleventh Edition of this book. See also Weichselbaum, Somogyi, and Rusk: loc. cit.

²⁶³ Van Slyke and Rieben: J. Biol. Chem., 156, 743 (1944); Rieben and Van Slyke: bid., 156, 765 (1944).

¹⁵⁴ Looney and Dyer: J. Lab. Clin. Med., 28, 355 (1942).

Procedure: Transfer 0.5 ml. of serum to a small clean test tube containing 7 ml. of distilled water, add 1 ml. of 1.5 per cent sodium tungstate, mix by tapping, and follow with 1 ml. of 2.5 per cent copper sulfate solution. Stopper and shake well, then add 0.5 ml. of 2.5 per cent silver nitrate solution. Stopper and shake again, then allow to stand 15 to 20 minutes. Pour onto a small dry filter (Whatman No. 5 is recommended), returning the first portion of filtrate to the funnel to ensure obtaining a clear filtrate.

Transfer 3 ml. of the filtrate to a clean 15-ml. graduated conical centrifuge tube, 256 and in a second similar tube place 3 ml. of the standard potassium solution, containing 0.03 mg. of potassium. Add 1 ml. of 95 per cent alcohol and 1 ml. of distilled water to each tube, mix by tapping, and place in a water bath at 18° to 22° for five minutes. Add 2 ml. of the freshly prepared and filtered silver cobaltinitrite reagent, mix by tapping, and replace in the water bath. Allow to stand 2 hours, then centrifuge for 15 minutes at 2800 r.p.m. Carefully remove the supernatant fluid down to the 0.2-ml. mark with a capillary pipet. Add 7 ml. of wash reagent down the sides of the tube, slanting the tube but disturbing the precipitate as little as possible. Again centrifuge for 15 minutes, decant the supernatant fluid, invert the tube, and allow to drain on filter paper for five minutes. Wipe excess fluid from the mouth of the tube, and repeat the washing and draining twice more.

To the washed precipitate in the centrifuge tube, add 10 ml. of 0.2 normal sodium hydroxide, breaking up the precipitate by blowing the alkali in or by tapping the tube. Place in a boiling water bath for 10 minutes. Remove, cool, and make up to 10 ml. with water. Mix well and centrifuge. Transfer 2 ml. of supernatant to a 100-ml. volumetric flask. Add 5 ml. of water, followed by 1 ml. of 50 per cent hydrochloric acid, and 2 ml. of 0.5 per cent sulfanilamide solution. Mix by lateral shaking, allow to stand three minutes, then add 1 ml. of the naphthylethylenediamine reagent. Dilute with water to the 100-ml. mark, and allow to stand five minutes before reading in the colorimeter or photometer. For photometric measurement, set the photometer to zero density at 520 mg with a blank prepared by treating 2 ml. of water in a 100-ml. volumetric flask by the procedure described above for 2 ml. of supernatant from the alkali treatment.

²¹⁵ Reagents Required: The sodium tungstate, copper sulfate (CuSO₄ 5II₂O), and silver nitrate solutions are prepared on the indicated basis from reagent-grade chemicals. Keep the silver nitrate solution in a brown bottle.

Standard Potassium Solution. Prepare a stock standard by dissolving 2.229 g. of pure dry potassium sulfate in water in a 1-liter volumetric flask, dilute with water to the mark, and mix. Preserve with a little toluene. This solution contains 1 mg. of potassium per ml. and is stable indefinitely. Prepare a working standard fresh daily by diluting 1 ml. of stock standard to 100 ml. with water in a volumetric flask. This solution contains 0.03 mg. of potassium in 3 ml.

Silver Cobaltinitrite Reagent. Prepare a sodium cobaltinitrite solution as follows: (A) Dissolve 25 g. of crystalline cobalt nitrate in 50 ml. of water, and add 12.5 ml. of acetic acid. (B) Dissolve 120 g. of reagent-grade sodium nitrite in 180 ml. of water. Add 210 ml. of B to all of A, place in the hood, and blow air through the solution until all of the nitrous oxide fumes have been driven off. This solution is stable for about 1 month if stored in the refrigerator. It must be filtered each time before using. To prepare the silver cobaltinitrite reagent, add 1 ml. of 40 per cent silver nitrate solution to 20 ml. of filtered sodium cobaltinitrite solution, shake well and filter. Prepare fresh for each series of analyses.

Wash Reagent. Mix 2 volumes of 95 per cent ethyl alcohol with 1 volume of ether and 2 volumes of water.

50 Per Cent Hydrochloric Acid. Mix 1 volume of water and 1 volume of concentrated hydrochloric acid.

Sulfanilamide Solution. Dissolve 0.5 g. of pure sulfanilamide powder (not the tablets) in a mixture of 30 ml. of glacial acetic acid and 70 ml. of water. Prepare fresh weekly.

Naphthylethylenediamine Reagent. Dissolve 0.1 g. of N-(1-naphthyl)-ethylenediamine dihydrochloride (obtainable from Eastman Kodak Co., Rochester, N.Y.) in a mixture of 30 ml. of acetic acid and 70 ml. of water. Prepare fresh weekly.

²⁵⁶ Tubes should be cleaned with bichromate-sulfuric acid cleaning mixture and rinsed well with distilled water just before using. The presence of even traces of ammonia must be avoided, since ammonia likewise forms an insoluble cobaltinitrite.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{10}{3} \times \frac{100}{0.5}$$
= mg. of potassium per 100 ml. of serum

The standard corresponds to a serum potassium of 20 mg. per cent, covering the range from 10 to 40 mg. per cent satisfactorily. To convert mg. per cent potassium into milliequivalents per liter, divide by 3.9.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{10}{3} \times \frac{100}{0.5}$$
= mg. of potassium per 100 ml. of serum

At 520 m μ , and in a 1-cm. cuvette, the standard has a density of approximately 0.160, and the agreement with Beer's law is such that up to 35 mg. per cent may be accurately determined. For higher values, or for photometric measurement at greater depth of solution, develop the color on 1-ml. instead of 2-ml. portions of the final standard and unknown supernatants. No change in calculations is involved.

Interpretation. The potassium concentration of human blood serum or plasma is relatively constant, ranging from about 16 to 22 mg. per cent, or 4.1 to 5.6 milliequivalents per liter. The potassium content of red cells is from 15 to 20 times as great as that of plasma. This indicates the essential uselessness of whole blood potassium determinations, depending as they must largely on the red cell count, and also emphasizes the importance of preventing hemolysis in obtaining serum or plasma for potassium analyses. The potassium content of plasma gradually increases on standing in contact with red blood cells; this is of importance in connection with the storage of whole blood in blood banks. Pathologically, increased serum potassium has been noted in acute bronchial asthma, in uremia, and in Addison's disease. Decreases have been noted at the time of seizure in familial periodic paralysis. The role of potassium in plasma is unknown; the plasma level may reflect to some extent the level in the body tissues and cells where potassium is abundant, being in fact the chief base present. In the body tissues and cells potassium appears to be the physiological equivalent of the plasma sodium in osmotic pressure regulation and acid-base balance.

DETERMINATION OF IRON

1. Introduction. The iron-containing compounds of biological material may be divided into two main groups; (a) heme compounds, (b) non-heme compounds. Heme iron is found in such substances as hemoglobin, cytochrome, catalase, etc., where it is firmly bound in organic combination with the porphyrin nucleus (see Chapter 22) and does not react with iron reagents until after liberation from such combination. Non-heme iron on the other hand appears to be largely extractable from tissues by suitable

means and can be determined directly in the extracts as inorganic iron. There appears to be a rough correlation between the extractable iron of tissues and the fraction of the total iron which is absorbable and utilizable by the animal.²⁵⁷

Total iron is determined after wet or dry ashing, the iron being estimated in the ash solution by titrimetric²⁵⁸ or colorimetric methods. Of the many color reagents for iron, the best appear to be thiocyanate,²⁵⁹ thioglycollic (mercaptoacetic) acid,²⁶⁰ o-phenanthroline,²⁶¹ 2, 2'-bipyridyl ("a, a'-bipyridine"),²⁶² and protocatechuic acid.²⁶³

The total iron of blood is present almost entirely in the form of hemoglobin; the amount present will therefore vary with the hemoglobin content, and may be used as a measure of the latter (see p. 564). The amount of non-hemoglobin iron in blood is a matter of dispute, particularly with regard to that portion which is said to be in the red cells. According to Shorland and Wall,²⁶⁴ the total non-hemoglobin iron of human blood is somewhat under 1 mg. per 100 ml. of whole blood, corresponding to about 2 per cent of the total blood iron; other investigators give higher values. Blood plasma contains about 0.1 mg. per cent of iron;²⁶⁵ plasma iron may be of significance in iron transport and metabolism.

2. Determination of Total Iron in Blood, Foods, and Other Biological Material: Methods of Elvehjem and of Kennedy: Principle. The material is oxidized by ignition or by wet ashing. The acid solution is made alkaline and boiled to change pyrophosphate to orthophosphate. Thiocyanate is added, the ferric thiocyanate extracted with amyl alcohol²⁶⁶ and determined colorimetrically. The method is suitable for substances relatively high in phosphate (such as milk) and for most biological material. For substances high in iron (as blood) the original procedure of Kennedy or the method of Wong may be used (see p. 564).

Method of Elvehjem:²⁶⁷ Ash a sample of the dried material containing 0.1 to 0.3 mg. of iron.²⁶⁸ A few drops of nitric acid may be used to get rid of last traces of carbon. Dissolve by digesting with diluted HCl (1:1) at near the

²⁵⁷ Kohler, Hart, and Elvehjem: J. Biol. Chem., 113, 49 (1936). Their procedure for the determination of available iron is described in the Eleventh Edition of this book. See also Borgen and Elvehjem: J. Biol. Chem., 119, 725 (1937).

²⁶⁵ Barkan and Walker: J. Biol. Chem., 135, 37 (1940). For a study of the determination of plasma iron, see Kitzes, Elvehjem, and Schuette: J. Biol. Chem., 155, 653 (1944).

²⁶⁶ Thompson (loc. cit) recommends extraction with isobutyl alcohol.

²⁶⁷ Elvehjem: J. Biol. Chem., 86, 463 (1930). For iron content of animal tissues, see Elvehjem and Peterson: J. Biol. Chem., 74, 433 (1927).

²⁶⁶ Farrar (J. Biol. Chem., 110, 685 (1935)) dusts tissue materials with iron-free calcium carbonate prior to ashing, in order to avoid loss of iron as chloride by volatilization.

boiling point for 15 minutes or longer. Cool, make distinctly alkaline with 40 per cent NaOH (iron-free) and boil for one hour. Make acid with about 5 ml. of concentrated HCl and dilute to a volume of 50 ml. To 1 ml. of standard solution of iron²⁶⁹ (equivalent to 0.1 mg. of Fe), add 5 ml. of concentrated HCl and dilute to 50 ml. Measure 10 ml. portions of standard and unknown into 50-ml. glass-stoppered cylinders. Add to each 10 ml. of amyl alcohol and 5 ml. of 20 per cent potassium thiocyanate. Shake thoroughly. Remove the colored layers of amyl alcohol with a pipet and compare in the colorimeter or determine the densities of standard and unknown in a photometer at 480 mg. Set the photometer to zero density with a blank prepared as follows: dilute 5 ml. of concentrated HCl to 50 ml. with water, mix, and treat a 10-ml. portion with amyl alcohol and thiocyanate, shaking as described for standard and unknown. Remove the amyl alcohol layer and use as a photometric blank.

Method of Kennedy: 270 Transfer 1 ml. of blood or a weighed piece of tissue to a 100-ml. Kjeldahl flask. Add 5 ml. of concentrated H₂SO₄ and 2 ml. of 60 per cent perchloric acid. Digest over a low flame until solution is colorless and dense fumes of SO₃ come off (about 10 minutes). Perhydrol may be used instead of perchloric acid. Cool, add a drop of nitric acid, and dilute to 100 ml. Carry out the same procedure on standard iron solution. Determine iron in 10-ml. aliquots exactly as in the preceding method.

Calculation. For colorimetric measurement:

Reading of Standard × mg. Fe in standard ×
$$\frac{100}{\text{Aliquot used}}$$
 = mg. of Fe per 100 g. or ml.

For photometric measurement:

The photometric characteristics of the thiocyanate color in amyl alcohol are similar to those already given in connection with the Wong blood iron method (p. 565). Any of the other color reagents for iron which have already been mentioned (thioglycollic acid, o-phenanthroline, etc.) may be used instead of thiocyanate, under the proper conditions. For details, see original papers.

DETERMINATION OF SULFONAMIDES ("SULFA DRUGS")

1. Introduction. 271 All of the "sulfa drugs" in use clinically at the present time are derivatives of the parent compound, sulfanilamide or p-aminobenzenesulfonamide. The structures of some of the more common sulfonamides and derivatives are as follows:

²⁶⁹ Standard Iron Solution. See p. 564.

²⁷⁰ Kennedy: J. Biol. Chem., 74, 385 (1927).

²⁷¹ For historical reviews, see Krantz: J. Am. Dent. Assoc., 31, 634 (1944); Fosbinder: J. Am. Pharm. Assoc., 33, 1 (1944).

No sulfonamides are found in blood or urine unless they have been administered; the level attained depends upon such factors as the size and rate of administration of the dose, the body weight of the individual, and the rates of absorption and elimination. The therapeutically effective level depends upon both the disease and the drug; blood analysis permits definition of blood sulfonamide concentration so that a given level may be altered or maintained as conditions warrant. A variable portion of the total blood sulfonamide, the exact amount depending largely upon the type of sulfonamide being used, is usually present as the acetylated derivative²⁷² (e.g., acetylsulfanilamide). Acetylation involves the amino group attached to the benzene ring. Marked differences exist between the free and the acetylated compound in respect to both therapeutic and toxic properties; distinction is therefore important. Acetylation appears to occur largely in the liver. Other metabolic derivatives of certain of the

²⁷² Marshall, Bratton, and Litchfield: Science, 88, 597 (1938).

sulfonamides are known, such as hydroxy derivatives, possibly combined with glucuronic acid;²⁷⁸ the significance of these is at present obscure.

2. Determination of Sulfonamides: Method of Bratton and Marshall:²⁷⁴ Principle. Blood is deproteinized with trichloroacetic acid. The protein-free filtrate is treated with nitrous acid to diazotize any free sulfonamide present, excess nitrous acid is destroyed, and the diazotized sulfonamide is coupled with N-(1-naphthyl)-ethylenediamine to form a stable red color which is then compared with that developed in a standard treated in the same way. The procedure is the same for all the common sulfonamides which have a diazotizable amino group in the molecule, the only difference being that a standard containing the particular sulfonamide being determined is used in each case. Since acetylation renders the sulfonamide incapable of diazotization, only the unacetylated sulfonamide will react in the colorimetric procedure. To determine acetylated sulfonamide, total sulfonamide is determined after acid hydrolysis, which frees the amino group. The difference between free and total sulfonamide represents acetylated sulfonamide.

Procedure: 275 Measure 2 ml. of oxalated blood into a small flask and from a buret add 30 ml. of saponin solution. Allow to stand for several minutes, then add 8 ml. of 15 per cent trichloroacetic acid solution. Mix well, allow to stand five minutes, and pour onto a dry filter.

Free Sulfonamide: Transfer 10 ml. of the protein-free filtrate to a small flask or wide test tube, add 1 ml. of sodium nitrite solution, and mix. Allow to stand three minutes, then add 1 ml. of ammonium sulfamate solution and again mix. After two minutes' standing, add 1 ml. of the N-(1-naphthyl)-ethylenediamine solution and mix. The color develops almost immediately and is stable for several hours if not exposed to direct sunlight. Read the color in a colorimeter or photometer as described below.

²⁷³ Scudi: Science, 91, 486 (1940); also Scudi and Jelinek: J. Pharmacol., 81, 218 (1944).

274 Bratton and Marshall: J. Biol. Chem., 128, 537 (1939).

²⁷⁵ Reagents Required: Saponin Solution. Dissolve 0.5 g. of saponin in water and dilute to 1 liter. This solution is not absolutely necessary, the saponin merely serving to hasten hemolysis of the red cells. The blood may be laked with water instead of saponin solution, in which case the diluted blood is allowed to stand 15 minutes before adding the trichloroacetic acid.

15 Per Cent Trichloroacetic Acid. Dissolve 150 g. of reagent-grade trichloroacetic acid in water and dilute to 1 liter. Stable indefinitely. To prepare a 3 per cent solution from this, dilute 1 volume with 4 volumes of water.

Sodium Nürite Solution. Dissolve 0.1 g. of pure sodium nitrite in water and dilute to 100 ml. Prepare fresh daily.

Ammonium Sulfamate Solution. Dissolve 0.5 g. of ammonium sulfamate in water and dilute to 100 ml. Stable indefinitely.

N-(1-Naphthyl)-ethylenediamine Solution. Dissolve 0.1 g. of N-(1-naphthyl)-ethylenediamine dihydrochloride (obtainable from Eastman Kodak Co., Rochester, N.Y.) in water and dilute to 100 ml. Store in a dark glass bottle in the cold. Prepare fresh each week.

4 N Hydrochloric Acid. Dilute 40 ml. of concentrated hydrochloric acid to 100 ml. with water. Mix and titrate a 5-ml. portion with standard 1 N sodium hydroxide. Adjust to exactly 4 N. Stable indefinitely.

Standards. Prepare a stock standard as follows: dissolve in water exactly 0.1 g. of the particular sulfonamide being determined, and transfer with rinsings to a 1-liter volumetric flask. Dilute to the mark with water, and mix. In preparing this standard, use the pure powdered drug, not the tablets. This standard is stable for months in the cold. To prepare dilute standards containing 1.0, 0.5, and 0.2 mg. per cent, measure 10, 5, and 2 ml. respectively of the stock standard into 100-ml. volumetric flasks containing 18 ml. of 15 per cent trichloroacetic acid. Dilute with water to the 100 ml. mark and mix. Store in the cold, and prepare fresh every few days.

Total Sulfonamide: Transfer 10 ml. of the protein-free filtrate to a test tube or other container graduated at 10 ml. and add 0.5 ml. of 4 N hydrochloric acid. Place in a boiling water bath for one hour, cool, and adjust the volume to 10 ml. with water. Treat with sodium nitrite solution, etc., just as described above for free sulfonamide.

For colorimetric measurement, compare the color developed on the unknown with that obtained by treating a 10-ml. portion of standard solution in the same manner as the unknown. Since the concentration of sulfonamide in blood may vary widely, several standards should be prepared and the unknown matched against the most suitable one. Satisfactory standards contain 1.0, 0.5, and 0.2 mg. per cent of the sulfonamide. At a blood dilution of 1:20, these standards correspond to blood levels of 20, 10, and 4 mg. per cent respectively. It is convenient to set the 1-mg. standard at 10 mm. in the colorimeter, the 0.5 mg. standard at 15 mm., and the 0.2 mg. standard at 20 mm.

Calculation:276

Reading of Standard
Reading of Unknown × 20 × mg. per cent concentration of standard
= mg. per cent free (or total) sulfonamide in blood

For photometric measurement, transfer the colored solution to a suitable container and read in a photometer at 530 millimicrons.²⁷⁷ Set the photometer to zero density with a blank obtained by treating a 10-ml. portion of 3 per cent trichloroacetic acid with nitrite, sulfamate, etc., as in the treatment of the unknown. From the photometric density of the unknown, and the density of a known standard, preferably determined at the same time, calculate as follows:²⁷⁶

Density of Unknown
Density of Standard × 20 × mg. per cent concentration of standard
= mg. per cent free (or total) sulfonamide in blood

The density of a standard containing 0.2 mg. per cent sulfonamide in a 1-cm. cuvette is approximately 0.300 at 530 millimicrons (Fig. 183). This means that at this solution thickness, bloods containing up to about 10 to 12 mg. per cent sulfonamide may be read satisfactorily, since agreement with Beer's law is excellent over a wide range. Higher concentrations produce colors which are too deep for precise measurement, and in such cases the determination must be repeated at a greater dilution of the blood (or of the 1:20 filtrate, diluted with 3 per cent trichloroacetic acid). If a solution thickness greater than 1 cm. is used in the photometer, the range of reading is proportionately reduced. If some dilution other than 20 is used, this dilution should replace the 20 in the above calculations. Bratton and Marshall point out that dilutions of 1:50 or 1:100 may be employed in this procedure if photometric measurement is used, thus

276 With some of the sulfonamides, correction factors are necessary to correct for drug lost during the precipitation of the proteins. With sulfanilamide, sulfaguanidine, sulfapyridine at levels less than 5 mg. per cent, and free sulfathiazole, no correction factors are needed. For sulfapyridine levels greater than 5 mg. per cent, multiply the results for both free and total drug by 1.1 to obtain the correct values. For acetylated sulfathiazole, subtract the uncorrected free value from the uncorrected total value and multiply the difference by 1.3.

²⁷⁷ Filters or wavelength settings from 520 to 540 m μ give equally satisfactory results (see Fig. 183).

permitting the use of fingertip blood (0.1 to 0.2 ml.). The only precaution is that the final concentration of trichloroacetic acid in the protein-free aliquot taken for analysis should be 3 per cent.

Interpretation. The major factors influencing the level of blood sulfonamide content have already been presented (p. 602); depending upon circumstances, the total blood sulfonamide concentration may range from a trace to as high as 20 mg. per cent or more, with a variable proportion of this in the acetylated form. It is the level of *free* drug which is of

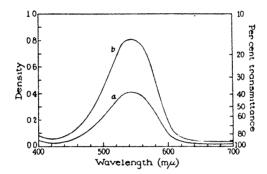

Fig. 183. Absorption spectra of colored solutions obtained in Bratton-Marshall sulfonamide method, for standards containing (a) 0.25 mg. per cent, and (b) 0.50 mg. per cent sulfadiazine. Solution depth, 1 cm.

therapeutic importance; it is usually considered clinically that effective levels of free sulfonamide range from 3–7 mg. per cent for sulfathiazole to as high as 15 mg. per cent for sulfanilamide and sulfadiazine. Those metabolic derivatives other than acetylated forms which have thus far been recognized do not appear to require hydrolysis before reacting in the colorimetric procedure, and will therefore be included in the value for free sulfonamide content; the extent to which this occurs, and the precise significance of these derivatives has not as yet been evaluated.

DETERMINATION OF IODINE

Method of McCullagh: 278 Principle. The iodine is converted to iodide by digestion in alkaline solution, and separated from interfering substances by distillation from acid solution. It is then oxidized to iodate, which in turn is used to liberate iodine from an excess of added iodide in acid solution. The iodine is titrated with sodium thiosulfate. In the analysis of tissues or materials containing only a small proportion of organic matter, the alcoholic extraction may be omitted. In foods where it may be necessary to use large samples to obtain the 2 or 3γ necessary for accurate estimation, the fusion may be conducted in several crucibles, and the alcoholic extracts combined.

²⁷⁸ McCullagh: J. Biol. Chem., 107, 35 (1934); Stimmel and McCullagh: J. Biol. Chem., 116, 21 (1936). This method is adaptable to tissues and foods, as well as blood.

Procedure: 279 Fusion: 10 ml. of blood (or an amount of material containing about 2 to 37 of iodine) are boiled with 12 ml. of saturated KOH solution in a 300-ml, nickel crucible until foaming ceases. The Bunsen flame must be carefully manipulated at the beginning to control excessive foaming; goggles should be worn as a protection against possible spatter due to

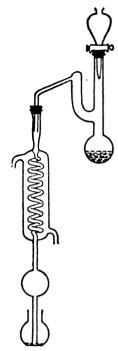

Fig. 184. Distillation apparatus for micro-determination of iodine (McCullagh).

careless manipulation. Organic material may be washed down the sides of the crucible with a little water. This entire operation requires less than 10 minutes. To drive off gases the crucible is placed in the muffle furnace at 250° for 30 minutes (or less). The temperature is then raised to 360° over a period of 30 minutes, and allowed to remain at that temperature another 10 minutes, after which the crucible is removed.

Extraction: Sufficient water is added to the fused mass to form a fluid paste on cooling. This is extracted by thorough stirring with 25 ml. of 95 per cent ethyl alcohol, which is decanted from the sludge into another 300-ml. nickel crucible. The extraction is then repeated four more times with 10-ml. portions of alcohol. To the combined extracts 0.5 ml. of saturated KOH is added. The alcohol is evaporated on a steam bath and the crucible placed in the muffle furnace at 385° for 15 min-

Distillation: The ash is dissolved in water and transferred quantitatively to a modified 50-ml. Claissen flask which has the auxiliary tubulation sealed, thus eliminating the use of a rubber stopper and reducing the condensing surface. The distillation apparatus is arranged as in Fig. 184. The end of the tube leading from the condenser goes to the bottom of a 50-ml. extraction flask which contains water just sufficient to cover the end of the condenser tube, 0.2 ml. of a 3 per cent solution of sulfuric acid, and 0.2 ml. of a 10 per cent solution of sodium bisulfite. To the contents of the Claissen flask are added quickly 2 ml. of 50 per cent solution of sulfuric acid, 1 drop of a 10 per cent solution of ferric sulfate.260 and 2 ml. of a 3 per cent solution of hydrogen peroxide (Superoxol diluted to make a 3 per cent solution). More acid is added if necessary to make the solution definitely acid, as indicated by the presence or absence of ferric

hydroxide. A glass bead is added to prevent bumping. The flask is immediately closed with the stopper and dropping funnel, the outlet of which has been drawn to a point. The contents of the flask are then boiled vigorously over a microburner, care being taken, however, to avoid flooding of the side arm of the Claissen flask. One or two additional 2-ml. portions of 3 per cent hydrogen peroxide are added through the dropping funnel during the distillation. Heating is discontinued during these additions to avoid carrying hydrogen peroxide over with the distillate. The distillation is

²⁷⁹ Purification of Reagents. Distilled water and alcohol may be made iodine-free by adding excess KOH and redistilling from glass. The completely saturated KOH solution should be washed in a separatory funnel with iodine-free alcohol. Concentrated H₂SO₄ is heated to 150° to 200° for 5 hours and then diluted with iodine-free water to make 50 per cent H2SO4. 10 per cent ferric sulfate in 1 per cent H2SO4 is purified by boiling. Bromine must be freed from iodine by placing 50 ml. in a retort, covering with a 1-cm. layer of 10 per cent CuSO4, and distilling into an ice-cooled receiver.

280 If the solution is brownish after the addition of the ferric sulfate, indicating the presence of excessive organic matter, an excess of saturated KMnO4 may be added to the hot mixture before distillation, and before the addition of H₂O₂, with which it undergoes double decomposition.

discontinued when the volume in the Claissen flask is reduced to about 5 ml. or when sulfates begin to crystallize on the side of the flask.

The extraction flask is placed on a wire gauze with asbestos center and the contents are boiled gently for 2 minutes to expel CO₂ and SO₂, a glass bead being used to prevent bumping. The solution is immediately made alkaline to litmus paper with 10 per cent KOH; this should not require more than 3 drops. The solution is then carefully boiled down to a volume of 5 or 6 ml.; 1 drop of methyl orange is added, and the solution is neutralized by the addition of 3 per cent H₂SO₄. Two drops of acid in excess are then added along with 5 drops of bromine water, which should cause the solution upon shaking to turn yellow immediately. It is then boiled down very cautiously to about 2 ml., and cooled on ice. This should require from 3 to 5 minutes in order completely to remove excess bromine with minimum loss of iodine.

Titration: One drop of a 1 per cent solution of starch and 2 drops of a 1 per cent solution of KI are added, and titration is carried out with a 0.001 N Na₂S₂O₃ which is delivered from a microburet or a 0.2-ml. pipet graduated to 0.001 ml. A blank (usually 0 and never more than 0.2 γ) should be run on all reagents.

Calculation. One ml. of 0.001 N Na₂S₂O₃ is equivalent to 21.2γ of iodine. When 10 ml. of blood are used, as described,

(Titration - Blank) × 212 = micrograms of iodine per 100 ml. of blood

Interpretation. Normal blood usually contains from 8 to 15γ I per 100 ml., of which half or less is alcohol-insoluble. This fraction is increased in hyperthyroidism and may represent active thyroid substance. 18 per cent or less of the total iodine in normal blood is probably in inorganic form. This is increased by iodine administration. In cretinism, the total iodine decreases.

Respiratory Exchange and Neutrality Regulation

General. The major function of the lungs in respiration is to facilitate the addition of oxygen to the blood and to remove excess carbon dioxide from the blood. The oxygen is carried to all the tissues, where it is utilized in the metabolic processes taking place within the cells. The chief end-products of these metabolic processes include H₂O, CO₂, urea, and various organic and inorganic acids such as lactic, uric, phosphoric, sulfuric, and the like. The production of end-products which are bases, such as ammonia and the various organic amines, is relatively unusual or confined to special tissues. Of the various end-products listed, only H₂O and urea are neutral substances and can be excreted by the body without bringing into play the various mechanisms of neutrality regulation which are the subject of this discussion.

The CO₂ produced in the tissues is removed by diffusion into the blood, where the major portion (approximately 70 per cent) at once undergoes hydration to form carbonic acid, the remainder combining with the blood proteins (including hemoglobin) to form carbamates (20 per cent), or remaining in physical solution (10 per cent). The newly formed carbonic acid must be immediately neutralized or the blood would become far more acid than is compatible with life; this neutralization is mediated largely through hemoglobin, as described below. The other acid end-products of metabolism are neutralized as soon as they are formed and exist in the blood and tissues as salts, neutralization being effected through reaction with such ions as the HPO₄ ion in the cells and the HCO₃ ion in the blood plasma. Thus carbonic acid is not only an important end-product of tissue oxidation, but it also plays a significant role in neutrality regulation. The level of the blood bicarbonate content is the most satisfactory single index of the ability of the body as a whole to neutralize acid endproducts of metabolism. The peculiar virtue of the carbonic acid-bicarbonate system in controlling the neutrality of the body lies in the volatility of carbon dioxide and hence its ready elimination by the lungs. The nonvolatile acids (uric, phosphoric, etc.) after conversion into their salts can be disposed of by the kidneys.

Role of Oxygen. A complete understanding of the mechanism of neutrality regulation and CO₂ transport in the blood requires knowledge of the part played by oxygen. The role of oxygen in this connection is illustrated in Fig. 185. Oxygen is found in the blood in two forms, (a) in physical solution, and (b) in combination with the respiratory pigment hemoglobin to give the compound oxyhemoglobin. The amount of oxygen in physical solution in the blood is relatively small, most of the oxygen

present being in the combined form of oxyhemoglobin. An equilibrium exists between the free oxygen in solution, the hemoglobin which is not combined with oxygen (so-called reduced hemoglobin), and oxyhemo-

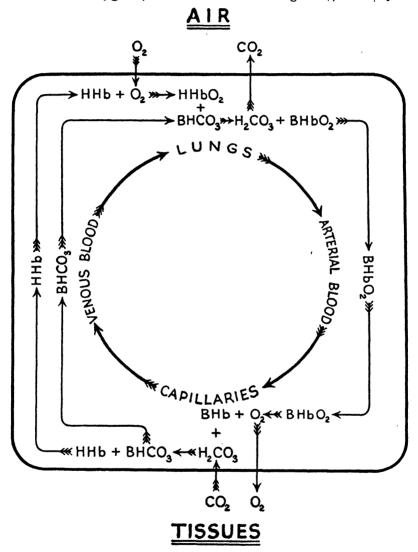

Fig. 185. Diagram showing role of oxygen in the transport of CO₂ by the blood.

globin; this relationship can be written as follows:

$$\begin{array}{ccc} \operatorname{Hb} & + & \operatorname{O_2} & \rightleftarrows & \operatorname{HbO_2} \\ \operatorname{Reduced} & \operatorname{Oxygen} & \operatorname{Oxyhemoglobin} \\ \operatorname{hemoglobin} \end{array}$$

From this it can be seen that when the amount of free oxygen in the blood is lowered, as by diffusion into the tissues, the content of oxyhemoglobin

will decrease and that of reduced hemoglobin will increase. This occurs when arterial blood is changed into venous blood. When venous blood reaches the lungs, it is distributed in the many capillaries of the alveoli, exposing a great surface to contact with the alveolar air. The oxygen tension of alveolar air is high enough to cause a considerable increase in the amount of dissolved oxygen in the blood. This in turn increases the amount of oxyhemoglobin at the expense of reduced hemoglobin, and when the aerated blood leaves the lungs as arterial blood practically all of the hemoglobin is normally in the form of oxyhemoglobin. This relation between oxygen tension and the degree of oxygenation of hemoglobin has been discussed in Chapter 22.

Now in addition to their relation with oxygen transport, the proteins oxyhemoglobin and reduced hemoglobin act as typical weak acids, being present in the blood partly in the unneutralized or free acid form (HHb, HHbO₂) and partly as salt ions (Hb⁻, HbO₂). At the pH of the blood, the reduced hemoglobin ion Hb⁻ has a greater affinity for the H⁺ ion than has the oxyhemoglobin ion HbO₂, i.e., reduced hemoglobin behaves as a weaker acid than oxyhemoglobin. When HbO₂ is converted into Hb⁻ in the tissue capillaries by the loss of oxygen from the blood, this increase in affinity for H⁺ ions on the part of the Hb ion (to form HHb) would tend to remove H⁺ ions from the blood and thus make it slightly more alkaline, if it were not for the fact that carbonic acid is entering the blood at the same time. It has been shown that, under normal circumstances, about 50 per cent of the entering carbonic acid is equivalent to this potential increase in alkalinity of the blood, i.e., will be "neutralized" without any net pH change in the blood at all. Since the carriage of this portion of the entering carbonic acid does not involve a change in pH of the blood, it is known as the *isohydric* carriage. Naturally, the exact reverse of the abovedescribed process occurs in the lung capillaries, where reduced hemoglobin is converted by oxygenation to oxyhemoglobin. This conversion liberates H⁺ ions from combination with Hb (the effect is as though acid were added to the blood), the liberated H⁺ ions combining with HCO₃ ions present to form H₂CO₃, which is then decomposed to CO₂ and H₂O and the CO₂ diffuses out of the blood into the alveolar air of the lungs.

It may be noted here that, in addition to the carriage of a portion of the entering CO₂ by the isohydric reaction, hemoglobin enters into carbon dioxide transport in at least two other recognized ways. One of these is to act as a typical buffer, in the manner described in detail below. Another is due to the fact that hemoglobin, as a protein, is capable of combining directly with carbon dioxide to form a *carbamate*, the reaction involving the free amino groups of the hemoglobin molecule:

$$H_{\text{PMH}} + CO^{2} \rightleftharpoons HPM \qquad \Leftrightarrow HPM \qquad + H+ COO-$$

The formation of carbamate in this manner is a general property of pro-

teins and amino acids and is not specific for hemoglobin, but, since hemoglobin is by far the most abundant protein in blood, a major portion of the CO₂ which is carried as carbamate is due to hemoglobin.

The existence of such a direct combination of hemoglobin and CO₂ was at one time disputed, but the work of Henriques, of Roughton, and of Stadie and O'Brien has established the significance of carbamate-bound CO₂ in respiratory gas exchange. While the actual amount of carbamate-

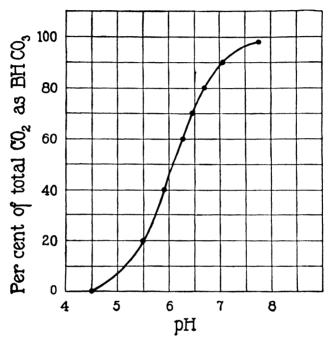

Fig. 186. Titration curve for the H₂CO₃:BHCO₃ system. (From Van Slyke: "Endocrinology and Metabolism," vol. 4, New York, Appleton, 1924.)

bound CO₂ in the blood is small relative to the amount of bicarbonate (see Table on p. 618), the ease of formation and breakdown of this type of compound in response to changes in CO₂ tension is such that from 20 to 30 per cent of the *extra* CO₂ added to the blood in the tissues and released in the lungs may be transported in this manner.

Role of Buffers. As has been indicated, the isohydric reaction accounts for only part of the CO₂-carrying power of the blood. When more CO₂ enters than can be neutralized in this manner, the blood becomes more acid, i.e., its hydrogen-ion concentration increases.

To understand the nature of this change, it is necessary to consider the general properties of buffer solutions (see also Chapter 1). A buffer solution ordinarily contains a weak acid and its salt, or a weak base and its salt. Such solutions are capable of taking up limited amounts of acid or base with much less change in hydrogen-ion concentration than would result from the same addition of acid or base to water or to sodium chloride

solution, neither of which have buffer power. A buffer system can act therefore as a reservoir of alkali for the neutralization of the acid end-products of metabolism. The efficiency of a buffer system in resisting change in reaction is greatest at the half-neutralization point, i.e., when the molar concentrations of salt and acid are equal. Fig. 186 represents a titration curve for a weak acid (carbonic), that is, a curve in which the per cent of total acid neutralized is plotted against the pH at each step in the titration. The S-shaped curve is characteristic of buffer acids or alkalies, and demonstrates that when 50 per cent of the acid is neutralized (ratio of salt to acid = 1), the slope (rate of change of pH) is least.

The relation between the reaction (pH) and the ratio of buffer acid (HA) to buffer salt (BA) is derived as follows. The equation for the electrolytic dissociation of a weak acid into hydrogen ions and anions is $HA \rightleftharpoons H^+ + A^-$. From the law of mass action we know that the velocity of this reversible reaction in either direction is proportional to the concentrations of the reacting constituents. That is,

Velocity (left to right) =
$$k_1HA$$

Velocity (right to left) = $k_2(H^+ \times A^-)$

in which the symbols also represent concentrations. At equilibrium the rate of reaction in each direction is the same, the equilibrium being dynamic. Therefore

$$k_1 \text{HA} = k_2 (\text{H}^+ \times \text{A}^-)$$

or transposing,

$$\frac{k_1}{k_2} = \frac{(H^+ \times A^-)}{HA} = K$$

K being the dissociation constant of the acid. Transposing again,

$$H^+ = K \times \frac{HA}{A^-}$$

In a solution of a weak acid and its salt, only a very small fraction of the anion, A^- , originates from the dissociation of the free acid, the rest coming from the dissociation of the salt, BA, into B⁺ and A⁻. Most salts in the concentration found in body fluids are ionized to the extent of 60 to 90 per cent. "If the degree of dissociation be represented by λ , the concentration of anions $A^- = \lambda BA$ and we may rewrite the last equation

$$H^+ = K \times \frac{HA}{\lambda BA}$$

Since λ varies to a relatively slight extent over ranges of concentration within such limits as are found in blood constituents, one may state as a close approximation that

$$\frac{K}{\lambda} = K_1$$

and

$$\mathbf{H}^+ = \mathbf{K}_1 \frac{\mathbf{H} \mathbf{A}}{\mathbf{B} \mathbf{A}}.$$

K₁ is called the "apparent dissociation constant."

By definition pH = $-\log H^+$ (see p. 20). (For example, the hydrogenion concentration [H⁺] at neutrality is 0.000,000,1 normal = 10^{-7} . Therefore the pH = $-\log 10^{-7} = -(-7) = 7$.) Taking the logarithms of both sides of the last equation,

$$\log H^+ = \log K_1 + \log \frac{HA}{BA}$$

and, changing signs, $-\log H^+ = -\log K_1 - \log \frac{HA}{BA}$

Substituting pH for $-\log H^+$, and, for an analogous reason, pK₁ for $-\log K_1$,

$$pH = pK_1 + \log \frac{BA}{HA}$$

This equation is known as the Henderson-Hasselbalch equation and is a most fundamental concept in the understanding of acid-base equilibrium in the body. The value of the constant pK_1 for various acids is numerically equal to the pH when the ratio of salt BA to acid HA is unity, since the log 1=0. Under this condition, it will be recalled, the maximum efficiency of the buffer action obtains. The following table gives the pK_1 values for the more important buffers in blood.

Buffer System	pK_1
BHbO ₂ :HHbO ₂	7.16
BHb: HHb	7.3
BHCO ₃ : H ₂ CO ₃	6.1
B ₂ HPO ₄ : BH ₂ PO ₄	6.8

With the Henderson-Hasselbalch equation in mind, consider what happens when acid is added to a buffer system. The added acid reacts with the buffer salt present to produce an equivalent increase in the amount of buffer acid, at the expense of the buffer salt, together with the salt of the entering acid which plays no part in pH change and may be disregarded. The decrease in buffer salt concentration and corresponding increase in buffer acid concentration, however, must necessarily change the pH of the solution in accordance with the demands of the Henderson-Hasselbalch equation. If the solution were not buffered, the change in pH on the addition of acid would correspond to the actual amount of added H+; in a buffered solution the change in pH is numerically much smaller, being equal to the change in the value of the logarithm of the ratio of buffer salt to buffer acid. It is for this reason that buffer solutions behave as they do in resisting gross changes in pH on the addition to the solution of acid or alkali, for it can be readily shown that an exactly analogous mechanism functions in the case of added alkali.

In a solution containing a number of different buffers, as is the case with the blood and tissues, the entering acid or alkali is buffered by all the buffer systems present, in proportion to their relative effectiveness at the given pH. Thus in the buffer systems of the blood:

BHCO ₃	\mathbf{BHb}	$\mathrm{BHbO_2}$	B_2HPO_4	BProtein
$\overline{\mathrm{H_{2}CO_{3}}}$	$\overline{ m HHb}$	$\overline{\mathrm{HHbO_2}}$	BH ₂ PO ₄	HProtein

the entrance of acid will cause a decrease in concentration of all the buffer salts (numerators) and an increase in concentration of all the buffer acids (denominators), accompanied by an equivalent change in pH as required by the Henderson-Hasselbalch equation.

It is well to note here that physiological limitations influence considerably the relative significance of the various buffers in the blood. Thus the chief buffer for *carbonic acid* is hemoglobin, since carbonic acid is formed from CO₂ and H₂O only in the red cells where most of the buffering reactions for carbonic acid take place (see below). On the other hand, the major buffering action for all acids other than carbonic acid is exerted by the plasma bicarbonate, protein, and phosphate buffer systems.

It is significant that the pH of maximum efficiency of these buffers is below the normal pH for blood, since as the blood pH falls, change of reaction is opposed with an efficiency which increases as the danger point is approached. While the ratio BHCO₃: H₂CO₃ at the pH of blood is about 20:1 and hence considerably removed from the ratio of maximum efficiency, the chief significance of this system rests in the fact that H₂CO₃ promptly dissociates yielding CO₂ which is expired; thus the actual efficiency of the CO₂ system in neutrality regulation is greater than would appear to be the case from a consideration of the buffer theory alone.

Role of the Red Cells. Serum separated from the red corpuscles ("separated serum") has only a slight buffer effect and CO₂-carrying power as compared with serum in contact with the cells ("true serum"). Investigation has shown that this is because practically all of the reactions associated with the transport of CO₂ by the blood take place primarily within the red cell itself, the serum (or plasma) being involved in a secondary manner only. The role of the red cell and of the plasma in the uptake of CO₂ by the blood is summarized in the accompanying diagram (Fig. 187).

As indicated in the diagram, CO₂ produced metabolically in the tissues diffuses as such into the plasma. Here a small amount remains in physical solution, and some possibly reacts also with the plasma proteins (PrNH₂) to form carbamate, the extra equivalent of acid thus formed being buffered by the plasma buffers (A⁻) in the usual way. By far the greater portion of the entering CO₂ (upward of 90 per cent) does not remain in the plasma, however, but diffuses rapidly through the red cell wall into the red cell itself.

Here it comes under the influence of the enzyme carbonic anhydrase. This enzyme is present in abundance in the red cell (and in certain other specialized tissues, such as the pancreas and the gastric mucosa) but is absent from the blood plasma. Its function is to act as a catalyst in the reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$. By virtue of its presence within the red

cell, much of the entering CO_2 is converted into H_2CO_3 , which immediately dissociates to give H^+ and HCO_3^- ions. A portion of the entering CO_2 (about 20 per cent) escapes hydration, however, reacting rapidly with the hemoglobin present to form carbamate. The net effect of these two reactions, therefore, is the production within the cell of an excess of H^+ and HCO_3^- ions, together with a small amount of carbamate ions. The amounts of these ions thus produced are such as to greatly alter the normal pH and osmotic equilibrium of the cell if they were not removed in some manner.

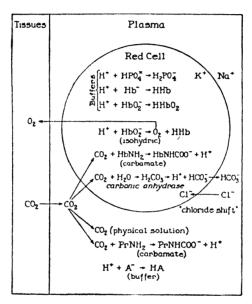

Fig. 187. Diagrammatic illustration of processes involved in the uptake of carbon dioxide by blood.

The H⁺ ions are removed in two ways, by the isohydric reaction and by buffer action. It has already been pointed out that oxyhemoglobin (HbO₂) is a stronger acid than reduced hemoglobin (Hb) at the pH of the blood. This means in effect that hemoglobin which has lost its oxygen has a greater affinity for H⁺ ions at a given pH than has oxyhemoglobin. Thus the liberation of oxygen from the blood to the tissues creates a situation which brings about the conversion of a portion of the H⁺ ions present to the un-ionized form (as HHb) without involving any pH change at all. This process, under the conditions prevailing in normal blood, accounts for the disposal of over 50 per cent of the extra H⁺ ions produced within the red cell from the entering CO₂. The remaining H⁺ ions react with the various buffer salt ions present in the cell to form an equivalent amount of un-ionized buffer acids. Since this typical buffer reaction involves a change in the ratio of buffer salt to buffer acid, the pH of the cell contents will change as demanded by the Henderson-Hasselbalch equation, and it is

this which accounts for the slight change in pH which follows the uptake of CO₂ by the cells.

The fate of the extra HCO₃ ions must now be considered. If they remained within the cell, the increased osmotic pressure would cause the cell to take up water and swell to a size far beyond physiological limits. It has been found by chemical analysis of cells and plasma that most of the extra HCO₃ ions diffuse out of the cell into the plasma, being replaced by an equivalent amount of Cl⁻ ions which diffuse from the plasma into the cell. This process is called the "chloride shift," and it has been estimated that as much as 80 per cent or more of the extra bicarbonate of venous plasma (as compared to arterial plasma) is due to diffusion from the red cells.

The chloride shift has been attributed by Van Slyke to the existence of a Donnan equilibrium (see p. 11) across the red cell membrane. It can be shown that, in the case of the red cell, it is a consequence of the Donnan theory that at osmotic equilibrium the ratio of bicarbonate-ion concentrations in cell and plasma is proportional to the ratio of chloride-ion concentrations in cell and plasma, i.e.,

$$\frac{[\mathrm{HCO_3^-}]_{cells}}{[\mathrm{HCO_3^-}]_{plasma}} = k \cdot \frac{[\mathrm{Cl^-}]_{cells}}{[\mathrm{Cl^-}]_{plasma}}$$

An increase of bicarbonate-ion concentration within the cell disturbs this equilibrium and it is partially restored by migration of bicarbonate ions from the cell to the plasma, accompanied by an equivalent migration of chloride ions from the plasma to the cell. At the same time, a certain amount of water diffuses from the plasma into the red cell, and this accounts for the slight increase in size of the cells of venous blood as compared to arterial blood.

The phenomena that have just been described take place during the uptake of CO₂ by the blood in the tissue capillaries to form venous blood. When the venous blood reaches the lungs, the entrance of oxygen reverses all of these processes. Bicarbonate in the cell is converted into carbonic acid which is dehydrated to CO₂ and diffuses out of the cells into the plasma, from whence it passes into the alveolar air of the lungs. Bicarbonate ions migrate from the plasma to the cell and undergo the same reactions, chloride ions returning from the cell to the plasma at the same time. The various other reactions are likewise reversed in an analogous manner. Thus the red cell is carried through the entire mechanism first in one direction and then in the other direction as it makes a complete circuit of the body.

The quantitative nature of the changes that normally take place in the blood in its transition from the arterial to the venous state is illustrated by the data of the following table, adapted from Stadie and O'Brien.²

¹ J. Biol. Chem., 117, 439, (1937).

¹ The hemoglobin ions likewise enter into this equilibrium. For a detailed discussion of the Donnan equilibrium as it is applied to the chloride shift, the reader is referred to Peters and Van Slyke: "Quantitative Clinical Chemistry," vol. I; see also Hitchcock: "Physical Chemistry for Students of Biology and Medicine," 3d ed.

cent	35.7	12.6	48.3	38.1	14.0	52.1	2.4	1.4	3.8	100.0

Study of this table shows the following:

- 1. In its passage through the tissues of the body, the arterial blood of the subject being studied has picked up about 3.8 ml. of $\rm CO_2$ per 100 ml. of whole blood. This is an increase of about 8 per cent in the total $\rm CO_2$ content of the blood. With the R.Q. assumed to be 0.85, a normal value, this corresponds to the liberation of about 4.5 ml. of $\rm O_2$ from the blood at the same time, which is responsible for the change in oxygen saturation from 96 per cent to 74 per cent.
- 2. The increased CO₂ content of venous blood is accompanied by a rise in CO₂ tension of about 5 mm. of Hg, and a fall in pH of about 0.01 to 0.02 pH units.
- 3. Of the total CO₂ of blood, almost 90 per cent is in the form of bicarbonate, of which about three-fourths is found in the plasma and one-fourth in the cells. The remaining 10 per cent of the total CO₂ is about equally distributed between the forms of free CO₂ and carbamate. Plasma contains about twice as much free CO₂ and about half as much carbamate-bound CO₂, as is found in the cells.
- 4. Of the 3.8 volumes per cent of CO₂ added to the blood in the change from arterial to venous blood, which are ultimately released in the lungs, about three-fourths appears as extra bicarbonate, about one-fifth as carbamate, and the remainder as an increase in the free CO₂ content. The extra free CO₂ and extra bicarbonate are both distributed between cells and plasma in about the same proportion as that already present; almost all of the extra carbamate is found in the cells.
- 5. Most of the extra bicarbonate of venous blood is found in the plasma. Now it has been shown that the passage of blood through the capillaries is far too rapid to permit any appreciable hydration of CO₂ to H₂CO₃ (a necessary preliminary to the formation of bicarbonate) without the intervention of carbonic anhydrase, and this enzyme is found only in the cells. It follows, therefore, that most of the extra bicarbonate of venous plasma

must have come from the cells. This is accomplished by virtue of the "chloride shift" mechanism, an equivalent amount of chloride leaving the plasma and entering the cells.

Relative Importance of the Various CO₂-Carriers of the Blood. A CO₂-carrier of the blood has been broadly defined by Van Slyke as any substance present in the blood which increases the amount of CO₂ that may be taken up by arterial blood without a change in pH beyond the normal difference between venous and arterial blood. From this definition it is clear that the major CO₂-carriers of the blood include hemoglobin, bicarbonate, the plasma proteins, and phosphates. It is also clear that by far the most important CO₂-carrier of normal blood is hemoglobin since 80 per cent or more of the CO₂ carriage by the blood is mediated directly or indirectly through the presence of hemoglobin. Thus this compound plays as important a part in neutrality regulation and the transport of CO₂ as it plays in its more obvious function in O₂ transport.

Role of the Lungs. Due to the ease of elimination of CO_2 by respiration, the regulation of the neutrality of the blood is largely controlled by the H_2CO_3 : BHCO₃ system. By means of variation in the rate and depth of respiration and the rate of blood flow through the lungs, opportunity is afforded for very delicate adjustment of the hydrogen-ion concentration. The nervous control of the respiratory mechanism resides in the respiratory center in the medulla. Increases in CO_2 tension or hydrogen-ion concentration call forth corresponding responses in the ventilation of the lungs, and since changes in either factor take place concurrently, it is difficult to distinguish the effects of one from the other. It is probable that an increase in hydrogen ions in the respiratory center itself, secondary to that of the blood, may be the activating factor. Such increases may come about through diffusion of CO_2 or H^+ from the blood or by acid production within the center. The latter may explain the greater respiratory response which results from an insufficient oxygen supply to the center.

The rate of elimination of waste products through the lungs and the kidneys is partly controlled by the rate of blood flow through those organs. The diminished blood pressure following excessive pulmonary ventilation has been shown to be due to the loss of CO₂ rather than to the resultant rise in pH per se. There is, however, no constant relation between blood pressure and CO₂ tension among different individuals.

Role of the Kidneys. The role of the kidneys in neutrality regulation is concerned chiefly with the conservation of "fixed base" (sodium, potassium) to the organism. If a strong acid produced by metabolism within the tissues is neutralized by reaction with bicarbonate or basic phosphate to produce a salt, the base component of the salt thus formed (e.g., the Na of NaCl) is no longer a direct part of the "alkali reserve" of the body, and if present in excess will be excreted in the urine. If, however, the alkali reserve is low so that the organism needs to conserve fixed base, as when acid production exceeds the supply of available base, the kidney has the ability to excrete an acid urine (down to a pH as low as 4.8) as one means of conserving base. According to Pitts, this is probably accomplished by the reabsorption of base ions from the glomerular

ultrafiltrate and their replacement by hydrogen ions secreted into the tubular lumen. In effect, the following reaction occurs:

$$Na_2HPO_4 + H^+ \rightarrow NaH_2PO_4 + Na^+$$
(from (from (to (to blood) kidney) urine) blood)

The increase in the relative amount of acid phosphate to basic phosphate in the urine accounts for the more acid pH of the urine. If the urine is titrated with alkali back to the pH of the blood (the "titratable acidity," see Chapter 32), a measure of the extent to which the above reaction has contributed to base conservation will be obtained.

A second and equally important mechanism whereby the kidneys conserve fixed base is by the synthesis of ammonia, probably from glutamine and amino acids. The ammonia is excreted in preference to fixed base, as follows:

NaCl + NH₄⁺
$$\rightarrow$$
 NH₄Cl + Na⁺
(from (from (to (to blood) kidney) urine) blood)

The extent of ammonia excretion is related to the need for base conservation, ordinarily being low or zero in alkalosis and high in acidosis. Thus by determining both the ammonia excretion and the titratable acidity of the urine, the extent of acid excretion by the body may be evaluated, and hence knowledge be gained concerning the state of acid-base balance.

It sometimes happens that there is an excess of base requiring excretion, as on diets high in alkaline ash or after administration of bicarbonate. In this event, extra base and bicarbonate will be found in the urine and the pH may rise to as high as 8.0.

pH and H₂CO₃:BHCO₃ Ratio. Inasmuch as the chief factor in the regulation of blood reaction is the H₂CO₃:BHCO₃ system, the relationship of variations in the latter to pH should yield valuable information concerning changes in the acid-base balance of the body. Applying the equation for the dissociation of a weak acid (see p. 613) to this case, the so-called Henderson-Hasselbalch equation is obtained.

$$pH = pK_1 + \log \frac{BHCO_3}{H_2CO_3}$$

The value of the constant pK₁ for blood plasma is 6.10. By measuring any two of the remaining variables, the third is of course determined. If we plot changes in bicarbonate concentration [BHCO₃] as ordinates, against carbonic acid [H₂CO₃] as abscissae, a straight line will result for any given ratio of the two, and hence for any given pH. The slope of this line will increase or decrease with corresponding changes in the [BHCO₃]:[H₂CO₃] ratio. The maximal as well as the normal ranges of these factors are dépicted in Fig. 188, constructed by Van Slyke. Since it was desired to use the customary form of CO₂ absorption curves, the coördinates are ex-

³ Van Slyke, Phillips, Hamilton, Archibald, Futcher, and Hiller: J. Biol. Chem., 150, 481 (1943).

pressed in terms of total CO₂ values, [BHCO₃ + H₂CO₃], as ordinates, and CO₂ tensions as abscissae. It will be noted that nine areas are set off by the three levels (high, normal, or low) of each of the two variables. The nine areas represent conditions of acid or alkali excess or deficit, which are either compensated (pH normal) or uncompensated (pH above or below normal). That is, a condition of alkali deficit (low alkali reserve) may be either compensated by a corresponding diminution in carbonic acid so that the [BHCO₃]:[H₂CO₃] ratio remains normal (about 20:1), or it may be uncompensated by the failure to remove sufficient CO₂, in which case

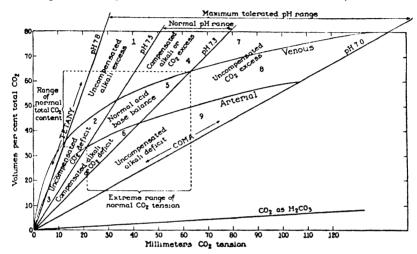

Fig. 188. Normal and abnormal variations of the BHCO₃, H_2 CO₃, CO₂ tension, and pH in oxygenated human whole blood drawn from resting subjects at sea level. (Van Slyke.) The bicarbonate CO₂ at any point is obtained by subtracting from the total CO₂ the relatively small amount present as H_2 CO₃ indicated by the slanting line near the bottom of the illustration.

the pH falls and the condition of uncompensated alkali deficit results. It is therefore obvious that "acidosis" cannot be regarded as merely a lowering of the pH, since the acidosis may accompany a deficit of CO₂ so marked as to result in a more alkaline reaction of the blood. Moreover, an abnormally acid reaction may occur even with an increase of alkali reserve provided CO₂ is present to excess. In order, therefore, to combine the effects of both alkali reserve and reaction, Van Slyke has broadly defined acidosis as a condition caused "by the formation or absorption of acids at a rate exceeding that of their elimination . . . [which] . . . may be considered to have caused an abnormal state when it has either increased the hydrion concentration of the blood or lowered its alkali reserve below the extreme normal limits." The conditions which fall into the different areas have been observed both clinically and experimentally.

Disturbances of the Acid-base Balance. These are divided into two clinical types by Peters and Van Slyke, viz., (1) metabolic types, in which

the primary disturbance is in the relation between alkali and acids other than H₂CO₃, and (2) respiratory types, in which the primary disturbance involves the CO₂ content of the blood. In the table below the more

DISTURBANCES OF ACID-BASE EQUILIBRIUM OF BLOOD

Area (Fig. 188)	Acid-base Balance	Conditions	Associated Symptoms	Compensatory Mechanisms
1 Uncompen- sated Alkali Excess	[BHCO ₃] increased without proportionate rise in [H _r -CO ₃], therefore pH increased	Overdosage of Na- HCO ₃ . Excessive vomiting (pyloric ob- struction) or gastric lavage (loss of HCl). X-ray or radium treatment	If marked, tetany	Diminished respira- tion (rise in alveo- lar CO ₂) to hold back CO ₂ Diuresis and in- creased NaHCO ₂ excretion
2-3 Uncompensated CO2 Deficit	[H ₁ CO ₃] decreased without propor- tionate fall in [BHCO ₃], there- fore pH increased	Hyperpnea, voluntary or induced (oxygen want, e.g., at high altitudes) Fever Hot baths	If marked, tetany	Retention of acid metabolites (low NH; and titratable acidity of urine) Excretion of Na- HCO;
4 Compensated Alkali or CO: Excess	[BHCO ₃] (or [H ₂ -CO ₃]) increased but balanced by proportionate rise in [H ₂ CO ₃] (or [BHCO ₃]), therefore pH normal	Alkali excess NaHCO2 therapy, with slow absorption CO: excess Retarded gas ex- change (e.g., em- physema) with CO2 tension chronically increased	Cyanosis due to deficient oxygen exchange	CO ₂ retention BHCO ₃ retention
5 Normal	[BHCO ₃] and [H ₂ - CO ₃] normal at ordinary altitudes			
6 Compensated Alkali or CO: Deficit	[BHCO ₃] (or [H ₂ -CO ₄]) decreased but balanced by proportionate fall in [H ₂ CO ₄] (or [BHCO ₃]), there- fore pH normal	Alkali deficit Accelerated produc- tion (e.g., diabetes) or retarded elimina- tion (e.g., nephritis) of nonvolatile acids Experimental acid in- toxication Diarrheal acidosis of infancy (marasmus) CO1 deficit Overventilation at	Пурегр пеа	Increased respira- tion ("blowing off CO?") Accelerated NH ₃ formation and acid excretion Same as in Areas 2
		high altitudes (oxy- gen want)		and 3
7-8 Uncompensated CO ₂ Excess	[H ₂ CO ₃] increased without propor- tionate rise in [BHCO ₃], there- fore pH decreased	Retarded respiration as in pneumonia (physical obstruc- tion) or morphine narcosis (deadening of respiratory center) Experimental re- breathing Cardiac decompensa- tion	Dyspnea	Increased respira- tion. Accelerated NH1-formation and acid excretion. Probable shift of acid from blood to tissue
9 Uncompen- sated Alkali Deficit	[BHCO ₃] decreased without propor- tionate fall in [H ₂ - CO ₃], therefore pH decreased	Terminal stages of ne- phritic acidosis, and diabetic acidosis (compensated by in- sulin therapy) Deep ether anesthesia Certain cardiac cases Eclampsia	Dyspnea .	Increased respira- tion. Increased acid excretion and NH1-formation (ex- cept probably in nephritis)

important conditions associated with disturbance of acid-base balance are shown, together with their causes and the physiological mechanisms brought into play for their compensation.

Ketosis is the condition in which abnormal amounts of β -hy-

droxybutyric acid, acetoacetic acid, and acetone accumulate in the body fluids and may be readily detected in the urine. These three compounds are commonly known as the "acetone bodies." Of the three acetone bodies. B-hydroxybutyric acid and acetoacetic acid are primary products, acetone being derived from the decarboxylation of acetoacetic acid. They appear to have their origin principally from the metabolism of the fatty acids of fats, and to a lesser degree from certain amino acids resulting from protein cleavage. This is discussed in detail in Chapter 33. They are apparently formed in the liver, and then further oxidized in the other tissues of the body where they are capable of furnishing a large amount of energy. In diabetes mellitus, the body either does not possess the normal power of oxidizing these substances or else they are produced in excessive amounts. At any rate, we find them in the blood and urine in abnormal quantity. Likewise, in the absence of dietary carbohydrate and in other conditions of faulty carbohydrate metabolism, they are also increased in amount in both blood and urine. Ketosis as it appears in the human organism is not entirely the same as in other species, such as the rat, dog, rabbit, goat, pig, and cow. Rats are very resistant to the development of ketosis.

The significance of ketosis in connection with acid-base balance lies in the fact that acetoacetic acid and β -hydroxybutyric acid exist in the blood and urine largely in the form of their alkali salts. Their production has therefore required an equivalent amount of body base for neutralization. Excessive amounts produce a severe demand on available base, and when they are excreted in the urine most of this base is lost to the organism. The acidosis of diabetes mellitus may be largely due to ketosis. Acidosis occurs in many conditions, however, without a concomitant ketosis.

The presence of acetone bodies in the urine in appreciable quantity was originally taken as an index of acidosis, the severity of which was judged by the estimation of the amount of these substances present in the urine. That this is not a reliable index is shown by the occasional observation of a pronounced acidosis with no appreciable increase in urinary acetone bodies. A high urinary ammonia coefficient (ammonia N:total N) was once looked upon as an indication of acidosis. However, this factor is not specific in diagnosis in spite of the fact that the majority of such cases show a high urinary ammonia value because certain dietetic changes may produce high urinary ammonia. Fatal acidosis has been observed in uremia, and in nutritional disorders of infants, with no pronounced increase in the ammonia coefficient. In this connection, it is possible that in renal disability the ammonia-forming function of the kidneys is impaired.

Conditions of disturbed acid-base balance are best diagnosed and their course followed not by the determination of acetone bodies or ammonia in either urine or blood, but by the determination of certain other factors which are more or less typical of acidosis. These include the following:

- 1. The determination of the "alkali reserve" of the blood.
- 2. The determination of the alkali tolerance of the patient.
- 3. The determination of the carbon dioxide tension of the alveolar air.
- 4. The determination of the hydrogen-ion concentration of the blood.

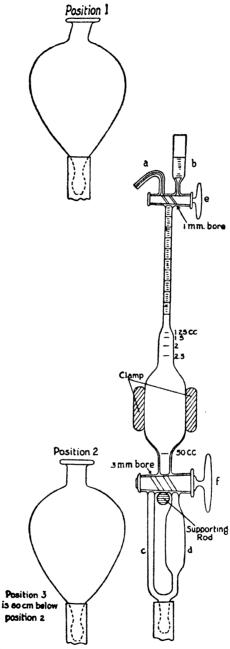

Fig. 189. Van Slyke volumetric carbon-dioxide apparatus.

METHODS

1. Simple Demonstration of the Presence of Carbon Dioxide in Expired Air: Into each of two small flasks or large test tubes introduce 25 ml. of a clear saturated solution of barium hydroxide. After an ordinary inspiration, expire through a bent glass tube or pipet dipped beneath the surface of the solution in the first flask. Repeat the experiment with the second flask but hold the breath as long as possible after the inspiration before breathing out through the tube. Note the relative amounts of precipitate of barium

carbonate formed. To another flask add 30 ml. of water, one or two drops of barium hydroxide solution and a few drops of 0.04 per cent phenol red. Expire into this solution until a change takes place. What does this change indicate?

2. Alkali Reserve: Direct Method.

a. Carbon Dioxide Capacity of the Plasma (Van Slyke and Cullen): Principle. The plasma from oxalated blood is shaken in a separatory funnel filled with an air mixture whose carbon dioxide tension approximates that of normal arterial blood, by which treatment it combines with as much carbon dioxide as it is able to hold under normal tension. A known quantity of the saturated plasma is then acidified within a suitable pipet, and its carbon dioxide is liberated by the production of a partial vacuum. The liberated carbon dioxide is then placed under atmospheric pressure, its volume carefully measured, and the volume corresponding to 100 ml of plasma calculated.

APPARATUS. The apparatus used in the estimation of the carbon dioxide content of the plasma is illustrated in Figs. 189 and 190. It is made of strong glass in order to stand the weight of mercury without danger of breaking, and is held in a strong screw clamp the jaws of which are lined with thick pads of rubber. In order to pre-

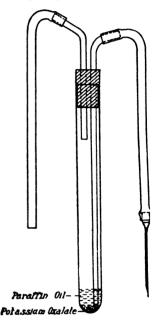

Fig. 190. Aspirating tube used to collect blood.

vent accidental slipping of the apparatus from the clamp, an iron rod of 6 or 8 mm, diameter should be so arranged as to project under cock f between c and d.

Three hooks or rings at the levels, 1, 2, and 3 serve to hold the leveling bulb at different stages of the analysis. The bulb is connected with the bottom of the apparatus by a heavy-walled rubber tube.

It is necessary, of course, that both stopcocks should be properly greased and air tight, and it is also essential that they (especially f) shall be held in place so that they cannot be forced out by pressure of the mercury. Rubber bands may be used for this purpose but elastic cords of fine wire spirals, applied in the same manner as rubber bands, are stronger and more durable. Later models of this apparatus are equipped to overcome this difficulty.

After a determination has been finished, the leveling bulb is lowered without opening the upper cock, and most of the mercury is withdrawn from the pipet through c. The water solution from d is readmitted and the leveling bulb being raised to position 1, the water solution, together with a little mercury, is forced out of the apparatus through a.4

It is well to have a funnel draining into a special vessel to catch the water residues and mercury overflow from a. A considerable amount of mercury is thus regained if many analyses are run. It requires only straining through cloth or chamois skin to prepare it for use again.

Procedure: Drawing the blood. About 6 or 7 ml. of venous blood are aspirated into a centrifuge tube (see Fig. 190) containing a little powdered potassium oxalate and some paraffin oil. The tube is subjected to a minimum of agitation after the blood is in it. The slight amount of agitation necessary to assure mixture with the oxalate is accomplished by stirring with the inlet tube, rather than by inverting or shaking. The tube and contents are then centrifuged.

Saturation of Plasma with Carbon Dioxide: After centrifuging, about 3 ml. of the plasma are transferred to a 300-ml. separatory funnel, arranged as in Fig. 191, and the air within the funnel is displaced by either alveolar

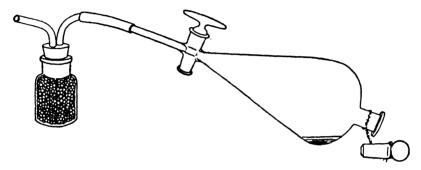

Fig. 191. Separatory funnel used in saturating blood plasma with carbon dioxide. (Courtesy, J. Biol. Chem., 30, 289 (1917).)

air from the lungs of the operator or a 5.5 per cent carbon dioxide-air mixture from a tank. This latter procedure is preferred, since error due to incomplete filling of the separatory funnel with air containing carbon dioxide at the proper tension is less likely to occur. The gas must be passed through a wash bottle containing water before entering the funnel.

When alveolar air is used, the operator, without inspiring more deeply than normal, expires as quickly and as completely as possible through the glass beads and separatory funnel. The stopper of the funnel should be inserted just before the expiration is finished, so that there is no opportunity for air to be drawn back into the funnel. In order to saturate the plasma the separatory funnel is turned end over end for two minutes, the plasma being distributed in a thin layer as completely over the surface of the funnel's interior as is possible. After saturation is completed, the funnel is placed upright and allowed to stand for a few minutes until the fluid has drained from the walls and gathered in the contracted space at the bottom of the funnel.

Determination of Carbon Dioxide: The cup should be washed out with water and 1 ml. of distilled water run in, and together with the entire apparatus should be filled with mercury to the top of the capillary tube by placing the leveling bulb of mercury in position 1. A sample of 1 ml. (or 0.5 ml. in case the amount of plasma available is very small) accurately pipeted, is allowed to run into the cup b in the apparatus represented in Fig. 189, the tip of the pipet remaining below the surface of the water as it is added. Add 1 drop of caprylic alcohol.

⁶ For at least an hour before the blood is drawn the subject should avoid vigorous muscular exertion as this, presumably because of the lactic acid formed, lowers the bicarbonate of the blood.

[•] If it is desired to keep the plasma for the estimation of carbon dioxide at a later time, it should be transferred to a paraffined tube, covered with a layer of paraffin oil, stoppered, and kept cold; under which conditions it is claimed that, if sterile, it may be kept for over a week without alteration of its carbon dioxide capacity.

⁷ It is desirable to keep the amount of caprylic alcohol small, as larger amounts may

With the mercury bulb at position 2 and the cock f in the position shown in the illustration, the plasma, water, and alcohol are admitted from the cup into the 50-ml. chamber, leaving just enough above the cock e to fill the capillary so that no air is introduced when the next solution is added. In the case of whole blood, some corpuscles settle to the bottom of the cup. These are suspended in the water by stirring them up with the last 0.5 ml. of water after the first 0.5 ml. has passed into the chamber. Finally, 0.5 ml. of 5 per cent sulfuric acid is run in.

It is not necessary that exactly 1 ml. of wash water and 0.5 ml. of acid shall be taken, but the total volume of the water solution introduced must extend exactly to the 2.5-ml. mark on the apparatus, if the table on p. 630 is to be used.

If the amount of plasma available is small, a little more than 0.5 ml. is saturated in a 50-ml. funnel, and exactly 0.5 ml. used for the estimation of carbon dioxide. In this case, the volume of distilled water and acid used to wash the plasma into the apparatus is halved, so that the total volume of water solution introduced is only 1.25 ml., and in the calculation the observed volume of gas is multiplied by 2.

After the acid has been added, a drop of mercury is placed in b and allowed to run down the capillary as far as the cock in order to seal the latter. A copper wire may be used to expel a bubble of air which may be trapped in the capillary. Whatever excess of sulfuric acid remains in the cup is washed out with a little water, using a medicine dropper.

The mercury bulb is now lowered and hung at position 3 and the mercury in the pipet is allowed to run down to the 50-ml. mark, producing a Torricellian vacuum in the apparatus. When the mercury (not the water) meniscus has fallen to the 50-ml. mark, the lower cock is closed and the pipet is removed from the clamp. Equilibrium of the carbon dioxide between the 2.5 ml. of water solution and the 47.5 ml. of free space in the apparatus is obtained either by mechanical shaking for one minute, or by turning the pipet upside down 15 or more times, thus thoroughly agitating the contents. The pipet is then replaced in the clamp.

After extraction of the gas the lower cock is opened, admitting the mercury into the extraction chamber rapidly until the meniscus of the water solution reaches the contracted upper portion of the chamber. At this moment the lower cock is partially closed and the remainder of the mercury is admitted at a rate sufficiently retarded to prevent oscillation of the water column in the calibrated portion of the apparatus when pressure equilibrium is reached. The pressure is then adjusted by placing the mercury surface in the leveling bulb above the mercury meniscus in the chamber by a height equal to one-thirteenth that of the water column, in order to balance the latter. After some practice controlled by a centimeter rule one can estimate this level with the eye to within 2 mm. of mercury, which is sufficiently accurate for most purposes. When the pressure has been adjusted, the lower cock of the apparatus is closed. The gas volume may then be read at leisure.

When, as in most plasma analyses, the CO_2 is not reabsorbed, no washing of the apparatus is necessary before using it for another determination, since the acid solution which wets the walls of the chamber contains a negligible amount of CO_2 .

Calculation. For most clinical purposes, results within one or two volumes per cent of the true values for CO₂ capacity may be obtained by multiplying the observed volume (uncorrected) by 100 and subtracting 12. More accurate results

appreciably increase results. With plasma 0.02 ml. is sufficient to prevent foaming and is measured most conveniently from a burst made by fusing a capillary stopcock to a pipet graduated in 0.01-ml. divisions.

⁸ With whole blood, in place of sulfuric acid use lactic acid made by diluting 1 volume of concentrated acid (specific gravity 1.20) to 10 volumes with water.

are obtained by means of the table on p. 630 in which the observed volume (corrected for pressure) is directly transposed into ml. of carbon dioxide chemically bound by 100 ml. of plasma. The value obtained from this table must be multiplied by 1.017 to correct for CO_2 reabsorbed by the solution after release of pressure. The barometer reading and room temperature are taken at the time of the determination. For convenience in the calculation values are given below for the ratio $\frac{B}{760}$ over the range usually encountered.

In case the volume of plasma taken for estimation of carbon dioxide content was 0.5 ml., the observed volume of gas is multiplied by 2 before it is used to calculate the volume per cent of carbon dioxide bound.

Interpretation. The carbon dioxide capacity of the plasma as determined by this method appears to indicate not only the alkaline reserve of the blood but also that of the entire body. The average normal value for man is 65 volumes per cent of carbon dioxide. The table on p. 631 shows the range of results obtained with normal and pathological plasma, as well as the relationship of the plasma bicarbonate to acid excretion, alkali tolerance, and alveolar carbon dioxide tension.

Barometer	$\frac{\mathrm{B}}{760}$	Barometer	B 760

b. Plasma Bicarbonate (Titration Method) Van Slyke: Principle. Plasma is treated with an excess of standard acid which is titrated back with standard alkali to the original pH of the plasma as drawn.

Procedure: Blood is drawn without stasis and without exposure to air into a glass syringe or tube coated with potassium oxalate and containing mineral oil (see Fig. 190). Then without exposure to air the blood is run into a tube under oil to the complete filling of the tube. A one-hole rubber stopper is inserted into the tube, expelling through the hole the oil that remains over the blood. The hole is closed with a glass plug and the tube centrifuged. The plug is then taken out and as the stopper is removed from the tube, oil is allowed to run in through the hole in the stopper to cover the surface of the plasma, so that it is never exposed to air. The plasma is then transferred under oil to another tube. Simply covering the blood with oil is not sufficient to prevent loss of CO₂ during centrifuging.

A standard for the end-point is prepared in accordance with Cullen's original directions for colorimetric hydrogen-ion determination. 20 ml. of neutral 0.9 per cent NaCl containing 7 drops of 0.03 per cent phenol red are placed in a round flask of about 100 ml. capacity and covered with a

Van Slyke: J. Biol. Chem., 52, 495 (1922).

layer of mineral oil. 1 ml. of the plasma is then introduced under the oil and the mixture is then stirred gently with a glass rod.

Another 1-ml. sample of the plasma is transferred to a similar round flask, 5 ml. of 0.01 N HCl, which is made up in neutral 0.9 per cent NaCl, are added, and the CO_2 is removed by whirling the mixture vigorously about the flask for at least one minute with a rotary motion so that the solution is whirled in a thin layer about the inner wall. 10 ml. of 0.9 per cent NaCl and 7 drops of the 0.03 per cent phenol red solution are added and 0.01 N NaOH is run in from a buret, which permits readings to 0.01 ml., until the color matches that of the standard. As the end point is approached, sufficient 0.9 per cent NaCl is added to bring the volume to 20 ml.

The 0.01 N NaOH, like the 0.01 N HCl, is made up by diluting 1 volume of 0.1 N solution to 10 volumes with neutral CO₂-free 1 per cent NaCl. The use of saline solution instead of water has the advantage of preventing the formation of a permanent cloudy precipitate of globulin.

A peculiar phenomenon occurs as the end point is approached. Each drop appears to change the color past the end point, but within a few seconds the color shifts back and it is seen that at least another drop is needed. Consequently, the final color comparison should not be made until at least 30 seconds after the last drop of 0.01 N NaOH has been added. It is better to overrun the end point by a drop, rather than stop short of it when in doubt.

Calculations. The number of ml. of 0.01 N NaOH used in the titration is subtracted from the ml. required to neutralize to the same indicator 5 ml. of the 0.01 N HCl used. The number is approximately 5 but usually varies from it slightly because of difference in factors of acid and alkali and because of the calibration error of the 5-ml. pipet used in measuring the acid. The maximum accuracy is obtained by performing a preliminary titration on 5 ml. of the acid plus 15 ml, of distilled water, using the same pipet, indicator, and end point as in the plasma titration. The titration result represents ml. of 0.01 M NaHCO. per ml. of plasma and it is transformed into terms of molecular concentration of NaHCO₃ by merely dividing by 100. If the NaHCO₃ molecular concentration is multiplied by 2240 or the number of ml. of 0.01 N HCl used in the titration by 22.4, the volume per cent of bicarbonate CO₂ in the plasma is obtained and the results can thus be compared with those obtained by the CO₂ method. The standard 0.01 N NaOH must be protected from atmospheric CO2 and kept in paraffined bottles to prevent solution of alkali from the glass.¹⁰ The buret should be filled with fresh solution each day. The carbonate-free solution is made by dissolving the NaOH in an equal volume of H₂O. On standing, the Na₂CO₂ settles to the bottom. 2.75 ml. of the clear supernatant solution are diluted to 5 liters and standardized by titration with neutral red against 0.01 N HCl. It is preferable to run the acid into the alkali as the color change occurs without the time lag observed when alkali is added to acid.

Interpretation. The results agree closely with those of the CO₂ capacity method over the range of bicarbonate concentrations (0.03 to 0.01 M) ordinarily en-

10 Testing Standard 0.01 N NaOH for Carbonate. The solutions should be made up using only boiled water, be kept in paraffin-lined bottles, and be protected from atmospheric CO₂ by soda-lime tubes. They should be tested for carbonate as follows:

To 5 ml. of 0.01 N HCl in a 200-ml. round flask, add from a freshly filled buret about 4.8 ml. of the 0.01 N NaOH to be tested and 0.3 ml. of neutral red solution. The mixture should be strongly acid to the indicator. The solution is rotated for one minute in the flask to permit the escape of CO₂, and is then transferred to a 50-ml. Erlenmeyer flask and titrated as in plasma analyses, the total amount of 0.01 N NaOH required to give the end point being noted.

A duplicate titration is performed in the same way except that there is no agitation to remove carbon dioxide, the 0.01 N HCl plus 20 ml. of water being placed directly in the 50-ml. Erlenmeyer flask, and the 0.01 N NaOH being added with a minimum of stirring.

If there is no carbonate in the standard NaOH solution the two titrations give identical results. The difference should preferably not exceed 0.1 ml., and if it exceeds 0.2 ml. the alkali should not be used.

^{*} The temperature figures at the heads of columns represent the room temperature at which the samples of plasma are saturated with alveolar carbon dioxide and analyzed. It is assumed that both operations are performed at the same temperature. The figures have been so calculated that, regardless of the room temperature at which saturation and analysis are performed, the table gives the volume (reduced to 0°, 760 mm.) of carbon dioxide that 100 ml. of plasma are capable of binding when saturated at 20° with carbon dioxide at approximately 41 mm. tension. If the figures in the table are multiplied by 0.94 they give within 1 or 2 per cent of the carbon dioxide bound at 37°.

• Measured either in 24-hr. urine or in specimen from shorter period calculated to 24-hr basis.

• Measured either in 24-hr. urine or in specimen from shorter period calcola than is present.

• After bica-bonate administration likely to indicate more acidosis than is present.

The figures tabulated in this column also indicate the does of bicarbonate necessary to restore the alkali reserve to normal from acidosis of the severit; indicated by the corresponding plasma CO; figures in the first column.

countered in man, even in severe acidosis. Below this range the titration continues to give accurate results, while the CO₂ capacity method gives somewhat higher values. For clinical and most experimental purposes, however, it appears that the two methods give so nearly identical results that they may be used interchangeably.

3. Alkali Reserve: Indirect Method: Alveolar Carbon Dioxide Tension: Fridericia's Method: Principle. The method is based upon the absorption, by

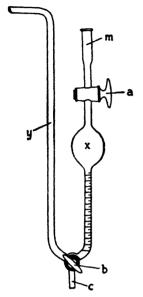

Fig. 192. Fridericia apparatus.

means of potassium hydroxide, of the carbon dioxide from a known amount of alveolar air. The apparatus is so graduated that the decrease in volume may be read in per cent.

Procedure: The subject must sit quietly in a chair and breathe naturally,12 holding the apparatus (shown in Fig. 192) in front of him with the cock a open and b in a position connecting x with v. After taking a normal inspiration he places the mouthpiece m into his mouth and blows as hard and as quickly as possible through the apparatus, thus washing it out and leaving it filled with alveolar air. The cock a is at once closed and the whole apparatus is immersed in water for five minutes. By this means the alveolar air in x and y is cooled to a temperature which remains constant throughout the experiment, and the contraction in volume causes the alveolar air in the lower part of y to be drawn back into x. At the end of five minutes the cock b is turned so as to connect v with c, thus closing x which then contains exactly 100 ml. of alveolar air at atmospheric pressure and at the temperature of the water in which the apparatus is immersed, this temperature remaining constant throughout the determination. The apparatus is removed from the water. the tube c is placed beneath the surface of some 10 per cent sodium hydroxide solution, some of the al-

kali is drawn up into y, the apparatus is held in such a position that y is rather depressed in order to prevent the escape of small bubbles of gas from x, the cock is turned so as to connect y with x, and some of the alkali is forced into x. The cock b is at once turned, closing x and connecting y with c, through which the remainder of the alkali is allowed to flow. The apparatus is inverted several times during the course of half a minute, which is sufficient time for the absorption of all the carbon dioxide. It is then returned to the water which rises through o into y, after which b is turned to connect y and x and the whole is allowed to remain for five minutes to again equalize the temperature. It is then raised slowly until the water in the graduated portion of x is at the same level as the water outside the apparatus, i.e., when the gas within the tube x is under atmospheric pressure. Cock b should now be turned to connect y and c, and the apparatus taken from the water and read.

Calculation. The reading of the bottom of the meniscus of the fluid in x is taken, and represents, without any further calculation or correction, the percentage of carbon dioxide in the alveolar air.

¹¹ Fridericia: Hospitalstidende, Copenhagen, 57, 585 (1914); Poulton: Brit. Med. J., 2, 392 (1915).

¹² It is especially important to caution the subject against the very natural inclination to take an abnormally deep inspiration just before blowing through the apparatus, and also to see that, in seeking to avoid this fault, the breath is not held just before the sample is taken.

 $^{^{13}}$ Any diffusion with the outside air at the top of y will not reach to the bottom of the tube owing to its length.

Interpretation. The sample of air obtained by this method (if properly taken) more nearly represents air whose CO₂ tension is the same as that of arterial blood. i.e., true alveolar air, than does air obtained by "rebreathing." The results obtained by this method, then, are from 5 to 10 per cent lower than those obtained by the Marriott method below. The average normal value for men is about 5.5 volumes per cent of carbon dioxide. In women and children the normal value is somewhat lower. In acidosis the carbon dioxide falls and in diabetic coma may go as low as 1 or 2 per cent. A value of 2 per cent means that coma may supervene within 24 hours. A value of 3 or 4 per cent is less dangerous; in the worst event coma will not come on for at least two or three days. For data as to alveolar carbon dioxide tension under different conditions, see the table on p. 631.

4. Alkali Reserve: Indirect Method: Alveolar Carbon Dioxide Tension: Marriott's Method. 14 While this method is open to criticism because of the liability of error in the collection of the sample and, more fundamentally, because of various factors (psychical, etc.) other than acidosis which may influence the carbon dioxide tension, nevertheless it is of considerable value and has been rather widely adopted for clinical use.

Principle. By rebreathing air under certain definite conditions, a sample is obtained whose carbon dioxide tension is virtually that of venous blood. The method of analysis of this sample depends on the fact that if a current of air containing carbon dioxide is passed through a solution of sodium carbonate or bicarbonate until the solution is saturated, the final solution will contain sodium bicarbonate and dissolved carbon dioxide. The reaction of such a solution will depend on the relative amounts of the alkaline bicarbonate and the acid carbon dioxide present. This, in turn, will depend on the tension of carbon dioxide in the air with which the mixture has been saturated and will be independent of the volume of air blown through, provided saturation has once been attained. High tensions of carbon dioxide change the reaction of the solution toward the acid side. Low tensions have the reverse effect; hence the reaction of such a solution is a measure of the tension of carbon dioxide in the air with which it has been saturated. A suitable indicator is added to the solution and its reaction (after the passage of the alveolar air) is determined by comparison with a set of suitable standards.

APPARATUS. The complete apparatus, including rubber bag for collection of sample, standardized phosphate mixture sealed in tubes, the standard bicarbonate solution, tubes, color comparison box and other accessories may be obtained from Hynson, Westcott and Dunning, Baltimore, Maryland.

Procedure: After collecting the alveolar air in a rubber bag as directed in the circular accompanying the outfit, fill the test tube one-fourth full with indicator solution. Place the capillary tube in the opening of the bag and, by releasing the pinchcock, allow the collected alveolar air to pass rapidly through the solution for about one minute or until color changes cease. Then stopper the tube and match the specimen immediately with the standard color tube nearest its color by placing a color tube on either side of it in the comparison box. Examinations should be made at temperatures from 20° to 25° C.

Calculation. The standard tubes are marked to indicate the carbon dioxide tension in millimeters of mercury, and the readings can be estimated to about 2 mm.

Interpretation. In normal adults at rest the carbon dioxide tension in the alveolar air, determined as described above, varies from 40 to 45 mm. Tensions between 30 and 35 mm. are indicative of a mild degree of acidosis. When the tension is as low as 20 mm., the individual may be considered in imminent danger. In coma, associated with acidosis, the tension may be as low as 8 or 10 mm. In infants, the tension of carbon dioxide is from 3 to 5 mm. lower than in adults.

¹⁴ Marriott: J. Am. Med. Assoc., 66, 1594 (1916).

5. Alkali Reserve: Indirect Method: Index of Acid Excretion in Urine:

Method of Fitz and Van Slyke: 15 Principle. The method depends upon the
determination of the rate of excretion of acid (NH₁ + titratable acid) from
which the plasma carbon dioxide capacity is calculated.

Procedure: Collect the urine for 24 hours (or, if desired, for a period of one or two hours during which the subject ingests neither food nor water). In the latter case, the urine collection should not be too soon after a meal. Carefully measure the volume of the urine and determine its ammonia content and the titratable acid according to the methods given in Chapter 32. Obtain the body weight of the patient.

Calculation. The plasma bicarbonate may be calculated by substitution in the following equation.

Plasma Carbon Dioxide Capacity¹⁶ =
$$80 - 5\sqrt{\frac{\overline{D}}{\overline{W}}}$$

D = Rate of excretion per 24 hours

W = Body weight in kilograms

The value D is equal to the product VC, in which V is the 24-hour volume¹⁷ expressed in liters, and C the sum of the ammonia (expressed as ml. of 0.1 N NH₃ per liter of urine) plus the titratable acid (expressed as ml. of 0.1 N acid per liter of urine). For practical purposes, the acid excretion may, without going through the calculation of the formula, be interpreted directly into terms of clinical severity of acidosis, as indicated in the table on p. 631, e.g., an excretion exceeding 27 ml of 0.1 N ammonia plus titratable acid per kilo indicates acidosis, which usually becomes critical in severity if the excretion approaches 100 ml. per kilo.

Interpretation. After careful investigation in which the relationship between the carbon dioxide capacity of plasma and the excretion rate and concentration of total urnary acid excreted in excess of mineral bases was determined, Fitz and Van Slyke concluded that no other equation including excretion rate and concentration was so satisfactory as the above.

The value
$$80-5\sqrt{\frac{\dot{D}}{W}}$$
 indicates, with an error which is usually less than

10 volumes per cent, the level of the plasma carbon dioxide capacity. Diabetics receiving bicarbonate administrations are exceptions, the blood bicarbonate in such cases being, as a rule, much higher than indicated by the urine.

Of the two indirect measures of alkali reserve, the alveolar carbon dioxide determination appears the more accurate in measuring the more severe stages of diabetic acidosis, such as are encountered in threatened coma, while the index of acid excretion is the more accurate in measuring the more common intermediate stages.¹⁸

In nephritis, acidosis (lowered blood bicarbonate) may occur without increase in acid excretion or even with decrease of the latter. Consequently the excretion cannot be used as an indicator of acidosis when nephritis is present.

For values of the acid index under different conditions, see the table on p. 631.

6. Alkali Tolerance. This method is quite reliable for proving the absence of acidosis, but is not particularly dependable for showing either the presence or

¹⁵ Fitz and Van Slyke: J. Biol. Chem., 30, 389 (1917); Van Slyke: J. Biol. Chem., 33, 271 (1918); Barnett: J. Biol. Chem., 33, 267 (1918).

¹⁶ The value 80 represents the maximum normal value of plasma bicarbonate. Under such a condition, the titratable acid and ammonia excretion tend to approach zero.

¹⁷ If the urine is collected for only one or two hours its volume is, of course, multiplied by 24 or 12 as the case may be.

18 Stillman, Van Slyke, Cullen, and Fitz: J. Biol. Chem., 30, 405 (1917).

¹⁶ Sellards: Bull. Johns Hopkins Hosp., 23, 289 (1912); Palmer and Henderson: Arch. Internal Med., 12, 153 (1913); Palmer and Van Slyke: J. Biol. Chem., 32, 499 (1917).

the degree of acidosis when it exists. This seems to be due in part at least to the fact that in conditions associated with acidosis the power of the kidney for excretion of alkalies may be markedly impaired.

Principle. Sodium bicarbonate is administered in small amounts, either by mouth or intravenously until the reaction of the urine changes from acid to alkaline. The amount of bicarbonate is then noted.

Procedure: Give (by mouth) 5 g. of sodium bicarbonate in 100 ml. of water to the subject under examination. Repeat every half hour until the total bicarbonate administration is equivalent to 0.5 g. per kilogram of body weight unless the urine becomes alkaline before that time. In case the urine does not become alkaline with the above bicarbonate ingestion, continue the administration of the alkali until the urine shows an alkaline reaction. The urine should be voided by the subject before each administration of bicarbonate. Test each specimen of urine with litmus, boiling those samples which are only faintly acid so that any bicarbonate present will be converted to carbonate. Note the number of grams of bicarbonate necessary to produce an alkaline urine.

Interpretation. Normally the administration of from 5 to 10 g. of bicarbonate is generally sufficient to produce an alkaline reaction in the urine, while in patients suffering from acidosis a greater amount is required. In general a maximum ingestion of 0.5 g. of bicarbonate per kilogram of body weight will produce an alkaline urine in a normal person. In mild acidosis this value may be increased to a maximum of 0.8 g., whereas moderate acidosis may show a value of 1.1 g. In severe acidosis with symptoms of acid intoxication the bicarbonate value may exceed 1.1 g. per kilogram of body weight. If an alkaline urine is obtained after the administration of 0.5 g. or less of bicarbonate per kilogram of body weight, one is safe in saying that no acidosis exists. When higher values are obtained, however, they should be confirmed by blood analysis before being accepted. For data as to alkali tolerance under different conditions, see the table on p. 631.

7. Hydrogen-ion Concentration of Blood: A. Colorimetric Method of Cullen²¹
as Modified by Hawkins:²² Principle. Blood is collected with precautions against loss of CO₂. The plasma is diluted with saline solution containing phenol red and the color obtained compared with that of standard phosphate mixtures of known hydrogen-ion concentration.

Procedure: Prepare two test tubes of the same diameter as are used to contain the standards (see below), one containing 5 ml. of 0.9 per cent sodium chloride solution and the other 5 ml. of saline indicator solution, 12 each covered with a 1-cm. layer of neutral mineral oil. Connect a Luer needle adapter, by means of a short piece of rubber tubing, to a 1-ml. Mohr pipet. Without stasis, insert the needle into the subject's vein, attach the adapter, and allow the blood to fill the pipet past the zero mark. (A tourniquet may be used to aid in finding the vein, but the blood should flow into another tube a few seconds after the release of the tourniquet, so that stasis is absent when the adapter is inserted into the needle.) Withdraw the needle from the vein and at once disconnect the rubber tubing from the pipet. Wipe the tip and introduce into each tube, under the oil, 0.4 ml. of the blood. Stir the contents carefully with a fine glass rod.

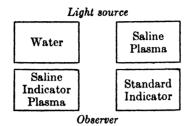

³⁰ Because of the likelihood of producing a condition of alkalosis, it is advisable not to continue the administration of bicarbonate without evidence from blood analysis showing an alkali deficit. In certain connections alkalosis may be as dangerous for the organism as acidosis (Grant: Arch. Internal Med., 30, 355 (1922).

²¹ Cullen: J. Biol. Chem., 52, 501 (1922).

²² Hawkins: J. Biol. Chem., 57, 493 (1923).

²² Prepare fresh for each determination. Add 2.1 ml. of 0.03 per cent phenol red solution to 100 ml. of 0.9 per cent sodium chloride solution. Adjust to approximately pH 7.4 by stirring with a fine glass rod dipped into 0.02 N alkali or acid, as the case may be.

Centrifuge both tubes at about 1500 r.p.m. for five minutes. Compare with standards²⁴ in a comparator block, estimating between two standards, if necessary. The tubes are placed in the following relative positions:

The object of the saline plasma tube is to compensate the standard for the slight color and turbidity of the plasma (Walpole principle). The tem-

²⁴ Reagents and Apparatus Required: Standards. Sørensen's phosphate standards are prepared from Merck's special reagents in steps of 0.05 pH from about pH 7.2 to 7.7. The M/15 phosphate solutions should be prepared from special reagent salts (Merck's are satisfactory) by dissolving the following quantities in distilled water and making each solution up to one liter.

Na ₂ HPO ₄ ·2H ₂ O "Sørensen salt"	 11.87 g.
or Na ₂ HPO ₄ anhydrous (Merck)	 9.47 g.
KH ₂ PO ₄	 9.08 g.

The proportions of acid and alkaline phosphates are given in the table. These mixtures may be kept for some weeks in pyrex glass in the refrigerator.

PHOSPHATE MIXTURES (PHENOL RED RANGE)

pН	M/15 Na ₂ HPO ₄	M/15 KH₂PO₄	pH	M/15 Na ₂ HPO ₄	M/15 KH₁PO₁
	ml.	ml.		ml.	ml.
7.00 7.05 7.10 7.15 7.20 7.25 7.30 7.35	61.1 63.9 66.6 69.2 72.0 74.4 76.8 78.9	38.9 36.1 33.4 30.8 28.0 25.6 23.2 21.1	7.40 7.45 7.50 7.55 7.60 7.65 7.70 7.75 7.80	80.8 82.5 84.1 85.7 87.0 88.2 89.4 90.5 91.5	19.2 17.5 15.9 14.3 13.0 11.8 10.6 9.5 8.5

Color Standards. These are prepared by adding 0.3 ml. of 0.03 per cent phenol red (phenol-sulfonephthalein) to 15 ml. of each of the standard buffer solutions. The concentration of dye required varies somewhat with different lots. It is best to prepare a concentrated stock solution, and determine by experiment the dilution required to give satisfactory depth of color over the desired pH range. The indicator solution must be neutral. After the addition of 1 drop to 3 ml. of redistilled water, the water must not be red.

The color standards must be renewed or checked against a fresh tube of dye at least once every week as there is a slow fading of color.

Apparatus. The comparator required is conveniently made from a block 3 × 6 inches. The holes for the tubes are of 1 inch diameter. The slits for the light are best made by boring two ½ inch holes and gouging out the remaining wood with a chisel. The tube must be of clear, nonalkaline glass of uniform diameter. Tubes 20 mm. in diameter are convenient.

Light. Either daylight or "Daylite" lamps are satisfactory.

Test for Neutrality. The redistilled water is usually about pH 6.2 to 6.5. The easiest

perature of the saline-indicator-plasma is obtained. It is desirable to make determinations at 20° C., by placing the plasma tubes, together with the necessary standard tubes, in a large beaker of water at 20°.

Calculation. The pH of the blood (human) at 38° C. is obtained from the following equation:

$$pH_{18}^{\circ} = \text{Colorimetric } pH_{t}^{\circ} + 0.01(t^{\circ} - 20) - 0.23$$

in which to represents the observed temperature. If the tubes are adjusted to 20°, the middle factor naturally drops out.

The empirical correction, -0.23 ("Cullen correction"), applied to adjust the colorimetric pH values to those determined electrometrically at 38°, compensates for the protein and salt errors in the colorimetric determination. The correction varies with the species of animal, but unfortunately is not as constant in each species as could be desired.

Receiver for Blood Shock-Hastings Pipet Comparator Block Fig. 193. Apparatus for Shock-Hastings method.

Hastings and Sendroy claim that the Cullen correction is unnecessary when the readings are made with the tubes at body temperature. Austin, Stadie, and Robinson have shown, however, that under pathological conditions in man, and in the dog, there is considerable variation in the Cullen correction, and Hastings and Sendroy's procedure does not eliminate it. For these cases, they state, corrections must be determined on each serum if colorimetric readings are to be relied upon.

According to Cullen and Earle the colorimetric method gives results at 20° C. 0.08 pH higher than the hydrogen electrode, and 0.14 pH higher than the quinhydrone electrode. The electrometric method using the glass electrode (see Chapter I) affords the most precise as well as convenient method for measuring pH of the blood.

Interpretation. The normal pH range of blood is between 7.30 and 7.50. The extreme limits of pathological variation which have been observed are 6.95 to 7.80. For the significance of abnormal pH values, see the table on p. 622.

B. Method of Shock and Hastings. 25 This is an adaptation of the preceding

method employing a special pipet which not only permits the determination of

test is that of using both phenol red and methyl red. The water should give no red color with either indicator.

The syringe, pipets, and tubes should be rinsed with redistilled water and dried. Syringes, tubes, and pipets, washed and sterilized in the usual manner employed in bacteriological laboratories, are often dried from alkaline water.

The saline solution must be adjusted to pH 7.4 as described above. The oxalate, when dissolved in water to a 0.5 per cent solution, should not be more alkaline than pH 7.2 to 7.4. The oil is tested by shaking with water containing phenol red and methyl red. The water must remain neutral.

35 Shock and Hastings: Proc. Soc. Exptl. Biol. Med., 26, 780 (1929). Also described in

cell volume as well as plasma pH, but also makes possible the transfer of the diluted plasma to the manometric apparatus for CO₂ determination. Blood is collected by finger puncture under paraffin oil in the conical receiver containing oxalate (Fig. 193). The Shock-Hastings pipet is filled to the 0.1-ml. mark, followed by phenol red saline solution to the 2-ml. mark. A control pipet is filled with 0.1 ml. of blood diluted with indicator-free saline solution. The tip of each pipet is covered with a bit of adhesive tape and a heavy rubber band (Eberhard Faber No. 84). The cell volume is read after centrifuging. The pH is read in a special colorimeter block containing comparator tubes of the same internal diameter as the bulb of the pipets. The contents of the pipet may then be transferred to the Van Slyke-Neill apparatus.

8. Acetone Bodies. For methods of determining acetone, acetoacetic and β -hydroxy-butyric acids in the blood see the References at the end of Chapter 23.

9. Determination of Oxygen and Oxygen Capacity (or Hemoglobin) of Blood: Volumetric Methods. It is possible to determine the oxygen of the blood using the same apparatus as that employed for the CO₂ estimation (see p. 625), suitable precautions being taken in collecting the blood for analysis. The oxygen content of blood represents the total volume of oxygen, both physically dissolved and combined with hemoglobin, present in 100 ml. of blood in the condition in which it flows through the veins or arteries. For the determination of oxygen content it is, therefore, necessary to collect the blood so as to avoid the oxygenating effect of air, i.e., under oil. An aspirating tube of the type illustrated in Fig. 190 is suitable for this purpose.

The oxygen combined with hemoglobin in arterial or venous blood differs from the oxygen content in that a correction is made for free, physically dissolved oxygen. The same precautions in the collection of the sample must, of course, be taken.

The oxygen capacity of blood represents the volume of oxygen required to combine with all of its hemoglobin (oxyhemoglobin and reduced hemoglobin). It therefore constitutes a measure of hemoglobin since it is established that 1 g. of hemoglobin combines with 1.36 ml. of oxygen, or, in other words, each ml. of oxygen capacity represents 0.736 g. of hemoglobin. Blood for this determination may be collected without precautions to avoid contact with air, inasmuch as aeration (oxygenation) is the first step in the procedure.

The oxygen unsaturation of venous or arterial blood is a measure of the absolute concentration of reduced hemoglobin, and is obtained by subtracting from the oxygen capacity (total hemoglobin), the oxygen combined with hemoglobin as defined above. The distinction between this and the relative unsaturation, which is the per cent of total hemoglobin in the reduced state, should be kept in mind. The use of the absolute rather than the relative expression is due to the fact that cyanosis is regarded as the result of an increased absolute concentration of the bluish reduced hemoglobin.

Determination of Oxygen Capacity: Stir the special oxygen reagent (see p. 649) to obtain emulsification of the caprylic alcohol. Introduce 7.5 ml. into cup b (Fig. 189), and de-aerate by shaking in the evacuated extraction cham-

ber. Mix the blood thoroughly with a stirring rod, and transfer to a 250-ml. separatory funnel in which it is completely aerated by rotating in a thin layer over the interior surface of the funnel. (For oxygen determinations other than capacity, simply mix the blood under the oil and omit aeration.) Force 6 ml. of the gas-free reagent into the cup of the apparatus. By means of a differential pipet (graduated to deliver between marks, Fig. 196), transfer exactly 2 ml. of the blood directly into the extraction chamber by keeping the tip of the pipet immersed to the bottom of the reagent in the cup and regulating the admission by the finger or stopcock on the pipet and cock e of the apparatus. Never allow more than a few ml. of blood to accumulate in the cup. An Ostwald transfer pipet may be used for this purpose, the final grop of blood being forced out of the immersed tip by expanding the air in the pipet with the heat of the hand, keeping the mouth of the pipet closed. Admit the remaining blood and all but 1 ml. of the reagent from cup b into the extraction chamber. With a medicine dropper discard the excess reagent and introduce a few drops of mercury as a scal. Evacuate and shake until the volume of extracted gas $(O_2 + CO_2)$ + N₂) is constant. This will be found to consume from 5 to 10 minutes and should be determined by measuring the gas at atmospheric pressure. Create a slight negative pressure within the pipet by bringing the level of solution to the 2-ml. graduation. Rinse cup b with distilled water and introduce 0.5 ml. of a 2 per cent NaOH solution previously de-aerated. By means of the negative pressure within the pipet, admit this solution slowly, followed by a thin stream of mercury, which serves to break the column of NaOH which usually forms in the capillary of the pipet. Allow one minute for drainage and bring the gas $(O_2 + N_2)$ to atmospheric pressure as described in the determination of CO₂. Read the volume of gas, the temperature, and the barometric pressure.

Calculations:

V = observed volume of gas (O₂ + N₂)

t = temperature in ° C.

B = barometric pressure in mm. Hg

w = tension of aqueous vapor (see p. 642)

Volume per cent O₂ capacity =
$$\left(\frac{(B - w)}{760(1 + 0.00367t)} \times \frac{100V}{2}\right) - 2.1$$

Values for the temperature and pressure correction factor are given in the table on p. 640. The following equation may also be used:

Volume per cent O₂ capacity =
$$\left(\frac{17.9(B-w)V}{t+273}\right) - 2.1$$

The value 2.1 in these equations corrects for oxygen and nitrogen physically dissolved at atmospheric pressure. For oxygen content subtract 1.36 (per cent N₂) instead of 2.1. For O₂ combined with hemoglobin subtract 1.7 or 1.5 for arterial or venous blood respectively, which corrects for free O₂ and N₂ at arterial or venous tension. O₂ unsaturation is obtained by subtracting O₂ combined with hemoglobin from O₂ capacity.

Hemoglobin (g. per 100 ml.) = 0.736 × volume per cent O₂ capacity For colorimetric determination of hemoglobin, see Chapter 23.

16. Determination of Carbon Monoxide in Blood: Gasometric Method of Van Slyke and Associates: Principle. A more exact quantitative procedure for the estimation of carbon monoxide than the colorimetric method given in Chapter 22 is a gasometric method based on the experiments of Van Slyke and

^{*} To calculate O_2 or hemoglobin when $O_2 + N_2$ volume is measured, multiply gas volume by f, to reduce to 0° , 760 mm., and by such factor as is necessary (100 when 1 ml. of blood is used, 50 when 2 ml. are used) to bring results to volume per cent basis. Then for

a, O₂ content, subtract.....b, O₂ bound by hemoglobin in venous blood, sub-. 1.36 vol. per cent N2

 $\frac{100a}{18.5} = 5.41d$ Per cent of normal hemoglobin (Haldane scale) =

Grams of hemoglobin per 100 ml. of blood = 0.736d

Per cent of total hemoglobin saturated with $O_2 = \frac{100b}{100c}$ or $\frac{100c}{100c}$ d

tract. 1.5 vol. per cent N₁ + dissolved O₁

c, bound by hemoglobin in arterial blood, sub-1.7 vol. per cent N: + dissolved O:

d, O₂ bound by hemoglobin in blood saturated with air at 20°, subtract.... 2.1 vol. per cent N₁ + dissolved O₂ 100d

Volumes per cent O_2 unsaturation = d - c or d - b† The dissolved air is given as measured at room temperature. It is subtracted from the air + CO: volume, measured after one extraction of plasma or aqueous carbonate solution, in order to obtain the CO₂, which is then multiplied by 1.017/ $\left(1 + \frac{8}{50 - 8} a'_{\text{CO}2}\right)$ in order to obtain the total volumes per cent of CO₂ in the solution analyzed. When whole blood is analyzed, the air correction cannot be used, because of the O₂ present, and the CO₂ must be determined by absorption with NaOH solution. The volume of gas absorbed is then multiplied by the above factor. The factor 1.017, being empirical, may vary slightly for different apparatus,

his associates. The mixed gases are extracted from the sample of blood in a Van Slyke pipet (Fig. 189), the oxygen and carbon dioxide are absorbed, and the carbon monoxide estimated in the residual gas either by absorption with Winkler's reagent or by correction for the nitrogen.

Procedure: Blood should be collected under oil in an oxalated tube. A special CO reagent²⁷ is required which differs from the O₂ reagent in containing lactic acid as well as more potassium ferricyanide. The reagent (7.5 ml.) is made gas-free and the mixed gases are extracted from 2 ml. of blood exactly as described under the determination of oxygen capacity (p. 638). Longer shaking may be required to arrive at constant volume, since CO is not so readily dissociated from its combination with hemoglobin. After the extraction, a negative pressure is created in the extraction chamber by raising the solution level to a point 2 to 3 cm. below the 2.5-ml. graduation. About 0.5 ml. of mineral oil is introduced into the cup and below this 1 ml. of alkaline pyrogallate reagent.28 The reagent is admitted until its level reaches the capillary of the cup, and the column that forms in the graduated capillary is broken by means of a stream of mercurv as described in the determination of oxygen capacity. A few minutes are allowed for drainage, the gas is restored to atmospheric pressure, and the volume read. The absorption of CO2 and O2 is repeated until the residual volume is constant. The CO may be estimated from this volume reading, the temperature, and barometric pressure.

If it is desired to determine the CO directly by absorption, proceed from this point by first drawing the mixed solutions in the pipet into reservoir d. This is to avoid mixing the alkaline pyrogallate solution with Winkler's reagent²⁹ to be used. Establish a slight negative pressure within the extraction chamber as described above. Rinse the delivery cup with distilled water and introduce into the pipet 0.5 ml. of Winkler's reagent. Absorption of CO takes place rapidly and the final gas volume should be read at once.

A method of magnifying small volumes of gas by reducing the pressure a definite amount below atmospheric, is described by Van Slyke and Stadie.³⁰

Larger samples of blood may be used, the amounts of reagents being proportionately increased.

Calculations.

V₁ = Observed volume of gas from 2 ml. of blood, after absorption by alkaline pyrogallate solution

V₂ = Observed volume after absorption by Winkler's reagent

B = Barometric pressure in mm. of Hg

w = Tension of aqueous vapor in mm. of Hg (see table below)

t = Temperature in ° C.

Volume per cent CO =
$$\left(\frac{(B - w)}{760(1 + .00367t)} \times \frac{100V_1}{2}\right) - 1.36$$

47 Special CO Reagent:

Saponin	 . 3.0 g.
Potassium ferricyanide	 . 8.0 g.

MANOMETRIC METHODS OF ANALYSIS OF GASES IN BLOOD AND OTHER SOLUTIONS³¹

Principle. The manometric methods of gas analysis differ from the more commonly used volumetric methods in that the latter involve reading the volume with the gas under a definite (usually atmospheric) pressure, whereas by manometric methods the pressure required to keep the gas at a fixed volume is observed. The advantages of this procedure are that a much lower degree of error is attainable, since in the former method the error in volume reading is many times greater than the error in reading of barometric pressure; calculation is greatly simplified, as barometric pressure and corrections for vapor tension and capillary attraction of mercury do not enter in; smaller quantities of material may be used; and accuracy is attainable over a wide range of gas concentration.

Apparatus. The apparatus consists of a short pipet with the upper stem closed by a stopcock, the lower connected with a glass tube. The latter descends, then turns to connect with a leveling bulb and a closed mercury manometer. The pipet is calibrated at two points to hold a ml. of gas for pressure measurement and A ml. of total volume, respectively, as shown in Fig. 194.

For analysis the sample of blood or other solution is introduced into the chamber over mercury, together with the reagents to free the desired gases from combination. A Torricellian vacuum is obtained, as in the "volumetric" apparatus, by lowering the leveling bulb, and the gases are extracted from solution by two or three minutes' shaking. The gas volume is then reduced to a ml. by admission of mercury and the reading p_1 is made on the manometer. The gases are either ejected or are absorbed by proper reagents, and the reading p_2 is taken, with the same gas volume. The partial pressure P of the gas at a ml. volume is

³¹ Van Slyke and Neill: J. Biol. Chem., 61, 523 (1924); Van Slyke: J. Biol. Chem., 73, 121 (1927). In addition to the methods here to be described, these papers give the details of the technique for the combined determination of all the gases in a sample of blood; methods for micro-analyses of fractions of a ml. of blood; for determination of gases in inquids saturated at high tensions; for determination of dissolved gases in water; and for the use of the apparatus in air and general gas analyses. Principles and numerous applications of the manometric methods are completely described in Peters and Van Slyka: "Quantitative Clinical Chemistry," Vol. 2, Baltimore, Williams and Wilkins Co., 1932.

then $P = p_1 - p_2$ mm. of mercury, from which the gas volume at 0° , 760 mm. may be calculated. Methylene or ethylene glycol or glycerol may be used as a dehydrating agent to moisten the upper part of the manometer tube.

The extraction chamber differs from that of the "volumetric" apparatus in being calibrated at only three points, viz., 0.5, 2.0, and 50 ml. The mercury seal

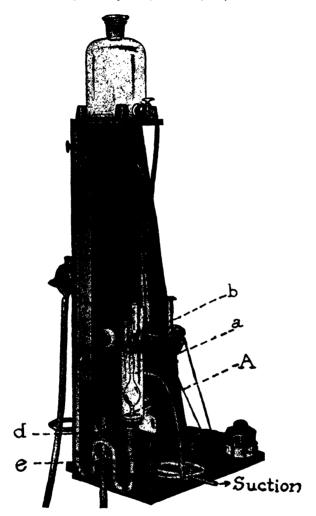

Fig. 194. Van Slyke and Neill portable manometric gas analysis apparatus.

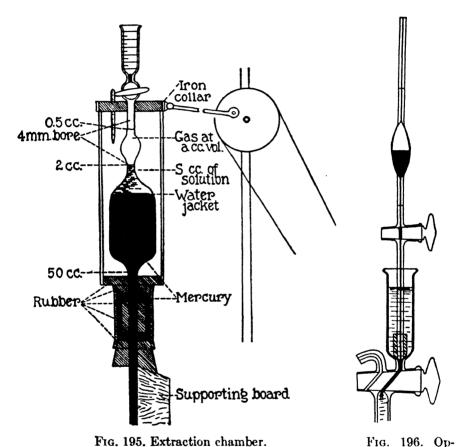

around the rubber joint at the bottom of the extraction chamber illustrated in Fig. 195 can be replaced by special heavy-walled rubber tubing. A mechanical shaker is provided. Air which diffuses through the rubber tubing of the leveling bulb is expelled through stopcock d. The stopcock at the bottom of the manometer permits withdrawal of the mercury.

The bottle on top of the frame holds distilled water. The lower bottle is to receive waste solutions drained out of the chamber after analyses. The most rapid and convenient way to transfer solution to the waste bottle is to force it up into the cup above the chamber and then draw it over into the bottle by suction.

If suction is not available, a narrow rubber drain can be run from the curved outlet capillary to the bottle.

For calibration of the apparatus and a method of constructing a simple but not necessarily inaccurate modification of the manometric apparatus, see the original papers.

Measuring Samples. In order to attain the advantage of precision offered by the manometric apparatus, accuracy in collecting and measuring samples is essential. Blood should be either (1) drawn directly from the vein, without stasis,

into the differential pipet from which it is to be delivered into the extraction chamber, or, better (2), collected under oil in an oxalated tube from which it can be drawn as needed. The corpuscles should be uniformly distributed with a fine stirring rod before each sample is withdrawn. A heavy walled Ostwald pipet graduated to deliver between two marks ("differential" pipet) and preferably provided with a stopcock should be used (see Fig. 196).

eration of deliv-

ery pipet.

Blood must be admitted at a rate slow enough to permit clear drainage of the pipet. Smooth delivery is usually obtained by using cock e or the cock of the pipet. Amounts of solution of 2 ml. or more may be run in under 1 ml. of mercury in the cup, the mercury then washing out the capillary. For smaller amounts, wash solution is necessary for complete transfer. An ordinary transfer pipet may

be used, the final drop of blood being expelled by keeping the tip immersed, closing the mouth of the pipet with the index finger, and grasping the bulb with the warm palm of the other hand. The expanding air drives out the remaining blood.

Cleaning the Apparatus. Preceding each analysis, the apparatus is cleaned by introducing 10 or 15 ml. of approximately 0.01 N lactic acid, shaking for 15 or 20 seconds in the evacuated chamber, and ejecting the extracted gas and solution. Adherent solution introduces no error in the subsequent analysis.

^{*} If calibration of an apparatus shows a value of a significantly different from the 0.500 or 2.000 ml. in the column heading, the factors in the column are corrected by multiplying them by $\frac{a}{0.500}$ or $\frac{a}{2.000}$.

Occasionally the apparatus should be kept filled overnight with chromic-sulfuric acid mixture, admitted through cock b by regulation of cock e. The latter is kept closed but the former open to allow the escape of gas.

Testing for Leaks. Test for leaks by introducing S ml. of water (Fig. 195) and extracting dissolved air for two minutes. Reduce the gas volume to a and read the pressure. If the temperature is constant, the pressure should not increase when this extraction is repeated.

Lubrication. Cocks b and e must turn smoothly but not leak. A thin layer of petrolatum is first applied, followed by a rubber paste (made by dissolving 1 part

of unvulcanized rubber in 5 parts of petrolatum, with heat), using relatively less of the first coating in warm weather.

Determination of Correction, c, for Manometer Depression Caused by Introduction of Absorbent Solution. The introduction of absorbent solution causes a lowering of the mercury meniscus in the chamber and hence in the manometer, by increasing the volume of fluid between the mercury and the a mark at the moment of reading (Fig. 194). This necessitates for the p₁ reading a correction, which is determined by blank analyses. The shape of the apparatus causes the

²² Van Slyke and Sendroy: J. Biol. Chem., 73, 127 (1927).

To obtain factor for a sample other than 1 ml., divide the above factors for 1 ml. by the ml. of sample analyzed: e.g., for a 2-ml. sample the factors are one-half of those for 1 ml.

To calculate ml. of CO₂, measured at 0°, 760 mm., in the actual portion of solution analyzed, use the above volume per cent factors for 1-ml. samples divided by 100.

area of the meniscus of the mercury in the chamber to vary according to the values of S and a. The value of c for 1 ml. of added solution may accordingly be from 1 to 4 mm., depending on the shape of the chamber and the volume of S.

Dilute absorbents (N NaOH) or hydrosulfite (20 per cent solution) have no significant effect on the vapor pressure in the chamber. Special precautions are required for alkaline pyrogallate solution (p. 641) because of the strong KOH.

When the final manometer reading is obtained after expulsion of the gases instead of after addition of an absorbing solution, c, of course, is zero.

Calculation. The general equation for calculating total gas content of a solution from the volume of gas extracted in an evacuated chamber of definite volume, as developed by Van Slyke and Stadie, 33 has been subjected to certain modifications and made adaptable to manometric calculations.

Vapor pressure is eliminated as a factor since it is the same for both pressure readings and cancels out in the equation $P = p_1 - p_2$. An *i* correction for reabsorption of extracted gas during the release of the vacuum is required for CO₂ just as in volumetric measurements, and amounts to about 1.014. For less soluble gases (O₂, N₂, CO) it is practically 1.000, reabsorption being negligible. A correction is also included for the effect of temperature on the specific gravity of mercury.

The use of the rather involved final equation is expedited by the tables constructed by the authors, which give directly the factors by which P, read at any given temperature under the conditions ordinarily employed, must be multiplied to obtain the volumes per cent of gas (see the tables on pp. 645 and 646). To express results as millimoles per liter, either use the table of millimole per liter factors given in the original papers, or divide volumes per cent of gas by 2.24 or in the case of CO_2 by 2.226.

Volumes per cent gas =
$$P \times \text{vol.}$$
 per cent factor mM. gas per liter = $\frac{P \times \text{vol.}}{2.24}$

Determination of CO, in Blood or Plasma:34 The apparatus having been cleaned (see p. 645), a drop of caprylic alcohol is drawn into the capillary above cock b, and 2.3 ml. of CO₂-free water per ml. of blood or plasma to be added are put into the cup. Stopcock b is closed, with e open. The blood or plasma is delivered beneath the layer of water in the cup from a pipet as described under "Measuring Samples." After the delivery of the sample, the residue of blood in the cup is run into the chamber below, followed by the water layer. Finally, 0.2 ml. of CO₂ -free 0.1 N lactic acid per ml of blood or plasma is added. Stopcock b is then sealed with a drop of mercury. The CO₂ is liberated by lowering the leveling bulb until the surface of the mercury has fallen to the A mark, closing cock e, and shaking the mixture for three minutes. The extracted gas is reduced to 2 ml. (a), the admission of mercury being regulated by stopcock e and the leveling bulb. If the fluid meniscus passes this point, readjustment must be made by first bringing the mercury meniscus to the A mark and equilibrating for a minute. Otherwise more reabsorption of CO₂ will take place than is provided for in the calculation. The adjustment being correct, the manometer is tapped with the finger, and the height of the mercury column read (p; mm.).

The variable amounts of O_2 extracted from whole blood make it necessary to determine CO_2 by absorption. This custom is also followed in plasma analyses, though it may be avoided by correcting for extracted air. The absorbent solution, 1 N NaOH is admitted under reduced pressure. After

¹³ J. Biol. Chem., 49, 30, 31 (1921).

¹⁴ Shohl determines both CO₂ and pH on 0.1 to 0.2 ml. of plasma. See J. Biol. Chem., 83, 759 (1929).

The alkali must be made gas-free and kept in properly protected reservoirs. 25 to 30 ml of 1 N NaOH are de-aerated in the extraction chamber and transferred under oil to a reservoir made from a calcium chloride tube (Fig. 197). This will keep for a day. For

measuring p_1 the pressure is diminished so that a space of several ml. is left between the water meniscus and the lower a mark. 2 ml. of gas-free alkali are measured into the cup from the reservoir, avoiding reabsorption of air. One ml. of alkali is admitted into the chamber. Absorption is complete in 30 seconds.

In analyses of serum or aqueous solutions of carbonates, the CO₂ may be absorbed with 0.2 ml. of 5 N NaOH. O₂ and N₂ are sufficiently insoluble in this medium to make de-aeration unnecessary. Only slight negative pres-

sure is required to admit it. Air-free 1 N NaOH must be used for whole blood.

After absorption of CO_2 cock b is sealed with mercury and the meniscus of the solution in the chamber is lowered a little below the a mark. Mercury is readmitted from cock e until the solution meniscus is again on the a mark. Cock e is closed and the reading of the manometer is taken $(p_2 \text{ mm.})$. The CO_2 pressure P_{CO_2} is

$$P_{CO2} = p_1 - p_2 - c$$

where c is the correction discussed on p. 646. This correction is determined in a blank analysis in which

Fig. 197. Use of calcium chloride tube reservoir.

Fig. 198. Bulb for preparing and storing gas-free solutions.

S ml. of water, made alkaline with 2 or 3 drops of normal NaOII, are extracted in the apparatus, p_1 and p_2 being read before and after addition of the same amount of alkali as used in the determination.

$$c = p_1 - p_2$$

To minimize error, all solutions must be measured very accurately, so that S varies within ± 0.05 ml. Also, sufficient time must elapse for temperature equilibrium to be established. (For other sources of error and refinements of technique, see the original paper.²⁶)

Calculation. See p. 647.

larger amounts of solution, the apparatus shown in Fig. 198 is suggested. It consists of two leveling bulbs connected by a rubber tube 1 meter long. One of the bulbs (illustrated) is provided with a glass capillary and stopcock. The bulb is half-filled with absorbent solution and extracted by evacuation and shaking. Solution is delivered into the extraction chamber directly from the capillary of this reservoir.

¹⁶ Austin (J. Biol. Chem., 61, 345 (1924)) has described a modification of this procedure to be used in CO₂ analyses of serum obtained after ether anesthesia.

Determination of Plasma CO₂ Capacity: CO₂ capacity, as a clinical measure of acidosis, may be determined by the volumetric method of Van Slyke and Cullen (p. 625). For the manometric determination, admit a drop of caprylic alcohol into the capillary of the cup, followed by 1.5 ml. of 0.1 N lactic acid. One ml. of plasma (previously saturated with alveolar air) is introduced below the acid. The solutions are admitted to the extraction chamber, cock b sealed, the chamber evacuated and shaken two minutes. p₁ is read as described above with the gas volume at 2 ml. The gas is ejected. the ejected portion of the solution returned to the chamber, and the pressure reduced so that the gas space is again 2 ml. The value p₂ and the temperature are then read.

Calculation. Pressure of extracted air and $CO_2 = p_1 - p_2$.

The CO₂ capacity is obtained from this pressure by the use of the nomogram (Fig. 199).

Determination of Oxygen in Blood: 37 Oxygen may be determined manometrically on 1-ml, samples of blood with a variation within 0.2 volume per cent.

The special O₂ reagent³⁸ is emulsified by rotating, and 7.5 ml. are measured into the apparatus and de-aerated by shaking in vacuo for three minutes. During the shaking, the mercury should be well in the neck below the bulb, to afford minimum exposure of surface, as mercury reacts with ferricyanide. One ml. of the well-mixed blood is drawn into a pipet, preferably such as described on p. 644. 6 ml. of the extracted reagent are forced into the cup, leaving 1.5 ml. in the chamber. The blood is introduced under the reagent directly into the chamber as described under "Measuring Samples." The pipet is carefully withdrawn and 1 ml. of reagent is permitted to flow into the chamber, rinsing through the blood in the capillary. The cock is sealed with a drop of mercury and the excess reagent discarded. The apparatus is evacuated and shaken three minutes. 1 ml. of air-free 1 N NaOH is placed in the cup and the CO2 absorbed by admitting 0.5 ml. of the hydroxide into the chamber under diminished pressure as described in CO2 determination on whole blood.

The solution meniscus is brought to 2 ml. (a) and p_1 (pressure of $O_2 + N_2$) is read. (For low O_2 values it is preferable to read p_1 with a at 0.5 ml.) As in the volumetric method, O₂ may now be determined either by making a correction for N_2 , or directly by absorption. In the first case, after p_1 has been read, the gases are ejected from the chamber and p_2 is determined with the solution meniscus at the same a mark.

The absorption method is resorted to for greater precision or when other gases (e.g., CO) are present. After p_1 has been read, cock e is opened, with the leveling bulb in position to produce a gas space of 4 to 5 ml. Cock e is then closed. 1.5 ml. of hydrosulfite solution 39 are introduced into the cup and by turning cock b admitted a drop at a time. As each drop trickles down it absorbs O₂ and the mercury in the manometer falls. After a few drops have been admitted no further perceptible fall occurs. Cock e is then

38 Special Oxygen Reagent:

Low results for oxygen may be accounted for by saponin of low hemolytic activity, in

which case the amount may be increased.

39 Grind up 100 g. of sodium hydrosulfite and 10 g. of sodium anthraquinone-β-sulfonate (Eastman Kodak Co.) and keep in stoppered bottle. To prepare absorbent solution stir 10 g. of this mixture in 50 ml. of 1 N KOH and quickly filter through cotton. De-aerate the solution and transfer to container under oil as described in the footnote on p. 647. One drop of 10 per cent FeCl: still further accelerates the absorption activity. The solubility of N: in this medium is negligible.

²⁷ Sendroy (J. Biol. Chem., 91, 307 (1931)) describes a shorter method for hemoglobin by manometric O2-capacity determination.

opened and the solution permitted to rise as near the stopcock as it will, with the leveling bulb in the lower ring. The remainder of 1 ml. of hydrosulfite is then added, completing the absorption of traces of O_2 . The gas is brought to the same a volume and p_2 is read on the manometer.

$$P_{O_2} = p_1 - p_2 - c_{O_2}$$

To check the completeness of O_2 absorption and the absence of air leakage, expel the N_1 and measure p_3 in the gas-free apparatus. The N_2 should

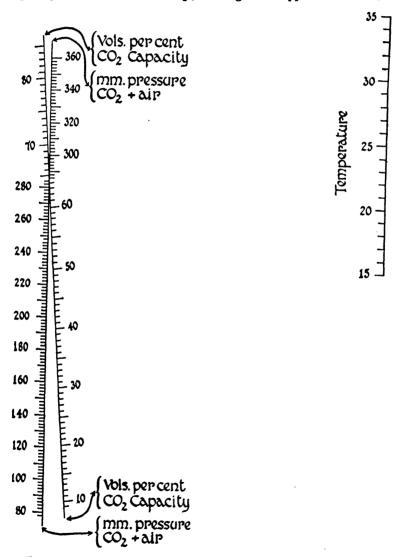

Fig. 199. Nomogram for calculation of plasma CO₂ capacity. A straight line connecting the observed points on the pressure and temperature scales cuts the CO₂ capacity scale at the point indicating the capacity.

approximate 1.2 volumes per cent in the O₂ content determination, or 1.4 volumes per cent in O₂ capacity.

An alternative absorbent for O_2 is the alkaline pyrogallate reagent (p. 641). This is not so clean or rapid as the hydrosulfite, but is more stable and its use is advised when O_2 determinations are done only occasionally. The gummy precipitate formed with the blood mixture necessitates mixing the solutions in the bulb of the chamber, well below the a mark, resulting in a greater negative pressure for the admission of the absorbent. One ml. of alkaline pyrogallate is admitted dropwise over four or five minutes. The pressure is then allowed to rise to atmospheric so that the upper tube is rinsed by the solution, thus avoiding a reduction of vapor tension due to the strong alkali. p_2 is read. The apparatus is cleaned with water after using this absorbent.

The c correction, when oxygen is determined by absorption, is due to two factors, the lowering of the mercury meniscus by the absorbent and the trace of O_2 left in the reagent after one extraction. To determine c, de-aerate 7.5 ml. of the special O_2 reagent for three minutes, expel 5 ml., leaving 2.5 in the chamber. Shake again for three minutes and then admit 1.5 ml. of air-free 1 N NaOH in the manner described for CO_2 . Read p_1 with a at 0.5 and 2.0 ml. Then run in the absorbent as in the analysis and obtain p_2 at both points. Use c_{O_2} corresponding to a in the analysis.

$$c_{01}=p_1-p_2$$

Eject residual N2 and read p1.

$$c_{N_2} = p_2 - p_3$$

If O_2 is determined indirectly by correcting for N_2 instead of by absorption, c is obtained in the same way, except that p_2 is measured after ejection of the $O_2 + N_2$, without preliminary absorption.

Calculations. The estimated corrections for dissolved O₂ and N₂ of blood in calculation of total or combined oxygen or oxygen capacity, given in the accompanying table, may vary somewhat with the cell content.

The corrections are subtracted from the volume per cent of gas as determined by the use of the table on p. 645.

ESTIMATED CORRECTIONS FOR DISSOLVED O2 AND N2 IN BLOOD

Blood	Determined	Sougl.t	Correction to Subtract

Determination of Carbon Monoxide Hemoglobin, of Methemoglobin, and of Hemoglobin by the Carbon Monoxide Capacity Method: 40 Principle. Car-

⁴⁰ Van Slyke and Hiller: J. Biol. Chem., 78, 807 (1928); 84, 205 (1929). Methods for smaller amounts of blood are also given. For a somewhat more accurate procedure for the determination of carbon monoxide in blood, see Sendroy and Liu: J. Biol. Chem., 89, 133 (1930).

bon monoxide is liberated from combination with hemoglobin by treatment with an acid ferricyanide solution. CO₂ and O₂ are absorbed with alkaline pyrogallol solution and CO determined by correcting for N₂ in the residual gas.

For determination of hemoglobin the blood is saturated with CO and the CO capacity determined. Volumes of CO absorbed are identical with those for O₂. This gives active hemoglobin.

CO without the aid of hydrosulfite does not change methemoglobin to carboxyhemoglobin. The difference between CO capacity with and without hydrosulfite

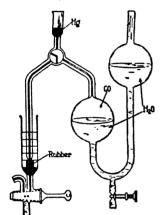

Fig. 200. Hempel pipet provided with three-way stop-cock⁴² (Van Slyke and Hiller).

treatment represents methemoglobin. Hemochromogen behaves like methemoglobin but is rarely present.⁴¹

Determination of Hemoglobin (Active) by CO Capacity: Draw 1 drop of caprylic alcohol into the capillary beneath the cup of the manometric apparatus. Measure 4.75 ml. of water into the cup. With stopcock pipet provided with rubber tip (see p. 644), run 2 ml. of blood directly into the chamber, followed by the 4.75 ml. of water. Place 1 to 2 ml. of mercury in the cup above the chamber. Fill the outlet capillary of a Hempel gas pipet containing CO (see Fig. 200) with mercury. Fit the tip of the pipet into the bottom of the cup as shown in the illustration. Turn the two cocks shown in the illustration so that CO gas43 can flow from the pipet into the chamber. The flow is regulated by the cock leading to the mercury leveling bulb of the manometric apparatus. With the leveling bulb in mid-position (a little below the bottom of the chamber), open this cock slowly, withdrawing mercury from the

chamber until CO enters to the 2-ml. mark. Close the cock of the chamber, seal with a drop of mercury, and evacuate. With the mercury meniscus at the 50-ml. mark, shake until equilibrium is reached (one minute or longer as determined in blank below). Eject the mixture of gases from the chamber.

Evacuate until blood solution is in lower fourth of chamber. Put about 1 ml. of mercury and 2 to 3 ml. of water in the cup. Through the mercury

⁴¹ Conant, Scott, and Douglass (J. Biol. Chem., 76, 223 (1928)) give a method suitable in the presence of hemochromogen.

⁴² The bulbs are of about 50 ml. capacity each. The capillary is of 1 mm. bore. When the pipet is not in use, a little mercury is let into the capillary leading to the CO bulb, to seal the three-way cock and prevent leakage around it. This drop of mercury in the capillary to the right of the cock is shown in the illustration. This pipet may also be used to store air-free solutions. In this case the solution replaces the CO gas shown above, and mercury is used where water is indicated in the above figure. Supplied by the makers of the Van Slyke-Neill apparatus.

tubing at least 15 mm. wide. Fill one (A) completely with water. A is also fitted with a thistle tube with stopcock and a side tube with stopcock connecting with a large test tube carrying a safety thistle tube containing mercury passing through the stopper only and a second thistle tube, with stopcock, reaching to the bottom of the test tube. Run into the test tube 3 ml. of anhydrous formic acid, and then, slowly, concentrated H₂SO₄, gently warming the mixture with a micro-burner. When about 300 ml. of CO and air have collected in A, drive this out by opening the thistle tube and lifting B. Continue generation until the CO from all the formic acid is collected in A. Clamp the tube between the two bottles with a screw clamp and detach the test tube. Carry out the entire procedure in a hood or in a free draft of air. Smaller vessels may be used if less CO is desired.

seal introduce 0.25 ml. of acid ferricyanide⁴⁴ solution, using a rubbertipped buret made by fusing a stopcock onto a pipet graduated in 0.01-ml. divisions. Before the tip of the buret is inserted into the mercury, move it through the water layer to dislodge ferricyanide crystals or air bubbles. Fill the capillary and bore of the cock with mercury but run none into the chamber. Evacuate, lowering the mercury to the 50-ml. mark. Shake slowly for about five seconds, and then vigorously for three minutes. Admit mercury until gas space is reduced to 5 to 6 ml. Measure 2 ml. of air-free 1 N NaOH⁴⁴ into the cup, running in slowly with the tip against the bottom of the cup. Allow 1 ml. of the NaOH to flow slowly into the chamber. Absorption of CO_2 is complete in less than 1 minute. Bring the volume of gas to 2 ml. Record the manometer reading as p_1 . Eject the gas. Seal the stopcock with a drop of mercury. Lower the fluid meniscus to 2 ml. Read the manometer again (p_2) .

Calculation. The hemoglobin content of the blood in terms of CO- or O₂-combining power is calculated by the equation:

CO or
$$O_2$$
 capacity = $(p_1 - p_2 - c)f$

where f is a factor obtained from the table on p. 645. c is determined by a blank analysis in which the procedure described above is repeated in every detail except that 2 ml. of water are substituted for the 2 ml. of blood. The correction is calculated as $c = p_1 - p_2$. The value of c, once accurately determined, can be used as a constant as it is small and insensitive to ordinary changes in laboratory conditions.

Determination of Total Hemoglobin and Methemoglobin: Wash apparatus with three successive portions of 10 to 15 ml. of water, to the first of which a little hydrosulfite solution is added. This is done by evacuating to the 50-cc. mark, running in the water, shaking for 15 to 20 seconds, and ejecting the solution.

Draw two drops of caprylic alcohol into the capillary beneath the cup. Measure into the cup 4.3 ml. of water. Using the stopcock pipet with rubber tip run 2 ml. of blood directly into the chamber, followed by a few drops of the water in the cup to wash blood through the capillary. From a microburet (see above) run 0.4 ml. of the ammoniacal sodium hydrosulfite45 solution into the chamber, followed by the water remaining in the cup. Put 1 to 2 ml. of mercury in the cup. Lower the mercury in the chamber to the 50-ml. mark. Run in CO from the Hempel pipet until the pressure on the manometer rises about 150 mm., the mercury remaining at the 50-ml. mark. If 100 mm, of CO are run in and then mercury admitted from the leveling bulb to raise the level to the 50-ml. mark, the proper pressure will usually be attained. Shake one and a half minutes. Eject gases from the chamber. Determine CO exactly as in the method above for active hemoglobin, except that 0.30 ml. instead of 0.25 ml. of the ferricyanide solution is run in. Determine correction c by running blank test on 2 ml. of water (see above). This c will be somewhat greater than in the method for active hemoglobin. The calculation is otherwise the same and gives total hemoglobin.

Methemoglobin = total hemoglobin - active hemoglobin

Manometric Determination of Other Substances. See footnote 31, p. 642. Other manometric methods are those for urea using the urease⁴⁶ or hypobromite⁴⁷

⁴⁴ Acid Ferricyanide Solution. To 92 volumes of stock solution, containing 32 g. of $K_*Fe(CN)_*$ per 100 ml., add 8 volumes of concentrated lactic acid of sp. gr. 1.2. It may be used for over two months. 1 N NaOH. Rendered air-free as described on p. 647.

⁴⁵ Ammoniacal Sodium Hydrosulfite. Pour 50 ml. of diluted (1:50) ammonia solution upon 2.0 g. of pulverized Na₂S₂O₄ contained in a 100-ml. beaker. Cover at once with a layer of paraffin oil. Dissolve by stirring with a rod for a few seconds.

Energy Metabolism

Historical. Combustion in living beings was first described by Lavoisier (1743-1794). This brilliant chemist discovered the true nature of oxygen, and how its union in the body with carbon and hydrogen resulted in the formation of carbon dioxide and water and in the production of heat. In experiments on man he determined that oxidation was increased by food, by a cold environment, and by muscular work. He knew the main constituents of the atmosphere and that nitrogen played no active part in animal respiration. Lavoisier was under the false impression that oxygen decomposed some fluid in the lung, causing the liberation of hydrogen and carbon with the subsequent oxidation of these elements and their excretion as carbon dioxide and water in the expired air. Scientists of a later date abandoned the theory of oxidation in the lungs, and favored the blood as the site of these chemical changes. This belief was strengthened by the discovery of gases in the blood by Magnus in 1837. Later it became known that, for the most part, oxidation occurred in the tissues and that the blood simply carried the gases to and from the lungs.

In 1842 Liebig announced that the substances burned in the body were carbohydrate, fat, and protein, and suggested that the urinary nitrogen would serve as an index of the extent of protein destruction. Ten years later Bidder and Schmidt described protein metabolism, and shortly afterwards Carl Voit measured protein waste by determining the amount of nitrogen in the excreta. Voit made the important discovery that muscular exercise did not increase protein metabolism. During many years of careful work, Rubner, a pupil of Voit, determined the fuel values of the foodstuffs and by means of a respiration calorimeter showed that the heat production as calculated from the respiratory exchange was the same as that obtained by the direct measurement of the heat given off by the body. In 1883, Rubner demonstrated the relationship between the surface area of the body and the heat production, thus providing a basis for comparison of the metabolism of different individuals.

In 1915 DuBois devised the most satisfactory method for estimating the surface area of the body, and later published normal standards of heat production for males and females, the accuracy of which has been fairly well established.

In America, Atwater, Armsby, Benedict, Lusk, DuBois, and their many associates have added valuable contributions to the knowledge of normal metabolism. Benedict and those associated with him in the Carnegie Nutrition Laboratory have in addition perfected various forms of respiration apparatus, and they are chiefly responsible for the extensive use of calorimetry in the clinic.

Physical and Chemical Bases of Animal Calorimetry: Gases. Gases are compressible fluids. The molecules of which they are composed

are under constant motion and tend to disperse. The gas therefore expands and fills all parts of the containing vessel and exerts pressure upon the enclosing walls. Heat increases the tendency to expand and so increases the pressure unless the container permits the gas to assume a larger volume. If the temperature remains constant and pressure is applied to the container, the molecules are forced closer together and the volume is decreased. Therefore, when we speak of a volume of gas, we must also state the temperature and pressure under which it was measured. Regardless of the experimental conditions of measurement, gas volumes are always recorded as the volume at standard temperature (0° Centigrade or 273° Absolute) and standard pressure (760 mm. of mercury at 0° C.¹). This is sometimes referred to as "standard conditions" or as "N.T.P." (normal temperature and pressure).

If the temperature is kept constant, the volume of a gas varies inversely with the pressure. (Boyle's Law.) Therefore, to express a volume of gas, measured at some other pressure, as its volume at 760 mm., the formula is:

Volume
$$\times \frac{\text{Pressure (corrected)}}{760} = \text{Volume at 760 mm.}$$

If the pressure on a gas remains the same and the temperature changes, the volume of the gas will vary directly $\frac{1}{273}$ (or 0.00367) of its volume at 0° C. for each degree of change in temperature. (Charles' or Gay Lussac's Law.) The coefficient of expansion of nearly all gases is 0.00367.

To convert the volume of a gas at temperature t° C., and at constant pressure, to its volume at 0° C., the formula is:

Volume
$$\times \frac{273}{273 + t^{\circ} C}$$
 = Volume at 0° C.

The two conversion equations given may be combined into a single equation as follows:

$$\frac{P \times V}{273 + t} = \frac{760 \times V_0}{273}$$

where P and V represent the experimentally determined pressure and volume, corrected if necessary, at the temperature t° C., and V_{0} represents the volume under standard conditions.

If a volume of gas is in contact with water, evaporation continues until the tendency of the water to evaporate is equal to the tendency of its vapor to condense, at which time the gas is said to be saturated with water vapor. The total pressure of the saturated gas and water vapor is equal to the sum of the pressures of the gas and of the water vapor. (Dalton's Law.) These are spoken of as partial pressures. The partial pressure of the water vapor increases with temperature. To determine the pressure of the gas in a dry state, the partial pressure of water vapor at the given temperature (see p. 642) must be deducted from the barometric pressure.

¹ The reading on a brass scale barometer is correct for only one temperature and must be corrected by the use of a correction table which gives the height at which the column of mercury would stand if the temperature were 0° C. For such a table, refer to a handbook of chemistry or physics. See also p. 628.

Example. The expired air of a man has a volume of 100 liters, the temperature in the gasometer is 22° C., and the brass scale barometer reads 767 mm. The pressure of expired air, dry, would be:

767 mm. -2.72 (barometer correction) - 19.63 (water vapor) = 744.65 mm.

The volume of dry air at 0° C. and 760 mm. would be:

$$100 \times \frac{744.65}{760} \times \frac{273}{273 + 22} = 90.66$$
 liters

Equal volumes of different gases or vapors under like conditions of temperature and pressure contain the same number of molecules. (Avogadro's Law.) Thus the density or mass per volume of any gas or vapor will depend upon the weight of its molecule. The molecular weight in grams of any gas or vapor has a volume of practically 22.4 liters at 0° C. and 760 mm. Hence the density of 1 liter of a gas at 0° C. and 760 mm. is molecular weight ÷ 22.4.

Density of gases at 0° C. and 760 mm.

1 liter of oxygen weighs 1.4292 g.

1 g. of oxygen occupies $\frac{1}{1.4292} = 0.6997$ liter

1 liter of carbon dioxide weighs 1.9652 g.

1 g. of carbon dioxide occupies $\frac{1}{1.9652} = 0.5089$ liter

HEAT. The heat which we recognize by temperature is the energy of molecular motion. This property is imparted to matter by chemical action, electric currents, and mechanical work. In animals the chemical source only need be considered and we may confine our attention to that form of combustion in which the substance finally appears in the completely oxidized form.

In animal calorimetry the unit of heat is the *large Calorie*, abbreviated Cal., which is defined as the amount of heat necessary to raise the temperature of 1 liter of water from 15° C. to 16° C.

Heat of Combustion in a Calorimeter.

1 g. of hydrogen gas produces 34.5 Cal.

1 g. of charcoal produces 8.0 Cal.

1 g. of starch produces about 4.2 Cal.

1 g. of glucose produces about 3.74 Cal.

1 g. of sucrose produces about 3.96 Cal.

Heat of Combustion in Animals.

1 g. of average carbohydrate produces about 4.1 Cal.

1 g. of average fat produces about 9.3 Cal.

1 g. of average animal protein produces about 4.25 Cal.

1 g. of average regetable protein produces about 3.98 Cal.

1 g. of average mixed protein produces about 4.1 Cal.

Oxidation of Carbohydrates. Carbohydrates, by the processes of digestion, undergo hydrolytic cleavage if necessary and are absorbed through the intestinal wall into the blood mainly in the form of glucose. Under normal conditions the blood contains 0.1 per cent or less of this sugar in the free state; over 300 g. or more may be stored as glycogen in the body tissues, principally in the muscles and in the liver. Glycogen is readily reconverted to glucose and it serves as a deposit to be drawn upon in an emergency. Glucose is the favorite body fuel, and is used prodigally when the supply is plentiful and thriftily in periods of starvation.

The oxidation of glucose is represented as follows:

	$C_6H_{12}O_6$	+ 602	$= 6CO_2 + 6H_2O$
Molecular weights in grams	180	192	264 108
Heat and volume equivalents	673.2 Cal.	134.34 liter	s 134.34 liters
Heat and volume equivalents	5.011 Cal.	per 1 liter	1 liter

Carbohydrates contain hydrogen and oxygen in the same proportion as is found in water. When these substances burn, outside oxygen is used to unite with the carbon forming a volume of carbon dioxide equal to the volume of oxygen absorbed. The ratio of the volume of carbon dioxide produced to the volume of oxygen absorbed is known as the respiratory quotient (R.Q.). This has a different value for each of the foodstuffs and serves as a means of determining what substances are being burned. From the above equation it is seen that the respiratory quotient for glucose is $\frac{CO_2}{O_2} = 1.0$ and that 1 liter of oxygen represents a liberation of 5.011 Cal.

In animal calorimetry the heat equivalent of 1 liter of oxygen is generally accepted as 5.047 Cal. when carbohydrates are burned in the body.

Oxidation of Fats. The fats and oils of our food are largely mixtures of palmitin, stearin, and olein (see Chapter 3). These substances are of similar chemical composition and when they undergo oxidation they yield about the same amount of heat. After absorption, fat passes from the blood to the tissues, where it is either burned or stored for future use. Fats have a high fuel value and they are continually being used by the body for this purpose. In the absence of carbohydrates, fats supply over 80 per cent of the body heat.

Fat combustion is usually represented by the oxidation of palmitin as follows:

From the above equation it is seen that when palmitin is burned the respiratory quotient is 0.704 and that 1 liter of absorbed oxygen liberates 4.655 Cal. Zuntz and Schumburg obtained slightly different figures for the oxidation of fat in the body. In their work the respiratory quotient was found to be 0.707 and the heat value for 1 liter of oxygen 4.686 Cal. If only mixtures of carbohydrate and fat were oxidized, the respiratory quotients would vary between 0.707 and 1.00, and from their value it

should be possible to determine the proportions of each of these foodstuffs burned. A table analyzing the oxidation of such mixtures on the basis of the so-called nonprotein respiratory quotient was prepared by Zuntz and Schumburg and modified by Lusk. (See below).

Analysis of the Oxidation of Mixtures of Carbohydrate and Fat*
(Table of Zuntz and Schumburg modified by Lusk)

^{*} The last column has been added to facilitate the expression of oxygen absorbed per minute in terms of Calories per hour,

Protein Metabolism. Proteins in the diet are completely broken down in the gastrointestinal tract to the form of amino acids, in which form they are absorbed into the blood and pass to the various parts of the body. Here they may be utilized either for incorporation into new tissue protein which is continually being broken down and resynthesized, or they may undergo metabolic reactions leading to the formation of nonprotein nitrogenous compounds of importance to the body, such as creatine, thyroxine, adrenaline, etc. Presumably they may also be utilized for the direct production of energy, although under ordinary circumstances protein is not considered to be primarily a fuel. Regardless of the intermediate steps in protein metabolism, which are discussed in detail in Chapter 33, the end-products of protein breakdown in the animal body include not only carbon dioxide and water, as for carbohydrates and fats, but also the urea of the urine and certain other nitrogenous constituents of the urine and feces, as well as such compounds as urinary sulfate produced by the oxidation of sulfur-containing amino acids. Hence to evaluate the contribution of protein to the total metabolism, and to distinguish it from the nonprotein metabolism, the analysis of urine and feces is necessary in addition to the measurement of the respiratory gas exchange.

A computation of protein metabolism by Loewy is as follows:

100 g. of meat protein contain:

in the feces:

leaving a residuum for the respiratory process of:

Deduct intramolecular water:

leavina

$$41.5~$$
 g. C $~~3.439$ g. H $~~$ for oxidation.

When CO2 is formed, 12 g. C unite with 32 g. O

Therefore 41.5 g. C unite with
$$\frac{32 \times 41.5}{12} = 110.67$$
 g. O

When H₂O is formed, 2 g. H unite with 16 g. O

Therefore 3.439 g. II unites with
$$\frac{16 \times 3.439}{2}$$
 = 27.512 g. O

In the above computation, 1 g. of urinary nitrogen represents:

$$\frac{100 \text{ g. protein}}{16.28} = 6.15 \text{ g. of muscle protein}$$

$$\frac{138.18 \text{ g. O}_2}{16.28} = 8.49 \text{ g. of O}_2 \text{ absorbed}$$

$$\frac{152.17 \text{ g. CO}_2}{16.28} = 9.35 \text{ g. of CO}_2 \text{ produced}$$

```
6.15 g. protein \times 4.25 (Cal.) = 26.14 Cal.
8.49 g. O_2 \times 0.6997 (liters) = 5.94 liters of O_2 for protein 9.35 g. CO_2 \times 0.5089 (liters) = 4.76 liters of CO_2 from protein
```

Respiratory quotient for meat protein
$$=\frac{4.76}{5.94}=0.801$$

Based on the analytical figures for the average protein it is estimated that 1 g. of urinary nitrogen represents the metabolism of 6.25 g. of protein, the absorption of 5.91 liters of oxygen, the production of 4.76 liters of carbon dioxide, and the liberation of 26.51 Cal.

An example of the practical application of the above constants is as follows:

A man (aged 38.5 yrs., height 159 cm., weight 90 lb.) was tested 14 hours after the last meal. An analysis of the urine showed an excretion of 0.16 g. of nitrogen per hour. The total respiratory exchange showed an absorption of 12.52 liters of oxygen and the production of 9.3 liters of carbon dioxide per hour.

0.16 g. of urinary nitrogen represents

```
\begin{array}{lll} 0.16\times & 6.25=1~g, \ of protein metabolized \ with \ the \ absorption \ of \\ 0.16\times & 5.91=0.95 \ liter \ of \ O_2, \ the \ production \ of \\ 0.16\times & 4.76=0.76 \ liter \ of \ CO_2, \ and \ the \ liberation \ of \\ 0.16\times & 26.51=4.24 \ Cal. \\ \hline Total \ CO_2 \ (or \ O_2) - protein \ CO_2 \ (or \ O_2) = nonprotein \ CO_2 \ (or \ O_2) \\ 9 \ 3 \ \ liters \ CO_2 - 0.76 \ liter \ CO_2 = 8.54 \ liters \ CO_2 \\ 12.52 \ liters \ O_2 - 0.95 \ liter \ O_2 = 11.57 \ liters \ O_2 \\ \hline \frac{8.54 \ liters \ CO_2}{11.57 \ liters \ O_2} = 0.74 \ (nonprotein \ R.Q.) \\ \hline \end{array}
```

From Zuntz and Schumburg's table (modified by Lusk, see p. 659), it is seen that when the nonprotein R.Q. is 0.74, 1 liter of O_2 represents the liberation of 4.727 Cal., and 12 per cent of the nonprotein heat comes from carbohydrate and 88 per cent from fat.

```
11.57 liters O<sub>2</sub> × 4.727 = 54.69 Cal. (nonprotein)
12 per cent of 54.69 = 6.56 Cal. from carbohydrate
88 per cent of 54.69 = 48.13 Cal. from fat
54.69 + 4.24 (protein Cal.) = total of 58.93 Cal. per hour
```

In this computation 7 per cent of the body heat was derived from the combustion of protein, 11 per cent from carbohydrate, and 82 per cent from fat.

As Richardson points out, the measured respiratory quotient is not necessarily the metabolic quotient and it gives no information concerning the intermediate steps in the conversion of consumed O₂ to CO₂. Non-oxidative processes which promote CO₂ production such as acid formation (e.g., diabetes or excessive muscular activity) or acid retention (e.g., nephritis), and conditions which diminish the CO₂ output (e.g., insulin or

alkali therapy, etc.) exercise an important influence on the respiratory quotient. Taking these factors into account, however, studies of conditions of abnormal carbohydrate and fat metabolism such as diabetes and ketosis, and of the physiology of food utilization and muscular activity, have been greatly advanced by measurements of the respiratory quotient.

Respiration. The ventilation of the lung and the exchange of gases between the alveolar air and the blood are usually referred to as external respiration, as contrasted with the exchange of gases in the tissues known as internal respiration. (See Chapter 12.) Any disproportion between external and internal respiration affects the oxygen or carbon dioxide content of the blood. The tension of oxygen in the blood is lowered when the lungs are extensively disordered, as in pneumonia, and during periods of supreme muscular effort; under these conditions the oxygen requirement of the tissues is greater than the oxygenating power of the lung. An unusual increase in the supply of oxygen in the lung has but a very slight effect on the tension of oxygen in the blood, and practically no effect on the rate of combustion in the tissues. Of greater interest is the carbon dioxide tension of the blood, which is nicely regulated by an adjustment of the ventilation of the lung, and of the circulation of the blood, so that these mechanisms parallel the rate of combustion in the tissues.

There is a general parallelism between the heat production, the heart rate, and the ventilation rate. However, the heart rate is not solely determined by the requirements of respiration, and ventilation can be voluntarily controlled. A rapid heart and an increased ventilation rate make one suspect that the metabolism is increased, but the rate of heat production cannot be predicted from these phenomena.

EXTERNAL RESPIRATION. Atmospheric air is of very constant composition the world over. Advantage is taken of this fact in computing the respiratory exchange, that is, the amount of oxygen absorbed and the amount of carbon dioxide produced in a given time.

Atmospheric air has the following composition:

Carbon dioxide	0.03 per cent
Oxygen	20.94 per cent
Nitrogen	79.03 per cent

Under ordinary conditions, at each breath a person inspires about 500 ml. of air and of this amount only 350 ml. actually enter the lung and diffuse more or less with the 3000 ml. already there. The expired air includes the 140 ml. of the "dead space" and 350 ml. of partially mixed air from the lung (see Fig. 201). Expired air contains about 16 per cent oxygen, 4 per cent carbon dioxide, and 80 per cent nitrogen.

If we exhale forcibly and collect the last portion, the so-called alveolar air, we find that it contains about 14.5 per cent of oxygen and 5.6 per cent of carbon dioxide. That is, the air deep in the lung, where it comes in close proximity to the blood, has the greatest concentration of carbon dioxide and the lowest concentration of oxygen. These gases are in equilibrium with the gases in the arterial blood.

² For further discussion of the gas exchange in blood and tissues, see Chapter 24.

Fig. 201 shows that after an ordinary expiration, 1500 ml. of additional air can be forcibly expired; then, if the greatest possible inhalation is made, almost 4 liters of fresh air can be drawn into the lungs. This greatly

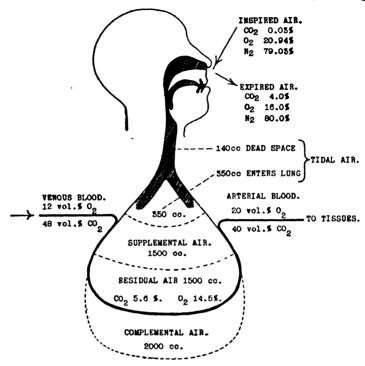

Fig. 201. Inspired and expired air.

The tidal air is that which enters and leaves the body with each normal respiration. The supplemental air is that which can be forcibly expired after a normal tidal expiration; this leaves in the lungs the residual air which cannot be voluntarily expelled. The complemental air is that which can be forcibly drawn into the lungs over and above a normal tidal inspiraton. The vital capacity is the greatest volume of air which can be expired following a forced inspiration; it includes the tidal, the supplemental, and the complemental volumes.

The inspired or atmospheric air is of constant composition. The composition of the expired air is not constant; it is determined by the varying factors of combustion in the tissues, the rate of blood flow, and the rate of ventilation in the lung. The alveolar air is the last portion of the supplemental air to be expired, and represents the composition of the residual air, and its gases are in equilibrium with the arterial blood. The blood in its passage through the lung gives off carbon dioxide and absorbs oxygen.

dilutes the carbon dioxide in the alveolar air and induces a rapid passage of the gas from the blood. If forced breathing is continued, a large amount of carbon dioxide, which is ordinarily stored in the blood, is in this manner "washed out" and may be erroneously regarded as carbon dioxide produced during a period of a metabolism test.

· The increased supply of oxygen due to forced ventilation has no effect on metabolism tests; in fact, as it has previously been stated, one can breathe pure oxygen without appreciably increasing its absorption. This fact is taken advantage of in the "closed circuit" types of respiration apparatus which require the rebreathing of air, rich in oxygen.

Nitrogen plays a passive role in respiration; the amount expired is the same as the amount inspired. As there is a definite proportion between the oxygen and the nitrogen of the atmosphere, it is possible to calculate the amount of oxygen inspired on the basis of the nitrogen in the expired air. The formula is:

$$V = \frac{20.94 \times \text{per cent N}_2 \text{ in expired air}}{79.03}$$

when V = volume of oxygen in inspired air corresponding to 100 volumes of expired air.

It must be emphasized that in order to measure successfully the carbon dioxide produced during a metabolism test of short duration, ventilation must be an involuntary act.

Energy Requirement. The energy requirement of the animal body may be divided into two functional classifications, viz., that for basal metabolism and that for active work. Basal metabolism includes the energy expended in respiration, blood circulation, intestinal contractions, activities of various organs, maintenance of muscular tonus, thermal equilibrium, etc. The basal metabolic rate is influenced by the amount of active protoplasmic mass (hence by height, weight, surface area, age, sex, composition of the tissues, etc.) and is governed by endocrine organs, particularly the thyroid and pituitary glands. For a discussion of the clinical aspects of basal metabolism and its measurement, see p. 665.

The energy consumed in work, play, and indeed all forms of voluntary activity, imposes an additional requirement for fuel over the basal, which depends on the nature and extent of the muscular work. Whereas an average man expends about 100 Cal. per hour while sitting at rest, his metabolism may increase to as high as six times this value with extreme physical effort.

Mary Swartz Rose summarizes the hourly expenditure of Calories of an average 70-kg. man under various conditions as follows: sleeping 65, awake lying still 77, sitting at rest 100, standing relaxed 105, walking slowly to moderately fast 200-300, running 5.3 miles per hour 570, swimming 500, walking down stairs 364, walking up stairs 1100, "light exercise" 170, "active exercise" 290, "very severe exercise" 600, dishwashing 144, carpentry or painting 240, sawing wood 480. From estimates such as these one may predict the calorific content of the diet necessary to meet individual requirements. A typical analysis for a 70-kg. man is given by Sherman as follows:

```
8 hrs. sleep at 65 Cal. = 520 Cal.
2 hrs. light exercise<sup>3</sup> at 170 Cal. = 340 Cal.
8 hrs. carpenter work at 240 Cal. = 1920 Cal.
6 hrs. sitting at rest at 100 Cal. = 600 Cal.
```

Total food requirement for the day, 3380 Cal.

The total energy requirement of different types of workers ranges from a minimum of 2000 to 2500 Cal. per day ("white-collar workers") to a maximum of 4000 to 6000 (lumbermen, excavators, etc.), of which about 1400 to 1900 Cal. are consumed in basal metabolism and the balance in various forms of activity.

BASAL METABOLISM

Basal metabolism, or the basal metabolic rate, is an expression of the heat production of the body in complete mental and physical repose, and in the postabsorptive state. For a successful test the subject must be in a "comfortable" environment, if "too hot" or "too cold" the result will be abnormally high. The body temperature must be within the normal limits and the patient must not be one who suffers from daily fevers. DuBois estimates an increase in metabolism of 7.2 per cent for each degree Fahrenheit in fevers. The patient must be quiet and preferably experienced with the test. Mental activity alone has but a slightly elevating effect upon the heat production. Emotional excitation will raise the metabolism 20 per cent or more. This is probably due to the stimulation of the adrenal glands as suggested by Aub. The emotional factor constitutes the greatest source of error in basal metabolism determinations. Technical errors have been reduced to a negligible quantity. It is not difficult to insure muscular repose and physical comfort, but it requires the utmost sympathy and tact to allay the apprehensions of the patient and insure physiological repose. A common practice is to test the patient repeatedly and to accept the lowest or the last result as the true basal rate; the fallacy of this is obvious when one considers that the number of such tests is usually determined by the endurance of the patient. DuBois conducts three or four tests and takes the average of the two lowest that show fair agreement. Even under favorable conditions it is possible, in unstable individuals, to get variations as high as 6 per cent in as many hours. These variations are physiological, not technical; the technique is more accurate than our ability to recognize or control emotional changes.

Clinical Interpretation of Basal Metabolism. In 1893 the clinical use of calorimetry was presaged by Friedrich Müller, who observed that patients with Graves' disease lost weight and had a marked nitrogenous waste despite the fact that the diet was adequate to maintain a normal state of nutrition. This observation was soon verified by Magnus-Levy, who determined the now well-known action of the thyroid gland in regulating the rate of combustion in the body. It is true that other factors affect the rate of heat production and that certain well-recognized diseases are accompanied by metabolic changes, but in the majority of cases variations in the basal metabolism can be interpreted as variations in the function of the thyroid gland.

In an extensive study of basal metabolic rate determinations, Boothby and Sandiford showed that 92.1 per cent of normal individuals have a basal metabolic rate within ± 10 per cent, and 99.3 per cent within ± 15 per cent of the DuBois standards. They found that a smaller percentage of these same subjects had basal metabolic rates within the same limits when the Harris and Benedict standards were used. These standards are discussed in the following section.

In clinical cases the basal metabolism may vary from 40 per cent below to 130 per cent above the average normal. In this discussion a tabulation of the findings in various disorders is avoided, because standing alone, the values are misleading. If no

^{*} Going to and from work, for example.

other cause can be found for an abnormal heat production, the result may be cautiously attributed to a disordered activity of the thyroid gland. Glands other than the thyroid may affect the rate of cellular combustion, but at the present time we know of two body substances only which change the rate of heat production, namely, thyroxine and adrenaline. The latter has a rapid, but fleeting, stimulating effect; the effect of the former lasts for several weeks. When the activity of the adrenal glands is decreased, as in Addison's disease, the basal metabolism is found to be subnormal. Hyperactivity of these glands may account for the temporary increase in metabolism occasionally found in nervous patients, who also show corresponding variations in pulse rate and in blood pressure.

The basal metabolic rate does not establish a diagnosis of hyperthyroidism. A patient afflicted with hyperthyroidism may be tested during an intermission and the basal metabolism would be within the normal limits despite the persistence of such clinical signs as nervousness, palpitation, tremors, and exophthalmos. Conversely, the test may detect active hyperthyroidism in patients showing few of the classical symptoms of the disease. The test does not tell the surgeon when it is safe to operate upon the patient, it informs him when it is least dangerous and he must base his operative prognosis upon the clinical condition of the patient and not upon the basal metabolic rate.

The onset of hyperthyroidism is accompanied by a progressive increase in heat production which may reach over 100 per cent above the average normal and persist for weeks after the glandular activity has subsided. Therefore, repeated tests are necessary in order to follow the course of the disease; an increasing rate indicates an active state of the gland and naturally precludes operative intervention; a decreasing rate gives a more hopeful outlook.

The pulse rate is largely dependent upon the rate of metabolism. Clinically, a decreasing pulse rate indicates a subsidence of the hyperthyroidism. Few patients with pulse rates below 50 have a basal metabolic rate above the average normal and few patients with pulse rates below 85 have any considerable increase in their metabolism.

Heat comes from oxidation in the active protoplasmic tissue of the body. The rate of heat production is not determined by surface cooling as one method of measurement would seem to imply (see footnote 19, p. 670); in reality, heat dissipation is regulated according to heat production. Any rapid change in the relative amount of protoplasmic tissue will cause changes in the basal metabolic rate when expressed in terms of weight or surface area. This partly explains the gradual drop in the basal metabolic rate during the glandular and muscular waste of starvation and in hospital patients during their early confinement to bed. A rapid accumulation of fluid in the body has a similar effect and it is quite common to find nephritics with marked edema having a basal metabolic rate of 20 to 30 per cent below the average normal. This must not be interpreted as a sign of hypothyroidism.

Under the basal conditions we measure the heat resulting from activities of the vital organs and from the intracellular chemical changes associated with life, growth, and development. These facts must be borne in mind and due allowance made for any unusual activity before the results are attributed entirely to the thyroid gland. Dyspnea, hypertension, cardiac decompensation, and tremors involve increased muscular activity and so raise the heat production. Certain diseases are characterized by increased cellular activity and in these cases the heat production is increased. The most outstanding of this group is leukemia in which disease the basal metabolic rate may be as high as in severe Graves' disease. Polycythemia, anemia, and Paget's disease of the bones are other conditions in which the increased heat production probably results from increased cellular activity. In this group possibly belongs the acute stage of acromegaly. In these conditions the basal metabolism is rarely over 25 per cent above the average normal. The possibility of self-administration of drugs such as iodine or thyroid extract must be considered in the interpretation of basal metabolic rate.

From birth to the age of one and a half years the basal metabolism increases at a remarkable rate. This is followed by a gradual decline until full growth and development is attained; constancy characterizes the rate in adult life, with a slight decline

as old age advances. Variations in the rate of growth and development in childhood cause abnormal results when judged by the age standard. In prematurely developed children the basal metabolic rate is low according to the age standard, but is probably normal for the stage of development if this could be accurately expressed. The difficulty in applying the test to children has resulted in a paucity of normal tests and great variation in the results obtained. The normal biological variations are much greater in children than in adults and may be greater than the pathological changes anticipated by the physician. Fortunately the test is rarely required before the age of puberty and the normal standards beyond that age are fairly well established.

The metabolism of women averages about 12 per cent below that of men, and due to the menstrual cycle, is more variable. There is usually, though not invariably, a premenstrual rise and a postmenstrual fall in the basal metabolic rate, which should be considered in the interpretation of results

There is some evidence of lower metabolic rates among certain oriental and tropical races.

Standards of Normal Basal Metabolism and Calculations. The heat production of normal individuals under basal conditions largely depends upon the factors of age, height, and weight. The normal standards are based upon thousands of determinations in several centers of investigation. A better appreciation of basal conditions and the elimination of a high proportion of first tests has resulted in a tendency toward lower standards in recent years. At the present time there are three different systems of predicting the normal heat production.

1. Aub and DuBois⁶ determine the heat production in relation to the surface area of the body; the surface area is estimated by the DuBois and DuBois⁷ formula which is based on the height and weight: $A = Wt^{0.425} \times Ht^{0.725} \times 71.84$, where A equals the area in sq. cm., Wt the weight in kg., and Ht the height in cm. In routine work the nomogram of Boothby and Sandiford⁸ (Fig. 202) may be used for determining the surface area. Stoner⁶ has computed tables of values for this formula in unit cm. and kg. intervals for the height range of 110 to 200 cm. and the weight range of 20 to 110 kg.

The original so-called Sage standards of Aub and DuBois have been modified on the basis of larger numbers of normal controls. Bailey's¹⁰ table covers the ages from 4 to 65 in yearly intervals, while Boothby and Sandiford¹¹ give values by years from 5 to 19 and in five-yearly intervals between 20 and 79 (see table on p. 669). These standards fail to reflect the modern downward trend, but since they are based on tests on patients, they may be better suited for clinical purposes than lower standards based on trained subjects.

2 The Harris-Benedict¹² multiple prediction equations and tables¹³ are based on a statistical study of the available data for the basal metabolism of normal men and women. The equations are,

```
For men, H = 66.4730 + 13.7516W + 5.0033S - 6.7550A
For women, H = 655.0955 + 9.5634W + 1.8496S - 4.6756A
```

- *Of interest in this connection are the observations of Benedict, Sherman, Campbell and Zmachinsky (J. Nutrition, 14, 179 (1937)) that middle-aged male rats not previously exercised were unable to adjust themselves to vigorous enforced exercise and declined rapidly, whereas female rats were benefited by similar treatment, showing a distinct tendency to lower basal metabolism. Basal metabolism in old age is the subject of a paper by Matson and Hitchcock: Am. J. Physiol., 110, 329 (1934).
- For prediction tables of normal heat production, reference should be made to books dealing in this subject (see the Bibliography at the end of this chapter).

 - 18 Harris and Benedict: Carnegie Inst. Wash., Pub. No. 279, 1919.
- ¹² Tables which greatly simplify the use of these formulas may be found in Carpenter; Carnegis Inst. Wash., Pub. No. 303, 1921. See also DuBois' book, cited above.

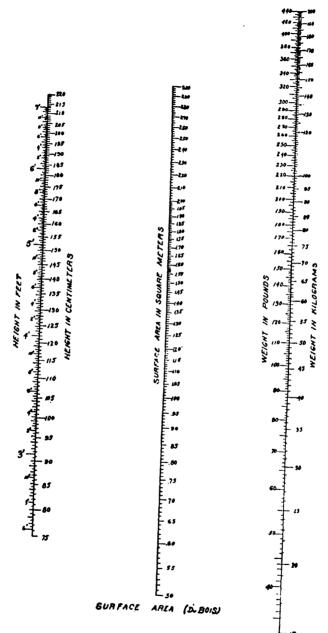

Fig. 202. Surface area nomogram. (Copyright, 1920, by Boothby and Sandiford.) A line connecting the height with the weight intersects the middle line at the corresponding surface area.

in which H = total heat production per 24 hours, W = weight in kilograms, S = stature in centimeters, and A = age in years. The Harris-Benedict standards average about 3 to 4 per cent lower than the Sage standards, and according to Benedict¹⁴ they should be even lower, especially for women. He recommends lowering the standards for women by 5 per cent. Benedict calls attention to the distinction between "hospital normals" and physiological standards, the use of the former being justified for clinical purposes only.

THE DUBOIS NORMAL STANDARDS AS MODIFIED BY BOOTHBY AND SANDIFORD*
(Cal. Der Sq. M. Der Hr.)

Age	Males	Females	Age	Males	Females
5	(53.0)	(51.6)	20-24	41.0	36.9
6 7	52.7 52.0	50.7 49.3	25–29	40.3	36.6
8	51.2	48.1	30-34	39.8	36.2
9	50.4	46.9	3 5–39	39.2	35.8
10	49.5	45.8	40–44	38.3	35.3
11	48.6	44.6	45-49	37.8	35.0
12	47.8	43.4			
13	47.1	42.0	50-54	37.2	34.5
14	46.2	41.0	55–59	36.6	34.1
15	45.3	39.6	60-64	36.0	33.8
16	44.7	38.5	65-69	35.3	33.4
17	43.7	37.4			
18	42.9	37.3	70-74	(34.8)	(32.8)
19	42.1	37.2	75–79	(34.2)	(32.3)

^{*} In using this table, the age should be determined to the nearest year. That is, 4 years 6 months to 5 years 5 months, inclusive, is taken as 5 years; to do this correctly the actual birthday must be known and is important for children. The DuBois height-weight formula for surface area was used.

3. Dreyer¹⁶ devised the following formulas for predicting the normal heat production, from a study of the normal cases reported by Magnus-Levy, by Benedict, and by DuBois:

For females,
$$D = \frac{\sqrt{W}}{0.1127A^{0.1333}}$$

For males, $D = \frac{\sqrt{W}}{0.1015A^{0.1333}}$

D= total Cal. per 24 hours, W= body weight in grams, and A= the age in years. Better results are claimed by Dreyer when the theoretical weight, computed from the sitting height and chest circumference, is used rather than actual weight. Tables simplifying the use of Dreyer's formulas are given by Stoner, ¹⁶ who finds no advantage in theoretical over actual weight. These standards are more successful than those discussed above, for predicting the metabolic rate of individuals of unusual configuration, and are receiving more attention in recent years.

These methods have been critically studied by Means and Woodwell,17 and by

¹⁴ Benedict: Am. J. Physiol., 85, 607 (1928).

¹⁵ Dreyer: Lancet, 2, 289 (1920); Dreyer and Hanson: "The Assessment of Physical Fitness," New York, Hoeber, 1921.

¹⁶ Stoner: Boston Med. Surg. J., 189, 236, 239 (1923); 191, 1026, 1030 (1924),

¹⁷ Means and Woodwell: Arch. Internal Med., 27, 608 (1921).

Boothby and Sandiford, ¹⁸ and by Krogh. The consensus seems to be that the Harris-Benedict predictions are the most reliable for average normal subjects; that the DuBois standards give results in average normal cases about 4 per cent too high; that in all cases, including those of exceptional build and age, the DuBois standards show less deviation than any of the others. ¹⁹

The method of predicting the normal heat production, and the normal standards, for infants and children are the subjects of several papers.²⁰

Calculations. The respiratory quotient (R.Q.) is the ratio of the volume of carbon dioxide produced to the volume of oxygen consumed during the same time interval.

R.Q. =
$$\frac{\text{CO}_2 \text{ produced}}{\text{O}_2 \text{ consumed}}$$
 = $\frac{\text{volume CO}_2 \text{ in expired air } - \text{volume CO}_2 \text{ in inspired air }}{\text{volume O}_2 \text{ in inspired air } - \text{volume O}_2 \text{ in expired air }}$

The measurement of the volume of inspired air is attended with technical difficulties. However, the actual volumes of gas disappear from the working formula as demonstrated below. If we let

 V_{\bullet} and V_{i} = volume of expired and inspired air C_{\bullet} and C_{i} = per cent CO_{2} in expired and inspired air O_{\bullet} and O_{i} = per cent O_{2} in expired and inspired air N_{\bullet} and N_{i} = per cent N_{2} in expired and inspired air

we may rewrite the above equation as follows:

$$R.Q. = \frac{C_{\bullet}V_{\bullet} - C_{i}V_{i}}{O_{i}V_{i} - O_{\bullet}V_{\bullet}}$$
 (1)

Since nitrogen is neither absorbed nor evolved, its volume in inspired and expired air remains unchanged. Therefore its percentage in inspired and expired air is in inverse ratio to their respective volumes. That is

 $N_i: N_o = V_o: V_i$

or

$$V_{i} = \frac{N_{\bullet}V_{\bullet}}{N_{i}}$$

Substituting this value in (1) and simplifying, we get

$$R.Q. = \frac{C_0 N_1 - C_1 N_0}{O_1 N_0 - O_0 N_1}$$
(2)

Substituting the values given for the composition of atmospheric air (p. 662) for O_i , C_i and N_i , we obtain

$$R.Q. = \frac{79.03C_{\bullet} - 0.03N_{\bullet}}{20.94N_{\bullet} - 79.03Q_{\bullet}}$$
 (3)

18 Boothby and Sandiford: J. Biol. Chem., 54, 767 (1922); Physiol. Rev., 4, 69 (1924).

Am. J. Diseases Child., 53, 348 (1937).

While the DuBois formula indicates a definite mathematical relationship to exist between the surface area and the quantity of energy produced, it has been disputed whether this is a true physiological relation. Benedict, the chief opponent of the surface area law, suggests, however, that "From the practical standpoint it is perhaps not a matter of importance whether the rate of metabolism is directly proportional to the surface area, whether it is controlled by the heat loss from the body, whether the heat loss is independent of the heat supply, or whether the heat produced is determined by the active mass of protoplasmic tissue and the stimulus to the cells. But it is important to know whether there is a referable basis which can be used intelligently for comparing various individuals." "Lectures on Nutrition," p. 51, Philadelphia, W. B. Saunders Co., 1925.

Simplifying,

R.Q. =
$$\frac{C_{\bullet} - 0.00038N_{\bullet}}{0.265N_{\bullet} - O_{\bullet}}$$

Since 0.00038No never varies significantly from 0.03, we have finally

$$R.Q. = \frac{C_{\bullet} - 0.03}{0.265N_{\bullet} - O_{\bullet}} \tag{4}$$

From this equation it is possible to calculate R.Q. simply from the CO₂ and O₂ percentages in expired air, since N₂ is obtained by difference.

Basal metabolism or basal metabolic rate (B.M.R.) may be defined as the percentile variation of the observed from the normal or predicted heat production for an individual of given height, weight, age, and sex in a postabsorptive state and in complete mental and physical repose. The heat production for a given period is obtained by multiplying the volume, at normal temperature and pressure, of oxygen consumed during that period by the calorific value for oxygen corresponding to the observed (or assumed) R.Q. Basal heat production may be expressed on an hourly or daily basis. The general formula for basal metabolic rate is therefore

B.M.R. =
$$\frac{273pv}{760t}$$
 \times $\frac{60(\text{or } 1440)}{m}$ \times C \times $\frac{1}{N}$ \times 100 100 (5)

Corrected volume of 01 consumed in m minutes

Factor for convergence to sion to normal per heat production production

basis

Cal. Ratio Convergence in to sion to normal per heat production production

 $\begin{array}{c} \text{Normal } \\ \text{Norma$

In this equation, p is the barometric pressure in mm. of mercury corrected for tension of aqueous vapor; v the observed volume, in liters, of oxygen consumed during the basal test period; m the duration of the basal test period in minutes; t the absolute temperature (° C + 273); C the calorific value per liter of oxygen²¹ corresponding to the observed (or assumed) respiratory quotient (see the table on p. 659). In the oxygen consumption methods the R.Q. is assumed to be 0.82, which corresponds to a calorific value per liter of oxygen of 4.825); and N, the normal or predicted basal heat production obtained from one of the various tables of standards.

In the usual form of oxygen consumption apparatus equipped with volumetric scales and CO_2 absorbents, v in equation (5) is obtained by subtracting the reading at the end from that at the beginning of the test period.

When the gasometric method is employed,

v = volume O₂ in inspired air - volume O₂ in expired air, or

$$v = 0.01O_{i}V_{i} - 0.01O_{o}V_{o}$$
 (6)

By substituting the value for V_i as above, and simplifying,

$$v = 0.01 V_o \left(O_i \frac{N_o}{N_i} - O_o \right)$$

in which V_e is the gasometer reading, R, multiplied by the gasometer factor, f, hence the volume of expired air in liters. By further substitution of the values for O_i and N_i given above, and simplifying,

$$v = 0.01 Rf(0.265 N_{\bullet} - O_{\bullet})$$

in which the variables are R, N_e, and O_e. This expression for v may be incorporated in equation (5).

The Aub and DuBois tables give the normal heat production in Cal. per sq. m. of body surface per hr. (A), which when multiplied by the surface area in sq. m. (S)

²¹ According to Magnus-Levy, the metabolism of protein furnishes on the average 15 per cent of the total calories. This may be taken into account by using figures for the calorific value of 1 liter of oxygen 1 per cent lower than those given in the table on p. 659.

gives the predicted hourly heat production. Making the proper substitutions in the above equation, and collecting constants, we obtain the following simplified formula.²²

B.M.R. =
$$\frac{2155 \text{ pvV}}{\text{tmSA}} - 100$$

In the *Harris and Benedict tables* for normal heat production, the values are expressed on a 24-hour basis. The coefficient in the equation becomes therefore $24 \times 2155 = 51720$, and the equation is

B.M.R. =
$$\frac{51720 \text{ pvC}}{\text{tm H}} - 100$$

in which H represents the predicted 24-hour heat production.

When the *Dreyer standards* are used, D, the predicted 24-hour heat production according to these standards, is substituted for H in the last equation.

In the oxygen consumption methods R.Q. is assumed to be 0.82. Hence 4.825 is substituted for C, in the above equations (see the table on p. 659) and the coefficients become 10,400 and 250,000 respectively. Further simplification is attained in routine practice by standardizing the basal test period and merging the value for m into the coefficient.

The calculations may be performed either on calculating machines or by logarithms, in which case five-place tables are used and the characteristics omitted, since the decimal place may be pointed off in the final result by inspection. A form sheet for logarithmic computation described by Boothby and Sandiford is shown in Fig. 203. The calculations involved in the interpretation of kymographic records of oxygen consumption are described in the legend to Fig. 207.

Animal Calorimetry. The rate of combustion may be determined by directly measuring the heat given off by the body. Every animal has an optimum temperature and this temperature is maintained by a nice balance between the heat produced by the life processes and the heat lost by the organism.²³ Gephart and DuBois estimate that in man, 24 per cent of the total heat loss results from the evaporation of water from the lungs and skin. A small amount of heat is lost in warming the ingested food, the urine, the feces, and at times the body itself; the remainder is lost by conduction and by radiation.

Lavoisier and Laplace measured the heat loss by placing a guinea pig in an ice chamber for ten hours and observing the amount of ice melted. Over a period of many years, the elaboration of this simple form of calorimeter has culminated in the construction of the Atwater-Rosa-Benedict Respiration Calorimeter.²⁴ With this apparatus, the heat of the body is determined indirectly from the respiratory exchange, and directly by a careful computation based on observations of all the known means of heat loss.

The principle of this apparatus was applied by Armsby²⁶ in the elaboration of a calorimeter for use with farm animals. Benedict²⁶ and associates also devised a respiration chamber for use with domestic animals. This apparatus was later modified for use in human calorimetry.²⁷ Respiration calorimeters have provided the means of acquiring most of the present-day knowledge of energy metabolism. They have been extremely valuable in proving the accuracy of indirect calorimetry.

Because of the expense of installation and the technical difficulties of operation of respiration calorimeters, heat production is usually measured indirectly, i.e., from

²² Stoner (Boston Med. Surg. J., 189, 195 (1923); J. Lab. Clin. Med., 12, 884 (1927); 13, 164 (1927)) has described these and other simplifications in the calculations for respiratory exchange, as well as data cards which are very useful in routine practice.

the gaseous exchange. Two types of methods are in use: (1) Open circuit methods, in which atmospheric air is breathed and expired air collected and analyzed; and (2) closed circuit methods, in which oxygen-enriched air is breathed and the consumed oxygen measured. The former procedure provides a more complete picture of respiratory exchange since it permits determination of the respiratory quotient. On

Fig. 203. Form sheet for study of respiratory metabolism.

the other hand, the closed circuit methods are much simpler technically and where only total metabolism must be determined are equally satisfactory. In the closed circuit method an average respiratory quotient of 0.82, corresponding to a calorific value for O₂ of 4.825 Cal. per liter, is assumed.

The various types of respiration apparatus on the market are simplified modifications of Dr. F. G. Benedict's²⁵ clinical respiration chamber illustrated in Fig. 204.

³⁶ Later developments in closed circuit apparatus and comparison with open circuit methods are discussed by Benedict: Boston Med. Surg. J., 193, 807 (1925).

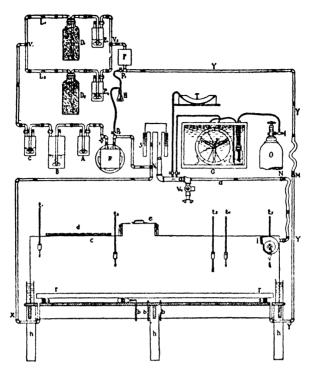

Fig. 204. Diagram of the cot chamber of Dr. F. G. Benedict. The upper part of the illustration shows the universal respiration apparatus with the following parts: R, blower; A, acid trap; B and C, water absorbers; V_1 and V_2 , two-way valves connecting with the carbon-dioxide absorbing system; D_1 and D_2 , carbon-dioxide absorbers: L_1 and L_2 , removable sections of the piping for the introduction of additional carbon-dioxide absorbers; E_1 and E_2 , water absorbers; F, sodium bicarbonate can; P_1 and P_2 and H, petcocks and barium hydroxide container for testing the efficiency of the carbon-dioxide absorbers; Y, Y, tube through which the air freed from carbon dioxide and water returns to the chamber; M and N, points at which the tubing is connected when the apparatus is used with a mouthpiece or nosepieces; S. spirometer; G, gas meter immersed in water; O, oxygen tank; T, manometer; V_3 and V_4 , three-way valves; a, a, a, tube connecting chamber with spirometer and oxygen supply. The lower part of the illustration shows the respiration chamber. X, outcoming air pipe; i, blower; c, window with water-seal d; e, hand-hole; t₃ and t₄, psychrometer thermometers; t_1 , t_2 , t_3 , t_5 , air thermometers; h, h, h, supports for chamber; b, b, b, tubes in bottom of chamber for various connections; r, r, bed; s, s, springs; m, pneumatic bulb.

In Europe certain types of closed circuit apparatus designed to measure CO₂ production as well as O₂ consumption are extensively employed, but these possess no great advantage over the Benedict type of apparatus which measures O₂ consumption alone.

Basal metabolism is usually determined in 10- to 15-minute periods using either one of the Benedici "closed circuit" methods as developed in the Carnegie Nutrition Laboratory, or a modified Tissot or "open circuit" method as used in the Mayo Clinic and in the New York Post Graduate Hospital. Obviously, the determination of urinary nitrogen in such tests is impracticable. It has been the custom in these institutions to apply the calorific values in the Zuntz and Schumburg table (see p. 659) directly to the respiratory exchange as measured, without computing separately the protein metabolized. DuBois points out that this procedure gives results about 1 per cent too high.

The Universal respiration apparatus dispenses with the chamber and requires the

patient to breathe through a mouthpiece at V4 (Fig. 204).

The Benedict Portable²⁹ includes all the principal parts of the Universal apparatus, in compact form. The gas meter is dispensed with. Oxygen is placed in the apparatus before the test is started, and its absorption is measured by a calibrated gasometer. Carbon dioxide is determined by weighing the absorber before and after the test.

The Benedict-Roth respiration apparatus (Figs. 205, 206) is extensively used in clinics for determining the basal metabolic rate of patients. Roth³⁰ has dispensed with the electric blower of the Benedict machines, and has inserted two Sadd valves to insure circulation of the oxygen. The spirometer bell is designed to have a volume of 20.73 cc. for every millimeter of height. This greatly simplifies the calculations. The fall of the spirometer bell during a test of six minutes represents the volume of oxygen absorbed by the patient. As with other Benedict apparatus, the respiratory quotient is assumed to be 0.82; this gives a heat value for 1 liter of oxygen of 4.825 Cal. "With a bell of this size, each mm. of the fall of the bell in a six-minute period represents exactly 1 Cal. per hour. (1 mm. in 6 min. = 20.73 cc. = 0 2073 liter per hour. 0.2073 × 4.825 = 1 Cal. per hour.)"

The form of this apparatus illustrated in Fig. 206 is provided with a kymograph which is self time-marking in minute periods. A pen attached to the counterweight traces the respiratory excursions and shows the lowering of the spirometer bell due to the absorption of oxygen. Fig. 207 illustrates the method of drawing the "oxygen consumption line," and of measuring the "rise" of this line for any six-minute period which may be selected on the tracing. If the moisture content of the circulating air is high, as is the case when Wilson Soda Lime is used as an absorber, a correction must be made for water vapor. Roth³¹ gives the factors for reducing the volume of absorbed oxygen to 0° C., 760 mm., dry (when the vapor tension is 80 per cent of saturation).

Procedure: The patient is tested before breakfast and after a 12- to 15-hour fast. A record is made of the sex, age, height, and weight. A rest in a semi-reclining position for half an hour must precede the test. During the rest period, the pulse rate, the respiration rate and the temperature are observed, and the patient is briefly instructed in order to secure his confidence and cooperation. The apparatus is tested for leaks as follows: a stopper is placed in the opening of the mouthpiece, a 200-g. weight is placed on the bell. The pointer should remain stationary for a minute or more. The weight and stopper are removed and the spirometer is filled with oxygen. The mouthpiece and later the nose clip are applied to the patient, care

³⁹ Benedict: Boston Med. Surg. J., 186, 667 (1918).

¹⁰ Roth: Boston Med. Surg. J., 186, 457, 491 (1922). This and other types of basal metabolism apparatus for clinical use are made by Warren E. Collins, Inc., 553H Huntington Ave., Boston, Mass.; Sanborn Co., 39 Osborn St., Cambridge, Mass.; and Jones Metabolic Equipment Co., 1870 Ogden Ave., Chicago, Ill.

³¹ A table for reducing volumes of 80 per cent saturated air to 0° C. and 760 mm., dry, is given by Roth: Boston Med. Surg. J., 186, 457 (1922).

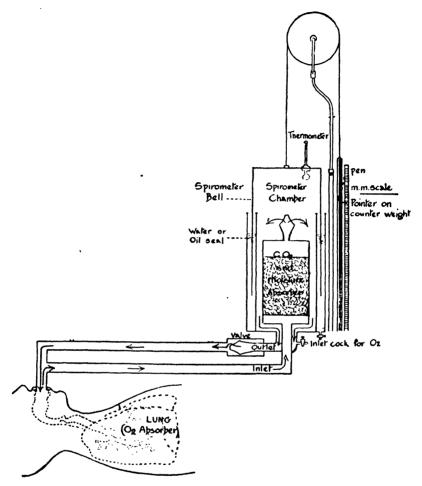

Fig. 205. Diagram of the Benedict-Roth respiration apparatus.* The patient breathes through a mouthpiece. The nose is clamped. Two tubes connect the mouthpiece with the spirometer. An inspiratory Sadd valve directs the oxygen from the spirometer chamber to the patient; an expiratory valve insures its continuous circulation. The expirations pass through soda lime which removes carbon dioxide. The calibrated spirometer bell is balanced by a counterweight which carries a pointer. The pointer shows the movements of the bell on a millimeter scale. A test is started with the chamber full of oxygen; as oxygen is absorbed by the patient the volume in the chamber decreases. The loss of volume represents oxygen absorbed during the period of the test. Correction is made for any change in chamber temperature during the test.

^{*} Slightly modified from Roth: Boston Med. Surg. J., 186, 491 (1922).

being taken to avoid leaks. The kymograph³² is started. The temperature of the spirometer, and the barometric pressure are recorded. The test is continued until a satisfactory uninterrupted section of exactly six minutes can be selected for subsequent measurement. Before stopping the test, a weight of 50 g. is placed on the bell and operation is continued for a few minutes; if a leak occurs it is shown by a sharp rise in the oxygen con-

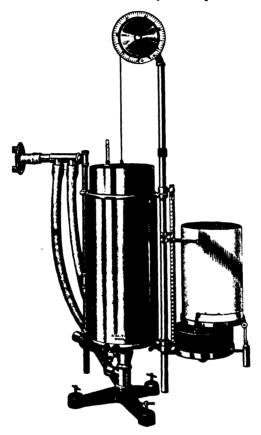

Fig. 206. Benedict-Roth respiration apparatus with kymograph.

sumption line. The temperature of the spirometer is again recorded. Fig. 207 shows a graphic record of a test, and the legend gives the necessary calculations for determining the basal metabolic rate.

Wesson³³ has described an apparatus and procedure for determining the respiratory quotient in small animals. A multiple-chamber respiration apparatus for small animals, based on the oxygen consumption method has been described by Benedict.³⁴

¹⁸ In the case of spirometers not equipped with kymographs, readings on the scale are made at the beginning and end of the periods. Stoner (Boston Med. Surg. J., 189, 193 (1923)) divides a ten-minute period into five two-minute periods, taking the average of ten spirometer readings at the beginning of each period. In this way he is able to select a four-minute period showing the least oxygen consumption, and also to avoid the error due to wide fluctuations in individual respirations.

³³ Wesson: J. Biol. Chem., 73, 499 (1927).

¹⁴ Benedict: J. Nutrition, 3, 161 (1930). This apparatus can be secured from Warren E. Collins, Inc., 553H Huntington Ave., Boston, Mass.

Benedict Student Apparatus¹⁵ (Fig. 208): Principle. The subject breathes through a mouthpiece connected with two Sadd valves attached to a metal can, three-fourths filled with soda-lime. A rubber bathing cap over the top encloses oxygenrich air and permits free breathing. The apparent volume of oxygen absorbed from the enclosed volume of air is measured by introducing dry room air into the can with a good grade of automobile grease plunger pump whose capacity is determined from

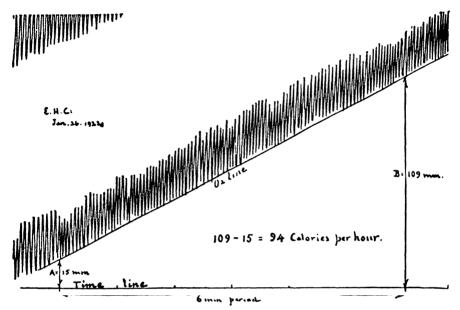

Fig. 207.* Graphic record of a metabolism test. E. II. C., male, aged 38. Height, 176 cm. Weight, 84 kg. Surface area, 2.0 sq. m. Barometric pressure, 745 mm. Average temperature, 24° C. (no increase during test). Rise of O_2 line in 6 minutes, 94 mm. = 94 Cal. per hour. Correction for temperature, pressure, and water vapor $94 \times 0.879 = 82.63$ Cal. per hour. Divide by surface area $82.63 \div 2 = 41.3$ Cal. per square meter of surface per hour, which is 5 per cent above the average normal (39.5) for this individual (Roth).

* A simplified data card for taking records of instruments not equipped with kymographs and for making the calculations, has been described by Stoner: Boston Med. Surg. J., 189, 195 (1923).

its internal dimensions. The time required to introduce six strokes of the plunger is recorded. From the apparent volume, reduced to 0° C. and 760 mm., and the time, the oxygen consumption is rapidly obtained.

A better understanding of this procedure may be obtained from the following example.

A typical experiment was made on a normal subject, a woman, 24 years of age, weighing (nude) 57.2 kg., and with a height of 157 cm. The room temperature was 19.6° C., the temperature of the pump was 18.3° C., and the barometer stood at 755.9 mm. The elapsed time from the beginning of the experiment to the complete consumption of the oxygen represented by the air discharged at each stroke of the pump, was as follows:

³⁵ Benedict and Benedict: Boston Med. Surg. J., 188, 567 (1923). This apparatus is obtainable from Warren E. Collins, Inc., 553H Huntington Ave., Boston, Mass. For details of the procedure consult the original paper or the Ninth Edition of this book.

Six full strokes with a length of stroke used in this particular apparatus corresponded to 2168 ml. apparent volume. From the tables for the reduction of volumes

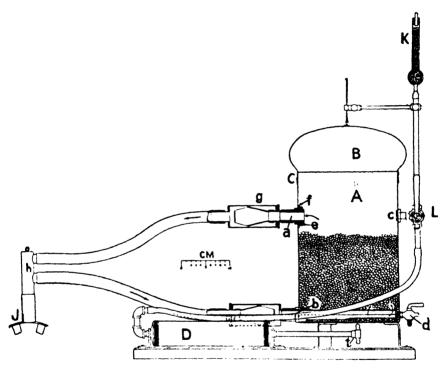

Fig. 208. Benedict's student model respiration apparatus. A, Metal can partly filled with soda lime; B, rubber bathing cap, held in place by rubber band, C. The subject breathes through the mouthpiece, j, which is attached to the metallic piece, h, connecting with two rubber tubes leading to Sadd respiratory valves on the can, A. The expired air enters through the opening, b, and is returned to the subject, freed of carbon dioxide, through the opening, a. The Sadd valves are enclosed in light brass housings, g. The opening, a, is stiffened by a lock nut, e, and a small, flat piece of iron, f, curved to fit the can. Oxygen for preliminary enrichment is admitted through the petcock, d, and measured amounts of dry air, drawn through the calcium-chloride tube, K, into the pump, D, are forced into the can through the valve, L, and the opening, c.

of air to 0° C. and 760 mm. it can be seen that at the temperature of the pump, namely, 18.3° C., and with the barometer at 756 mm., the factor is 0.932. The time for the six strokes is expressed as minutes and decimal parts of a minute, namely,

11.45 minutes. The formula $\frac{K \times m}{T}$ thus equals

$$\frac{2168 \times .932}{11.45}$$
 = 176 ml. O₂ consumed per minute.

Gasometer Method: Principle. In this method the subject breathes atmospheric air, and the expired air is collected and measured in a gasometer. Samples of the

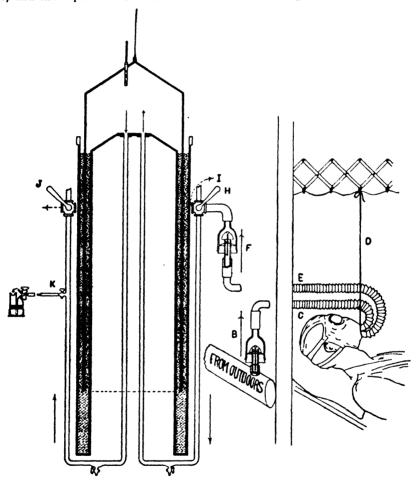

Fig. 209. Diagram of gasometer for collection of expired air.

expired air are then analyzed for carbon dioxide and oxygen, and from these factors the respiratory exchange is calculated. The method lends itself to wider usefulness in researches in the physiology of respiration, but the apparatus is quite expensive and requires considerable experience in its use. Since only small samples of gas are taken for analysis, the accuracy of the method is dependent on the precision of the technician.

Boothby and Sandiford, of the Mayo Clinic, use this type of apparatus and have described their technique in detail. Bailey³⁶ has added many practical improvements.

²⁶ Bailey: J. Lab. Clin. Med., 6, 657 (1921). Full details of his technique, including the methods of gas analysis, may be found in the Ninth Edition of this book.

Fig. 209 illustrates Bailey's arrangement of apparatus for the test. It will be noted that a head mask is used on the patient, who is sit-

uated on a cot in the room adjoining that in which the gasometer is located.

The Douglas Bag Method:³⁷ Principle. This method is similar in principle to the gasometer method, except that the expired air is collected in a wedge-shaped rubber bag of 30 to 100 liters capacity. The expired air is metered and analyzed for carbon dioxide and oxygen. The bag is portable and may be supported on the subject's back and so used for studies of respiratory exchange during work.

Principles of Gas Analysis. The Haldane method is used in determining the amount of carbon dioxide and oxygen in the expired air. A volume of air is drawn into a graduated buret, where it is saturated with water vapor and measured; the air is then passed back and forth into a potash pipet, where the carbon dioxide is removed; it is returned to the buret and again measured, the loss in volume representing the carbon dioxide. The oxygen is removed in a similar manner by passing the air into a second pipet containing alkaline pyrogallate solution, after which the gas is returned to the buret and measured, this loss in volume representing the oxygen in the sample of air.

Bailey⁵⁸ has introduced into the original apparatus several modifications of the original parts, the principal one being the adoption of Henderson's buret³⁹ with a four-way stopcock and oxygen absorber. These greatly simplify the assembling and cleansing of the parts and permit one to change the pyrogallate without disconnecting the apparatus (Fig. 210).

Considerable experience is required before accurate results can be obtained in gas analysis. Determinations should always be made in duplicate and the accuracy of the operator controlled by analyses of outdoor air at frequent intervals. The results for carbon dioxide should be within 0.02 per cent and for oxygen within 0.03 per cent of the standard values. (See p. 662.)

Hormones

The endocrine organs, or glands of internal secretion (see Fig. 211), are tissues whose function it is to secrete certain specific chemical substances known as *hormones* into the blood stream, which distributes them to all parts of the body. Certain tissues respond to their presence in a charac-

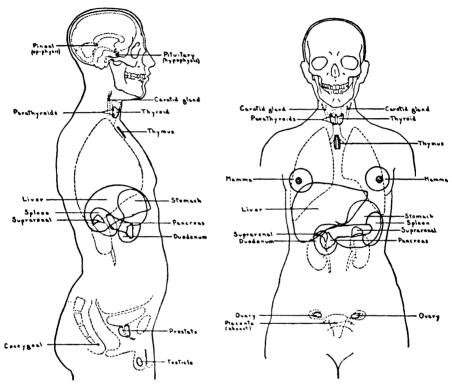

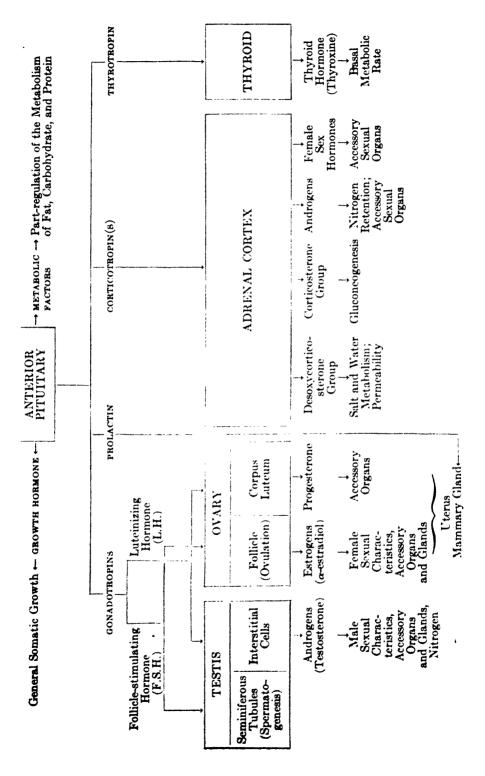

Fig. 211. Schematic chart of endocrine system. (From Barker, ct al.: "Endocrinology and Metabolism," New York, Appleton, 1924.)

teristic way, either increasing, decreasing, or modifying their processes of growth or of metabolic or physiological activity. The hormones are therefore chemical messengers serving to integrate the various activities of the body; they may themselves undergo metabolic transformations, such as partial or complete oxidation, or reduction; and recognizable products of these transformations, or the hormones themselves, may be excreted in the urine and in the bile.

The secretory activity of the endocrine organs varies from time to time. As the accompanying chart shows, the morphological structure and the endocrine activity of the gonads, adrenal cortex, and thyroid are largely controlled by hormones produced by the anterior lobe of the pituitary

(anterior hypophysis) which also produces hormones acting directly on the structure and function of nonendocrine tissues. The anterior pituitary in turn is partly controlled (directly or indirectly) by the concentration of hormones produced by the gonads, thyroid, etc., and also by the nervous system directly. Similarly, the posterior pituitary and the adrenal medulla are subject to direct nervous regulation. The control of the endocrine activity of the pancreas, parathyroids, and other possible sources of hormones is not fully understood. It will be noted in the chart that a single organ, or a single metabolic process, may be affected by more than one hormone, and often also by factors not endocrine in nature.

The hormones do not vary significantly in chemical structure from species to species, hence extracts from the endocrine organs of animals may often be used in treating disorders due to insufficient activity of a human gland; synthetic or artificial products, allied to or identical with the natural hormones, may be less costly. Disorders due to excessive activity—for example, when a tumor develops from endocrine cells—are often treated by surgical removal of the abnormal tissue; or, more rarely, by selective inhibitory drugs or by irradiation with x-rays. Chemically, the known hormones may be divided into two main groups. The first may be referred to as nitrogenous, and range in size and complexity from simple bases such as adrenaline to proteins of high molecular weight and undetermined structure. The second group, more homogeneous, may be called the steroid hormones.

THE STEROID HORMONES OF THE GONADS AND ADRENAL CORTEX

General Chemistry of the Steroids and Steroid Hormones. The basic saturated carbon ring skeleton of the steroids is illustrated in formula I

Depending on the chemical nature of the substituent (R) at C₁₇, the steroids may be divided into five classes: a. The sterols, like cholesterol and ergosterol (see Chapters 11 and 35), where R consists of an eight or nine carbon atom aliphatic side chain.

b. The bile acids (p. 371), where R consists of a five carbon side chain

terminating in a carboxylic acid group.

c. The cardiac aglycones, breakdown products of the heart-stimulating glycosides of strophanthus, digitalis, etc., which are characterized by a lactone ring substituted at C₁₇.

d. The sapogenins, derived from plant saponins, where R is comprised

of an ethereal ring system.

e. The steroid hormones, where C₁₇ bears a ketonic or hydroxyl group (the androgens and estrogens), or carries a substituted two carbon side chain (progesterone and the adrenal cortical steroids).

The steroid hormones all carry hydroxylic or ketonic oxygen on C₃. The summary on pp. 687-690 formulates the principal steroid hormones. and illustrates, by means of arrows, the metabolic pathways followed in the body in the course of their inactivation and excretion. The ovarian follicular hormones, the estrogens, all possess an aromatic or benzenoid ring A, while the hormones of the testis, corpus luteum, and adrenal cortex are all characterized by the presence in ring A of an α - β unsaturated ketonic grouping, the saturation of which leads to practically complete loss of physiological activity. In the course of this reduction, which is a common mechanism of inactivation in vivo, carbon atoms numbers 3 and 5 become asymmetric and hence four fully reduced geometrical isomers are possible in each instance. The hydroxyl group resulting on hydrogenation of the ketone may be oriented either cis or trans with respect to the angular methyl group at C₁₀. Respectively, the cis and trans epimers are designated by the suffixes β and α , and conventionally are differentiated in twodimensional formulas by the use of a solid and a dotted line. [Compare androsterone (III) and isoandrosterone (IV).] 3(β)-Hydroxy-steroids form with digitonin (a saponin from Digitalis) sparingly soluble addition compounds, whereas the epimeric $3(\alpha)$ -compounds do not. Likewise the hydrogen atom introduced at C₅ on saturation of a 4:5 or 5:6 double bond may be cis or trans oriented in relation to the angular methyl group at C₁₀; again, in planar formulation, the solid and dotted lines respectively are used [compare androsterone (III) and etiocholanolone (V)]. Because of this isomerism about C₅, there are two saturated parent hydrocarbons of the steroid hormones containing 19 carbon atoms, namely androstane (trans) and etiocholane (cis), and two pertaining to the hormones with 21 carbon atoms, namely pregnane (cis) and allopregnane (trans).

With the exception of equilenin, no naturally occurring steroid has been synthesized (equilenin (XI), one of the estrogens excreted exclusively by the mare, is unique in that both rings Λ and B are aromatic). Reactions leading to the conversion of one class of steroid into another are, however, well established, as in the preparation of many of the steroid hormones from the sterois and bile acids. While such products are commonly described as "synthetic hormones," they are in reality derived from starting materials of natural origin.

In general, all steroid hormones are insoluble in water but soluble in fat solvents, such as ether, acctone, alcohol, etc., and in vegetable oils, in which medium they are usually dissolved for administration to the body. They are relatively inactive per os, and consequently are given intramuscularly or subcutaneously. Esters of the hormones, such as the acetate, propionate, and benzoate, are much more valuable therapeutically than the free steroids, as their physiological action is more protracted owing to the delayed rate of absorption and utilization. The steroid hormones and their catabolites are eliminated in the urine in water-soluble form in conjugation with glucuronic or sulfuric acid.

Formulation of Steroid Hormones and Related Substances. The chemical name is given in each instance, followed by the commonly used name in parentheses. The arrows indicate metabolic pathways followed in the body.

Removal of the testes causes atrophy of the seminal vesicles, prostate, and other accessory organs of the male genital system. The effects are most pronounced if the operation is performed before sexual maturity, and are due to withdrawal of androgenic hormones, such as testosterone (II), secreted by the Leydig or interstitial cells. The androgenic hormones will restore the atrophied tissues in castrated animals, such as rats or mice, and are frequently assayed by their power to cause enlargement of the comb in the capon.

Testosterone (II) is the principal male sex hormone isolated from testis tissue. In the course of its metabolism in man it is reduced to androsterone (III), isoandrosterone (IV) and etiocholanolone (V), all of which are excreted in the urine (see 17-ketosteroids, p. 694). Testosterone and many other allied androgenic substances are prepared artificially from cholesterol. Methyltestosterone (VII), one of these which is not known to occur in nature, finds wide therapeutic application because it is highly active per os.

The International Standard male hormone unit is the activity equivalent of 0.1 mg. of pure androsterone. By comparison of comb growth in the capon, testosterone is about six times, and isoandrosterone one-seventh, as potent as androsterone, while etiocholanolone is practically inert. Administered parenterally, methyltestosterone and testosterone show equal activity; orally methyltestosterone is two to four times less active than parenterally, but about 20 times more potent than testosterone given by mouth.

THE OVARIES

The development of the accessory sex organs in the female is not so dependent on hormonal stimuli as in the male; nevertheless, extirpation

of the ovaries causes atrophic change in the uterus, vagina, mammary glands, etc., and in the plumage of poultry. In most mammals, mating occurs only during periods of heat or estrus, when the body is flooded with estrogenic hormones produced by the ovary and in particular by the Graafian follicles. In rodents estrus is accompanied by the appearance of cornified cells in the lumen of the vagina, from the walls of which they have desquamated. This reaction follows the administration of estrogenic substances to castrated animals, and is the basis of biological assay.

After ovulation in mammals, the ruptured Graafian follicle is transformed into the corpus luteum, which produces the hormone progesterone (XIII), whose chief function is to prepare the mucous membrane of the uterus for the implantation of the embryo. Progesterone is assayed by its power to cause a glandular "progestational" proliferation of this membrane in immature or castrate rabbits previously sensitized with estrogens. Gestation, in its early stages, is interrupted by destruction of the corpora lutea; when implantation and pregnancy occur, the active life of the corpora lutea is prolonged. In the later stages of human pregnancy, estrogens and progesterone are produced by the placenta; they act together in promoting mammary development.

The principal estrogens are α -estradiol (VIII), estrone (IX), and estriol (X); their relative activities are roughly 10:1:1 or less, but wide fluctuation in these proportions is observed by the different methods of testing. Only the first two are known to occur in liquor folliculi, where α-estradiol accounts for 90 per cent of the physiological activity, and hence is regarded as the chief ovarian follicular hormone. α -Estradiol and estrone are interconvertible in the animal organism, as the administration of either leads to the excretion of the other. Estriol has been isolated only from human pregnancy urine and from human placenta, and that organ is regarded as the main site of production. In gestation (Fig. 212), the estrogen output rises sharply with the growth of the placenta to a prepartum level of 12 to 40 mg. per dicm; estriol constitutes the chief catabolite (about 90 per cent of the total), but estrone is excreted in appreciable amount (ca. 10 per cent) together with traces of α -estradiol. The coniugate of estriol in human pregnancy urine has been isolated as the 16- or 17-monoglucuronide. Throughout the normal menstrual cycle, the urine estrogen content is low, of the order of 0.08 mg. per diem at the maximum. Biological assay reveals pre- and postovulatory peaks with the minimum output during the period of flow. While the chemical nature of the estrogens excreted in the nonpregnant state has not been established by isolation, partition experiments indicate that all three are eliminated.

None of the above-mentioned natural hormones has been prepared synthetically. Commercially equine and human pregnancy urine serve as sources of estrone and estriol respectively, and reduction of the former leads to α -estradiol. Throughout gestation in the mare estrone represents the most abundant excretory product. Estriol is not formed in this species, but considerable amounts of estrogens unsaturated in ring B as well as in ring A are eliminated; of the latter, equilenin (XI) is the most abundant, and its total synthesis has been accomplished.

Many synthetic derivatives of stilbene possess marked estrogenic potency, although they are nonsteroidal and do not occur in nature. Important among these is diethyl stilbestrol (XII) which, like other members of the group, is much more active orally than the free natural estrogens. The water-soluble conjugated estrogens of human and equine pregnancy urine (principally estriol glucuronide and estrone sulfate respectively) are also effective by mouth.

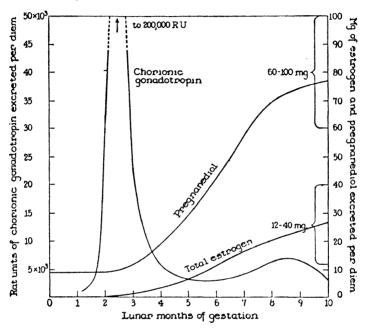

Fig. 212. Variation in urinary output of sex hormones and metabolites with period of gestation.

The International Unit is defined as the activity contained in 0.1 microgram of estrone. As the different estrogens cannot properly be compared because of variations in the time and period of action, a subsidiary standard exists for α -estradiol-3-monobenzoate which is the activity equivalent of 0.1 microgram of that substance.

Progesterone is produced by the corpus luteum of the ovary during the postovulatory phase of the menstrual cycle, and in much larger amounts throughout gestation by both the corpus luteum and the placenta. Traces are elaborated by the adrenal cortex in both sexes. The chief metabolite of progesterone (XIII) is the inactive pregnanediol (XIV), which is excreted in the urine in conjugation with glucuronic acid. Estimation of the sodium pregnanediol glucuronidate content of urine thus provides a useful index of luteal function. From 40 to 55 mg. of pregnanediol are eliminated during the normal menstrual cycle, the excretion beginning probably one to two days after ovulation and ceasing one to three days before the onset of uterine bleeding. A significant decrease in total output, or shortening of the period of excretion, indicates that progestation is not

sufficiently well developed or is of too brief duration to support implantation. From fertilization to the end of the ovarian phase of pregnancy (ca. three to four lunar months), urine pregnanediol remains at the maximum level associated with the luteal phase of the cycle (ca. 5 to 10 mg. per diem), and then rapidly rises with the growth of the placenta to a daily output at parturition of about 60 to 100 mg. (Fig. 212). A significant fall during the first third of gestation indicates corpus luteum deficiency or failure of the placenta to develop at the normal rate, either of which threatens abortion. A residual pregnanediol titer of the order of 0.2 mg. per diem remains in the urine of men and of women in the follicular phase of the cycle; presumably this is of adrenal cortical origin. Commercially progesterone is prepared from cholesterol or from pregnanediol. The International Unit is defined as the activity contained in 1 mg. of the pure crystalline substance.

THE ADRENAL CORTEX

The adrenal glands consist of two distinct tissues in close apposition: the adrenaline-producing medulla, derived from the sympathetic nervous system (see p. 701), and the much larger surrounding cortex, embryologically related to the gonads. Extirpation of the cortical tissue is fatal. Before death, the body loses sodium salts in the urine, and accumulates potassium; so that treatment with diets low in potassium and enriched with sodium salts is helpful. The blood becomes concentrated, the circulation sluggish, and renal function impaired. Carbohydrate stores are depleted, and blood sugar falls to low levels. Resistance to extremes of heat and cold, to infections and toxic drugs, to trauma and fatigue, is greatly diminished. Addison's disease, in which the cortex is destroyed. is characterized by asthenia, emaciation, low blood pressure, loss of sodium, pigmentation of the skin, and often hypoglycemia. Cortical extracts are assayed by their power to maintain adrenal ectomized dogs in life, or to increase the resistance of adrenalectomized rats to cold, or to restore liver glycogen levels, or to restore resistance to muscular fatigue. and by other methods; no existing method is perfectly satisfactory. In intact animals, such extracts tend to lower plasma potassium concentration, to increase the formation of carbohydrate from tissue proteins, and to decrease lymphocytes and lymphoid tissue. Clinically, cortical hyperactivity is associated with the Cushing syndrome (obesity, hypertension, osteoporosis, and diabetic tendencies) or with virilism or precocious masculinization.

About 30 steroids have been isolated from the adrenal cortex in the chemically pure state. Remaining after the separation of these compounds is the so-called "amorphous fraction," which is relatively much more water-soluble, and which retains a very high proportion of the activity of the original tissue. There is evidence that at least some of the isolated compounds are artefacts resulting from the chemical manipulation requisite to their crystallization, and that some may represent components of a labile complex.

Among the substances isolated are estrone (IX), progesterone (XIII),

several compounds void of adrenal cortical activity but possessing marked androgenic potency (particularly androstenedione, adrenosterone, and 17-hydroxyprogesterone), and at least six steroids which are relatively highly active with respect to replacement in part of cortical function. Physiologically and chemically the latter may be divided into two groups: (a) 17-hydroxy-desoxycorticosterone (XV) and desoxycorticosterone (XVI), and (b) corticosterone (XVII), 17-hydroxy-11-dehydrocorticosterone (XVIII) (Kendall's Compound E), 11-dehydrocorticosterone and 17-hydroxycorticosterone. Group (a) are salt-and-water active but without marked effect on carbohydrate metabolism, whereas group (b) promote gluconeogenesis but are only slightly active with respect to mineral metabolism. The former (the "desoxy" group) are characterized by the absence of oxygen substituted in the 11 position, while in the latter (the "O₁₁ series") C₁₁ bears an alcoholic or ketonic oxygen atom. In all, the side chain carries a ketone adjacent to a primary alcohol (the α -ketol grouping, as in fructose) and consequently the compounds reduce alkaline silver solutions. The amorphous fraction is highly potent as regards life maintenance and electrolyte balance, but without appreciable effect on glycogen deposition.

Little is known concerning the metabolism of the individual adrenal cortical steroids. Pregnanediol is excreted following the administration of desoxycorticosterone. Approximately two-thirds of the 17-ketosteroids of normal urine (see below) are of cortical origin, however, and it is presumed therefore that they represent transformation products of some of the cortical steroids. There are also excreted in normal urine metabolites of uncertain chemical nature which possess activity with respect to both mineral and carbohydrate metabolism ("urinary cortin"). The output is determined by biological assay and increases under conditions of stress.

With the exception of desoxycorticosterone (XVI), which is readily obtainable from cholesterol, the active cortical steroids are scarcely available in pure state, although dehydrocorticosterone has recently been prepared from desoxycholic acid (p. 372) in extremely minute yield. Commercial adrenal cortical extracts contain a mixture of many factors, standardized in terms of various biological units and of the equivalent weight of tissue.

17-KETOSTEROIDS

Human urines contain steroids carrying ketonic oxygen at C₁₇, some of which are phenolic while others are neutral. The latter are commonly called "17-ketosteroids." The principal members of this group are androsterone (III), etiocholanolone (V), isoandrosterone (IV), and dehydroisoandrosterone (VI); the first two of these arise in part from the testis, while all represent the excretion products of some of the steroids of the adrenal cortex. Accordingly, measurement of 17-ketosteroid output provides a biochemical index of testicular and adrenocortical activity.

The normal 17-ketosteroid excretion of men between the ages of 20 to 40 years averages about 15 mg. per diem; normal women in the same age group excrete approximately 10 mg. per diem. In children under 8 years of age, less than 1 mg. per diem is eliminated, but from this age on there is a gradual increase to adult values. Likewise in old age a significant

diminution is observed. As gonadectomy in the male decreases the average output from 15 to 10 mg., and is without effect in the female, it is concluded that approximately 10 mg. are derived from the adrenal cortex and 5 mg. from the testis. The human ovary is not a source of neutral 17-ketosteroid.

Disorders of the testis, adrenal cortex, and anterior pituitary may profoundly alter 17-ketosteroid excretion. In eunuchoidism values from normal to that of the surgical castrate (10 mg.) are reported, whereas in the rare cases of masculinizing tumors of the interstitial cells of the testis the output may reach 800 mg. per diem. In Addison's disease in the male, excretion falls to 1.2 to 6.4 mg., which represents the testicular output, while in the female practically no 17-ketosteroids are produced. In those cases of Cushing's syndrome not associated with carcinoma of the adrenal cortex, normal or only slightly elevated 17-ketosteroid values are observed (10 to 36 mg.), but when carcinoma of the cortex complicates the condition a much higher excretion is usually encountered (40 to 288 mg.). Similarly, in the adrenogenital syndrome, simple hyperplasia of the cortex leads to only a moderately high 17-ketosteroid output (up to 100 mg. approximately), whereas carcinoma generally gives rise to a more marked increase (ca. 100 to 250 mg.). In both instances, carcinoma may be distinguishable from hyperplasia by the higher excretion, and also by the increased proportion of the 3(\beta)-hydroxy-17-ketosteroids (chiefly dehydroisoandrosterone) to the $3(\alpha)$. Normally, and in hyperplasia, the β : α ratio is 1:9, whereas in carcinoma it may rise to about 1:1. In panhypopituitarism, a general underproduction of all anterior lobe hormones, the 17-ketosteroid excretion is low (0 to 3 mg.).

EXPERIMENTS ON STEROID HORMONES

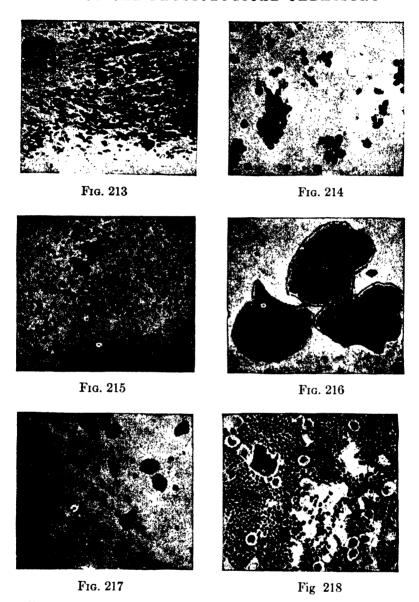

1. Partition and Estimation of the Estrogens of Urine: Principle. The determination comprises (a) hydrolysis of the water-soluble conjugates in urine, (b) extraction of the steroid moieties and their separation by partition between solvents, and (c) estimation of the estrogen content of the various fractions either colorimetrically (see Exp. 3) or by biological assay (see Exp. 4). Colorimetric methods are unsatisfactory when the estrogen output is less than 1.5 mg. per liter approximately, as in normal urine and throughout the first four months of gestation.

Procedure: Method of Bachman and Pettit: 100 ml. of human pregnancy urine are acidified to pH 2 (thymol blue) with HCl. 5 ml. concentrated HCl are added, and the mixture is boiled under reflux for one hour. The hydrolyzed urine is cooled and diluted with 100 ml. of distilled water, and extracted once with 200 and twice with 100 ml. of peroxide-free ether. The combined ether extracts are washed with 8 ml. of 9 per cent NaHCO: (anhydrous), which is discarded, and are evaporated to dryness. The residue is dissolved in the minimum volume of ethanol (not over 0.5 ml.), and diluted with 35 ml. of benzene.

Estriol and extraneous phenols and acids are now removed from the

(Continued on p. 697.)

benzene solution by extraction once with 35 and twice with 17.5 ml. of 9 per cent Na₂CO₃ (anhydrous) and once with 3.5 ml. of water; these extracts are combined and acidified to a pH less than 6 with HCl. The estriol fraction is collected with ether (three extractions with 40 ml.), which is washed with 12 ml. of 9 per cent NaHCO₃ and taken to dryness. The residue is again taken into benzene (50 ml.) with the aid of ethanol (0.5 ml.) and further purified by washing with 9 per cent NaHCO₂ (1 ml.) and by transference to water (extraction three times with 50-ml. portions). Evaporation of the combined water extracts to dryness *in vacuo* yields Fraction T, which is more than 50 per cent estriol by weight.

The first benzene solution (35 ml.) contains the estrone and α -estradiol which, after washing of the benzene solution once with 10 ml. of 45 per cent H_2SO_4 (by volume) and twice with 20 ml. of water, are removed by extraction with N NaOH (four times with 35-ml. portions). The combined alkaline extracts are acidified with HCl and extracted once with 225 and twice with 125 ml. of benzene. The combined benzene extracts are concentrated to about 50 ml., washed successively with 12 ml. of 45 per cent H_2SO_4 , twice with 25 ml. of 9 per cent Na_2CO_3 , and twice with 25 ml. of water, and evaporated to dryness (Fraction OD).

Both Fractions T and OD are purified sufficiently that they may be assayed colorimetrically (see Exp. 3). When a separate estimate of the α -estradiol and estrone content is required, Fraction OD is divided into ketonic (estrone) and nonketonic (α -estradiol) fractions by treatment with Girard's reagent³ prior to assay.

- 2. Isolation of Crystalline Estriol from Human Pregnancy Urine: Fraction T (Exp. 1) from late pregnancy urine readily yields reasonably pure estriol on crystallization from benzene. For this purpose 500 ml. or more of urine may be taken, all quantities of reagents and solvents being increased proportionately.
- 3. Kober's Color Reaction for Estrogens: The sample to be tested is evaporated to dryness in a test tube, to which is added 2 ml. of an equimolecular mixture of sulfuric and (o and p) phenylsulfonic acids. The test tube is heated for 10 minutes at 100° and at once cooled in ice. A red color gradually develops.
- 4. Biological Test for Estrogens:5 Young adult female rats or mice are ovariectomized. If the operation is complete, within a week the vaginal smear will contain only leukocytes. The smear may be obtained by washing out
- ¹ (CH₃)₁ NCl·CH₂·CO·NH·NH₂. Girard and Sandulesco: *Helv. chim. acta*, 19, 1095 (1936). For application of the method to the estrogens, see Talbot, Wolfe, MacLachlan, Karush, and Butler: *J. Biol. Chem.*, 134, 319 (1940).
- ⁴ Kober: Biochem. Z., 23), 209 (1931). The quantitative adaptation of this test is described by Cohen and Marrian: Biochem. J., 23, 1603 (1934), with modifications and improvements by Cartland, Meyer, Miller, and Rutz: J. Biol. Chem., 10), 213 (1935); Venning, Evelyn, Harkness, and Browne. J. Biol. Chem., 120, 225 (1937), and Bachman: J. Biol. Chem., 131, 455, 463 (1939). See also Pincus, Wheeler, Young, and Zahl: J. Biol. Chem., 116, 253 (1936).
 - Marrian and Parkes: J. Physiol., 67, 389 (1929).
- Fig. 215. Estrous smear: non-nucleated cornified epithelial scales (\times 40). This type usually appears within 48 hours after the first injection and is a certain criterion of the positive action of an extract.
- Fig. 216. Flat, cornified elements of the estrous smear stage (\times 250). Eosin stains these cells a brilliant red. Although the site of the former nucleus is apparent, all basophilic staining reaction has been lost.
- Fig. 217. Early stage of leukocytic infiltration (metestrum) (\times 40). Few nucleated epithelial cells have appeared as yet.
- Fig. 218. Late stage of the metestrum (\times 40). Enormous numbers of leukocytes, some cornified scales (in center of field), and many nucleated epithelial cells.

the vagina with a drop of saline solution, using a small home-made pipet with a rubber bulb, or by introducing a small pledget of moist cotton-wool on a loop of platinum wire, and in either case spreading the fluid on a clean microscope slide. It is not necessary to fix or stain the cells. Inject the animals with three 0.5 ml. doses of a solution of estrin in oil, or in 10 per cent alcohol made slightly alkaline, preferably allowing at least six hours to elapse between injections. Examine the vaginal smear on the second, third, and fourth days. The leukocytes will almost disappear, and the smear should come to consist of horny, scale-like squamous cells, and some epithelial cells still retaining their nuclei. The test can be made quantitative only if large numbers of animals are used, and their sensitivity to crystalline estrogens must be established. The response is affected by the strain of the animals, by the degree of subdivision of the dose and the solvent used, by the number of examinations made, and many other factors.

5. Determination of Sodium Pregnanediol Glucuronidate in Urine: Method of Venning: Urine is collected with four to five drops of tricresol as preservative and kept chilled until extraction to prevent hydrolysis. In the nonpregnant state a 48-hour specimen is required, in early pregnancy, a 24-hour specimen, and in late pregnancy, part thereof.

The urine is extracted three times with normal butanol (200, 100, 50 ml. per liter of urine). Gentle shaking (20 to 25 times) prevents formation of excessive emulsion. The combined butanol extracts are shaken vigorously. allowed to stand for one hour, when the urine which collects at the bottom is run off and the butanol is evaporated in a distilling flask almost to dryness under reduced pressure. The residue is taken up in 60 ml. of 0.1 N NaOH, again extracted three times with butanol (60, 20, and 10 ml.), and the combined butanol extracts are washed twice with 5 ml. of water and evaporated to dryness under reduced pressure. The residue is dissolved in exactly 5 ml, of water and transferred to a 125-ml, flask with several small portions of acetone. Volume is made to 100 ml. with acetone, and, after standing overnight in the refrigerator, pregnanediol glucuronidate precipitates. Most of the supernatant acetone is removed with suction without disturbing the precipitate. The remaining mixture is transferred to a 50-ml, centrifuge tube and centrifuged for 10 minutes. The residual acetone is carefully decanted, and the crude ester is dissolved in water for purification by reprecipitation. The amount of water used is dependent upon the weight; 2 ml. for quantities less than 5 mg.; 3 ml. for 5 to 10 mg.; and 5 ml. for more than 10 mg. The water is added to the original flask to dissolve adhering material and then transferred to the 50-ml, centrifuge tube containing the precipitate. The tube is warmed and the contents are filtered back with suction into the original flask. The tube is rinsed twice with small amounts of acetone which are filtered into the flask, and the volume is made to 100 ml. with acetone. After 12 hours in the refrigerator, the acetone is removed as before by suction and centrifugation. The precipitate is dissolved in 10 ml. of hot 95 per cent ethanol and filtered with suction into a tared beaker (30 ml.). The flask, centrifuge tube, and filter paper are washed twice with hot ethanol. After evaporation of the solution to dryness on the bath, the weight of the precipitate is determined.

Calculation. The percentage recovery of the ester depends upon the amount present and the volume of water used in the second precipitation; accordingly a correction factor is applied (see the table on page 699). Sodium pregnanediol glucuronidate contains 61.7 per cent pregnanediol.

⁴ Venning: J. Biol. Chem., 117, 473 (1937) and 126, 595 (1938).

Mg. pregnanediol excreted per diem

$$= \frac{\text{Wt. of ppt.} \times 0.617 \times 24 \text{ hr. volume} \times 100}{\text{Per cent recovery} \times \text{volume extracted}}$$

The melting point of the final precipitate should always be confirmed; sodium pregnanediol glucuronidate melts at 273° C. with evolution of gas.

- 6. Preparation of Adrenal Cortex Extract: Method of Cartland and Kuizenga:⁷ Minced whole beef adrenals are thoroughly extracted with 99 per cent acetone (2.5 liters per kg.) and again with 80 per cent acetone. The extracts are combined, filtered, and concentrated under reduced pressure (below 45°) till the acetone is removed. The aqueous residue is twice extracted with petroleum ether, which removes inert fats and is discarded, and then twice extracted with ethylene dichloride (400 ml. per kg. gland each time), which extracts the hormone but not adrenaline nor phospholipids. The ethylene dichloride soluble fraction is chilled to -15° and ice and precipitated solids are filtered off. The ethylene dichloride is removed under reduced pressure and the residue dissolved in ethyl alcohol. This is mixed with an equal volume of petroleum ether; water is then added to make the alcohol 90 per cent: this causes some of the petroleum ether to separate as an upper layer, which is removed in a separatory funnel and discarded: two further discarded petroleum ether fractions are obtained by diluting the alcohol further to 80 and finally 70 per cent. The alcohol is now removed under reduced pressure, below 45°, and the resulting aqueous colloidal solution suitably diluted to give a final preparation of volume 1 ml. per 49 g. gland, with NaCl added to make 0.9 per cent, and containing 10 per cent ethyl alcohol as preservative. This final solution is filtered and sterilized by Berkefeld filtration, and preserved in sterile ampoules in the refrigerator. (For details of this method, see the original paper.)
- 7. Determination of the Neutral 17-Ketosteroids of Urine: Principle. The steroids of urine are first set free from their water-soluble conjugates by acid hydrolysis and extracted with ether. After removal of phenolic and acidic impurities, the 17-ketosteroid content of the neutral residue is ascertained by quantitative application of the Zimmermann

⁷ Cartland and Kuizenga: J. Biol. Chem., 116, 57 (1936). See also Kuizenga, Wick. Ingle, Nelson, and Cartland: J. Biol. Chem., 147, 561 (1943).

reaction.⁸ This comprises coupling of the reactive 17-ketone group of the compounds with m-dinitrobenzene to form colored complexes, the intensity of which in the green region of the spectrum (520 m μ) is measured in the photoelectric colorimeter and compared with the color developed by known amounts of a pure crystalline 17-ketosteroid.

Nonspecific chromogens of urine cause some interference, but as these substances are mainly nonketonic and absorb light in the violet (420 m μ) as well as the green (520 m μ) region of the spectrum, their influence may be eliminated either by carrying out the color determination on the neutral ketonic fraction of urine, or by the application of a correction factor, which, in effect, subtracts the color component due to extraneous chromogens.

Procedure: A 24-hour specimen of urine is collected and measured. To a 100-ml. aliquot, 15 ml. of concentrated HCl are added. The mixture is refluxed for exactly 15 minutes, and then immediately chilled and extracted four times with 30-ml, portions of freshly redistilled ether. The combined ethers are washed four times with 2N NaOH (15-ml. portions) and then twice with water. On evaporation of the ether, the neutral residue is dissolved in 10 ml. ketone-free ethanol. In the development and measurement of the color, matched colorimeter tubes must be used. To the experimental tube are added, in order and with mixing after the addition of each, 0.2 ml. of the urine extract, 0.2 ml. of 2 per cent pure m-dinitrobenzene (prepared fresh) in ethanol and 0.2 ml. of 5N aqueous KOH (purest electrolytic grade). A control tube is made up in the same way containing 0.2 ml. of ethanol in place of the urine extract. Both tubes are incubated in the dark at 25 \pm 0.5° C. for exactly 105 minutes. 15 ml. of 80 per cent ethanol are now added to each, and, after mixing, the color intensity in each is measured in a suitable photoelectric colorimeter. To correct for the slight color developed by the reagents alone, the control tube is first inserted in the instrument with the 520 my filter in position, and the instrument adjusted to 0 density (100 per cent transmittance). The control is now replaced by the experimental tube, the reading noted and referred to the calibration curve pertaining to pure androsterone to give the equivalent number of mg. of this substance in the sample.

Calculation:

Mg. of 17-ketosteroids excreted per diem

$$= \frac{\text{Mg. observed} \times 24\text{-hr. volume of urine}}{2}$$

For the application of factors correcting for interfering chromogens, readings are taken at 420 m μ also. Consult Talbot, Berman, and Mac-Lachlan¹⁰ and Engstrom and Mason.¹¹ Alternately the determination may be carried out on the ketonic fraction separated from the total neutrals with Girard's reagent (for details, see Talbot, Butler, and MacLachlan¹²).

^{*} Zimmermann: Z. physiol. Chem., 233, 257 (1935).

Method used in the McGill University Clinic. See Callow, Callow, and Emmens: Biochem. J., 32, 1312 (1938); Holtorff and Koch: J. Biol. Chem., 135, 377 (1940); Talbot, Butler, MacLachlan, and Jones: J. Biol. Chem., 136, 365 (1940).

When differential estimates of the $3(\alpha)$ - and $3(\beta)$ -hydroxy-17-ketosteroids are desired, their separation is effected with digitonin prior to assay (for details, see Frame¹³).

NITROGEN-CONTAINING HORMONES

ADRENAL MEDULLA

This organ contains the active nitrogenous base adrenaline or epinephrine, which may also be prepared synthetically. Natural adrenaline is levorotatory, and is 12 to 15 times more active than its optical isomer. Adrenaline is β -hydroxy- β -3, 4, dihydroxyphenyl-ethylmethylamine:

It is a basic substance, insoluble in weak alkalies and in organic solvents. and forming salts with acids. The hydrochloride is the usual commercial product. It is readily destroyed by oxidation in alkaline solutions, and may give rise to amorphous, dark-colored melanins. It is quickly destroved in the blood, so that the effect of an intravenous injection rapidly passes on; it is slowly and incompletely absorbed from subcutaneous injection sites, and in many animals tends to produce abscesses when administered in this way. It does not exhibit its typical properties when given orally, though it is somewhat toxic. The physiological reaction to adrenaline is, in almost all organs, the same as the response to stimulation of the sympathetic nerve supply; the blood pressure rises because of arteriolar constriction, peristalsis is inhibited, the pupil dilates, the bronchial muscles relax, blood sugar and blood lactic acid are increased at the expense of glycogen stores, and the metabolic rate is temporarily increased. Adrenaline is believed to be liberated reflexly from the gland in "emergencies," as when the body is exposed to cold or shock or fatigue. Adrenaline may be determined by biological assay, usually by its effect on the blood pressure, or by chemical methods. Small amounts may be found in the prostate gland.

EXPERIMENTS ON THE ADRENAL MEDULLA

1. Preparation of Adrenaline: To each 100 g. of ground fresh adrenal tissue add 50 ml. of a 3 per cent solution of acetic acid in 95 per cent ethyl alcohol. Allow to stand for 12 to 24 hours and remove the liquid by straining. Reextract the residue twice for six hours, each time with the same volume of 3 per cent acetic acid in 60 per cent ethyl alcohol as before. After filtering, concentrate the extract in a flask under diminished pressure to about one-tenth of the original volume. The material which has precipitated should be removed by filtration and the filtrate concentrated under diminished pressure to about 2 to 3 ml. per 100 g. of tissue extracted. Transfer the solution to a test tube and add enough strong ammonium hydroxide to leave a strong odor of ammonia. Stopper and set aside in a cool place

¹¹ Frame: Endocrinology, 34, 175 (1944).

for several hours. Remove the precipitate by filtration and wash first with ice-cold water which has been boiled, then with cold alcohol and finally with ether. Dissolve the precipitate in 10 ml. of 10 per cent hydrochloric acid, reprecipitate, and treat the precipitate as before.

- 2. Properties of Adrenaline: Dissolve 0.1 g. of adrenaline in about 10 ml. of 0.1 per cent HCl and dilute to 100 ml.
 - a. Vulpian Reaction: Add a few drops of FeCl₃ solution. A green color will be produced which is a typical catechol reaction.
 - b. Comessatti Reaction: To 5 ml. of the solution add an equal volume of 1 per cent sodium acetate solution and about 1 ml. of 0.1 per cent mercuric chloride solution. A rose-red color will be obtained. Warming of the solution to 40° to 50° C. will hasten this reaction.
 - c. Test the solution with Ehrlich's diazo reagent (see Chapter 29 and Appendix).
 - d. Ewins Reaction: Add to 1 ml. of the solution an equal volume of 0.2 per cent potassium persulfate; a reddish color is produced which is specific and may be quantitatively determined.¹⁴
 - e. Fluorescence: A faintly alkaline solution of adrenaline, even if extremely dilute, shows a bright apple-green fluorescence for some minutes when irradiated in a quartz vessel with ultraviolet light from a mercury vapor lamp.

THE PANCREAS

Removal of the pancreas in cats and dogs produces symptoms similar to diabetes mellitus in man. Blood sugar increases greatly and glucosuria occurs; the glycogen stores of liver and muscle are depleted; the blood is charged with fat, and acetone bodies (acetoacetic acid, β -hydroxybutyric acid, and acetone), accumulate in the blood and are excreted in the urine,

Fig. 219. Crystalline zinc insulin. (Courtesy, Dr. D. A. Scott.)

to produce acidosis, coma, and death, usually within three weeks. These symptoms do not follow when the digestive pancreatic juice is prevented from reaching the intestine, or even when the acinar cells which secrete this juice degenerate; they are rather due to removal of solid clumps of cells, the islets of Langerhans, which have no connection with the ducts but form a hormone, *insulin*, which is discharged into the blood and regulates carbohydrate metabolism.

Diabetic symptoms appear when the islet cells are damaged by administration of alloxan, or in some species by prolonged administration of certain anterior-pituitary extracts which produce hyperglycemia. The first useful pancreatic extracts were prepared by extracting the pancreas with acid alcohol, and increasing the concentration of alcohol in the filtered extracts until insulin was precipitated. Refinements of the method led to the isolation of insulin in crystalline form as a zinc salt. Insulin is a protein, somewhat of the albumin type, but unusually soluble in moderately

¹⁴ Barker, Eastland, and Evers: Biochem. J., 26, 2129 (1932).

dilute alcohol and acetone. It is destroyed by digestive enzymes, and must be protected from pancreatic trypsin during extraction; hence, also, it is ineffective orally. Insoluble compounds of insulin with basic proteins (protamines or globin) and zinc are used therapeutically, since they are slowly absorbed from the tissues and injections need not be given so frequently. In normal animals, insulin lowers the blood sugar, thus eventually producing convulsions unless counteracted by the administration of glucose, or substance yielding glucose. The unit was at one time defined as one-third of the amount which will, in five hours, lower the blood sugar of a fasted rabbit to the convulsive level (45 mg. per 100 ml.), but assay is now conducted by comparing the activity of an unknown sample with that of crystalline insulin, either in lowering the blood sugar of rabbits or in inducing convulsions in mice: crystalline insulin is reckoned at 22 units per mg.

Some consider that insulin is an essential catalyst in the biological oxidation of carbohydrate; for example, that it favors the action of the enzyme hexokinase in forming glucose-6-phosphate as a first step; others believe that insulin checks the new formation of carbohydrate from fat (at least from glycerol) and protein, which in the absence of insulin is supposed to flood the organism with sugar; others again hold that lack of insulin inhibits reactions whereby a large proportion of dietary carbohydrate is converted into fat. The consequences of pancreatectomy are less marked in animals from which the anterior pituitary, or the adrenal cortices, are removed; they are in any case less marked in species other than the cat and dog.

EXPERIMENTS ON THE PANCREAS

- 1. Preparation of Insulin: Method of Jephcott:15 To 1 kg. or more of fresh, finely minced beef pancreas, add 4 volumes of extraction liquid, consisting of 750 ml. of ethyl alcohol, 250 ml. of distilled water, and 15 ml. of concentrated hydrochloric acid. Shake or stir for two hours at 37° and filter through a double layer of cheesecloth; extract the residues as before. Combine the filtrates and add concentrated ammonia till alkaline to litmus; centrifuge, and discard the precipitate. (Insulin may be precipitated quantitatively by adding one and a half volumes of absolute ethyl alcohol and two and a half volumes of ether and allowing to stand in the cold.) A purer preparation is obtainable as follows: After centrifuging, drive off the alcohol with a blast of air at 37° and add 40 g. of ammonium sulfate per 100 ml. The precipitate which rises to the top contains the insulin; it is ground with 70 per cent alcohol and filtered. To the filtrate add an equal volume of 95 per cent alcohol, and discard any precipitate which forms: now add eight volumes of 95 per cent alcohol to precipitate the insulin, which is filtered off and dried, and dissolved in water (1 ml. per
- 10 g. of pancreas) containing 0.1 per cent tricresol.
 2. Effect of Insulin on Blood Sugar: Take a 1-ml. sample of blood for a sugar determination from the marginal ear vein of a 2-kg. rabbit which has been starved for 24 hours. Then inject subcutaneously 5 to 10 units of insulin. Observe the rabbit carefully for symptoms of hypoglycemia, such as hyperirritability, palpitation of the heart, convulsions, and coma. Another sample of blood should be drawn as soon as distress is evident and a third when the rabbit is in convulsions. To relieve the induced hypoglycemia.

¹⁸ Jephcott: Tr. Roy. Soc. Canada, sec. 5, 25, 183 (1931).

inject 10 ml. of 10 per cent glucose solution intravenously. After recovery, take another blood sample for a sugar determination. Compare the blood sugar values. It is also possible to save the animal by injecting 0.5 ml. of

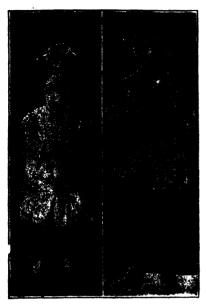

Fig. 220. Effect of thyroxin on growth of a cretin. The illustration shows the same child, in the same dress, before and after receiving thyroxin for one year. Increase in height, 6 inches. (From Kendall: Ind. Eng. Chem., 17, 525 (1925).)

1: 1000 epinephrine (adrenaline) subcutaneously after the first convulsions; or convulsions may be averted by feeding glucose upon a leaf of lettuce, or by giving glucose by stomach tube, or intraperitoneally.

THE THYROID

The thyroid gland consists of a framework of connective tissue enclosing numerous vesicles lined with epithelium. flattened in the resting state and cubical or columnar (almost obliterating the colloid-filled cavity of the vesicle) when highly active. Marked enlargement of the gland is known as goiter. It may be associated with normal or subnormal activity, in which case it is related to a deficient intake of iodine and is chiefly found in inland regions, for example around the Great Lakes, where the soil. water, and vegetation are iodine-poor. It may also be associated with increased thyroid activity (Graves' disease, exophthalmic goiter). The thyroid is far richer in iodine than any other tissue. The iodine is chiefly built into the characteristic protein thyroglobulin, which makes up a large part of the colloid in the vesicles and may be isolated in rel-

atively pure form.¹⁶ Thyroglobulin on hydrolysis yields thyroxine, the structure of which was determined and confirmed by synthesis to be

 β -[3:5-diiodo-4-(3':5'-diiodo-4'-hydroxy-phenoxy)-phenyl]- α -aminopropionic acid. This is usually obtained in the racemic form, but is originally levorotatory. The administration of thyroxine or of substances containing it produces only in part the picture of Graves' disease: high metabolic rate, increased pulmonary ventilation and circulation rate tending to overwork the heart, extreme nervous restlessness, sometimes protrusion of the eyeballs (exophthalmos). Deficient thyroid activity produces myxedema (see Fig. 221), with low basal metabolism, mental

16 Heidelberger and Palmer: J. Biol. Chem., 101, 433 (1933).

and physical sluggishness, and formation of a curious puffy tissue under the skin. The extreme form, in which severe deficiency dates from infancy, is known as *cretinism* (see Fig. 220), and is marked by stunting, deformity and feeblemindedness. It is uncertain whether the actual hormone discharged by the gland is thyroxine, thyroglobulin, or some molecule of intermediate size. The hormone appears to act as a stimulant of all metabolic processes; its effect is slowly developed and long-lasting, and it is not in general possible to discern it by applying thyroxine to isolated

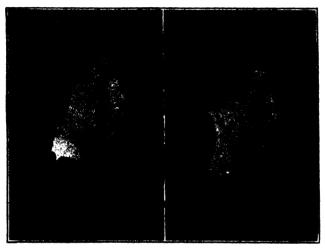

Fig. 221. Effect of thyroxin on myxedema. The time interval between pictures is three weeks. The total amount of thyroxin used was less than 20 mg. (From Kendall: *Ind. Eng. Chem.*, 17, 525 (1925).)

tissues or organs. Thyroxine is too insoluble to be given advantageously by mouth, but it is not destroyed during digestion so that preparations of desiccated thyroid gland, given orally, are cheap and fully active. Methods of biological assay depend chiefly on measurements of the metabolism of myxedema patients, or of small animals; less accurate methods depend on the facts that thyroid-treated mice become resistant to the poison acetonitrile (CH₃CN), and that thyroid substance accelerates the metamorphosis of tadpoles. Thyroxine may also be determined chemically by its iodine content, but it must be remembered that thyroglobulin also contains the more soluble, physiologically inactive amino acid diiodotyrosine:

Experiments with the radioactive isotopes of iodine indicate that the gland, unless previously saturated, takes up iodide from the blood for the synthesis of diiodotyrosine and thence of thyroxine. These reactions can

be inhibited by treatment with large doses of sulfonamide drugs or with thiourea, thiouracil, and related compounds, which thus gradually produce signs of hypothyroidism accompanied by goiter. Thiouracil is being used experimentally in the treatment of Graves' disease; the administration of iodine also produces a remission, which though often temporary is valuable in preparation for operation, and which is due to retention of colloid within the gland.

THE PARATHYROIDS

The parathyroid glands are small compact bodies, usually four in number and closely apposed to or within the thyroid. If they are removed, the level of calcium in the blood serum falls; this in turn causes neuromuscular hyperexcitability, tremors of the skeletal muscle, and panting which produces alkalosis. With calcium deficiency, this leads to violent tonic and clonic convulsions in which the animal sooner or later dies from arrest of respiration, symptoms best seen in the dog. It is a coincidence that derivatives of guanidine (HN:C(NH₂)₂) produce similar convulsions. Acid extraction of ox parathyroids yields extracts which maintain parathyroidectomized dogs alive and free from tetany, and which in normal dogs produce an elevation of serum calcium. The (Hanson) unit is one onchundredth of the amount required to raise the serum calcium of normal, 20-kg, dogs by 1 mg, per 100 ml., though larger increases can be more accurately measured. A large single injection may accelerate the renal excretion of phosphates and raise the serum calcium to twice its normal level in 12 to 15 hours, usually without disturbance to the health of the animal: but if the calcium is maintained at a high level by repeated injections, the blood becomes concentrated and the circulation sluggish, kidnev function fails, and hemorrhage occurs in the gastrointestinal tract, The calcium mobilized by the parathyroid hormone comes from the skeleton, where it is probable that the hormone stimulates the formation and activity of the osteoclasts. After prolonged treatment or in the presence of a parathyroid tumor, the bones are demineralized and become fibrous and cystic (hyperparathyroidism: osteitis fibrosa). There is some tendency for the body to lose its responsiveness to parathyroid extracts; this is particularly well seen in the rat. The extracts being obtained by rather drastic procedures, there is no certainty that the principle they contain is the unaltered natural hormone; it is of protein nature 17 and destroyed by digestive enzymes.

EXPERIMENTS ON THE PARATHYROIDS

1. Preparation of Parathyroid Extract: Method of Collip: Place the fresh ox parathyroids, from which the visible fat and connective tissue have been removed, in a small flask or test tube, cover with an equal volume of 5 per cent hydrochloric acid, and keep in a boiling water bath for one hour. Allow to cool and remove the congealed fat mechanically. Then make the solution faintly alkaline with sodium hydroxide and add acid to the point of maximum precipitation of protein which is just barely acid to litmus. Filter and dissolve the precipitate in weak alkali and reprecipitate as before. Filter again and combine the filtrates, adding 0.1 per cent tricresol

¹⁷ Ross and Wood: J. Biol. Chem., 146, 49 (1943).

as preservative and keep the combined filtrates, which constitute the desired extract, in an icebox until ready to use.

2. Effect of Parathyroid Extract: Draw 8 to 10 ml. of blood from the saphenous or other suitable vein of a dog weighing at least 10 kg. Save this for determination of serum calcium (p. 589). Inject subcutaneously, every three hours for the next 9 to 12 hours, 10 Hanson units of commercial parathyroid extract (or a quantity of extract equivalent to one ox parathyroid) per kg. of body weight. Draw blood samples after the last injection, and again 12 hours later. Note the occurrence of depression and anorexia, the increased concentration of the blood and the rise in serum calcium.

THE ANTERIOR PITUITARY OR HYPOPHYSIS

The anatomy of the pituitary gland, or hypophysis cerebri, is complex: the pars nervosa is a downgrowth from the hypothalamic region of the brain, and consists of modified nervous and glial cells, while the rest of the organ is derived from Rathke's pouch, an upgrowth from the roof of the

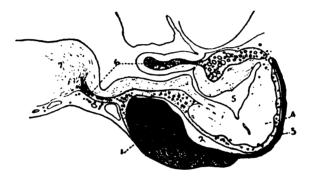

Fig. 222. Hypophysis of cat. 1, Pars anterior; 2, hypophysial cleft; 3, pars intermedia; 4, pars nervosa; 5, infundibular cavity; 6, pars tuberalis; 7, optic chiasm. (From Best and Taylor: "Physiological basis of Medical Practice," courtesy, William Wood & Co.)

mouth. This gives rise to the pars tuberalis, which surrounds the stalk of the pars nervosa like a collar and spreads along the base of the brain, to the pars intermedia, closely apposed to the anterior surface of the nervosa and usually separated by a cleft (the cavity of the embryonic pouch) from the large, glandular pars anterior which lies in front and on either side of it. The gland can be broken in two at the cleft, leaving the intermedia and tuberalis adherent to the nervosa as a complex called the posterior lobe. The whole organ rests in a more or less fitting cavity in the sphenoid bone, the sella turcica.

Removal of the whole organ, or of the anterior lobe alone, produces the following effects (best seen in the rat): cessation of growth; atrophy of the ovaries or testes, which cease to function in producing germ cells and as endocrine organs; atrophy of the thyroid, the reduction of thyroid activity lowering the metabolic rate; atrophy of the adrenal cortex, which may be the cause of an increased susceptibility to toxins, infections, etc., and of a

tendency to dissipate carbohydrate stores and toward hypoglycemia; cessation of lactation, if in progress. The administration of suitable extracts, or implantation of anterior-lobe tissue, more or less corrects these deficiencies. It is uncertain how many distinct active principles are present in such extracts, but the following are widely recognized: a growth hormone, capable of producing accelerated growth in young animals; a thyrotropic hormone, stimulating the thyroid gland to overactivity, reflected in histological change, discharge of iodine-containing hormone, and raised basal metabolic rate: an adrenotropic or corticotropic hormone, capable of restoring the atrophied adrenals of the hypophysectomized animal; one or more substances apparently intervening directly in metabolism rather than through the mediation of another gland, and producing such effects as the "glycotropic" resistance to the hypoglycemic action of insulin, the "glycostatic" maintenance of muscle-glycogen in fasting, the "ketogenic" transfer of fat from depots to liver and production of acetone bodies by the fasted or fat-fed rat, and the "diabetogenic" elevation of the blood sugar and fall of the respiratory quotient, with ketosis, obtainable only in certain animals and only with large doses of crude extracts, but leading at times to such damage to the islets of Langerhans as to produce a permanent diabetic state; prolactin, the "lactogenic" hormone, which stimulates milk secretion in fully developed mammary glands, and the glandular development of the crop seen in pigeons of both sexes while rearing their young; and gonadotropic substances, which stimulate the sex glands to both germinal and endocrine activity (for example, producing premature ripening of follicles, ovulation, formation of corpora lutea, and secondary estrus changes in the uterus and vagina in immature rats and mice). It is commonly thought that there are at least two gonadotropic substances, generally referred to as the follicle-stimulating hormone (FSH) and interstitial-cell-stimulating or luteinizing (ICSH or LH) hormone. A similar but not identical substance, called prolan, or anterior-pituitary-like (APL), or chorionic gonadotropin is formed in the human placenta during pregnancy and is excreted in the urine. The Aschheim-Zondek and Friedman tests, based on this fact, are the most accurate means now available of diagnosing early pregnancy; they also serve to diagnose hydatidiform mole and chorionepithelioma, in which abnormally large amounts of prolan are excreted. Yet another gonadotropin of chorionic origin (PMS) appears in the serum, but not the urine, of the pregnant mare. In various species. gonadotropic substances of pituitary origin appear in the urine when the sex glands are removed or have ceased to function; and it is evident that the pituitary does not merely control many other endocrine glands, but that it is in turn to some extent controlled by them.

The anterior pituitary hormones are of protein nature, are largely unstable to heat, and are destroyed by digestive enzymes; chemically pure preparations of the luteinizing, 18 adrenotropic 19 and lactogenic 20

hormones have been obtained; the thyrotropic hormone²¹ and chorionic gonadotropins²² have been almost as highly purified. It is very interesting that the chemical properties of such hormones may vary from species to species. Animals treated with large doses of anterior-lobe hormones over long periods may become refractory to them, a phenomenon believed to be due to the appearance in the blood of antagonistic substances of unknown origin, called *anti-hormones*. Clinically, overactivity of the anterior lobe is associated with giantism and acromegaly (often accompanied by diabetic symptoms), and congenital underactivity with dwarfism and infantilism; in Simmonds' disease the gland is almost wholly destroyed.

THE POSTERIOR PITUITARY

The posterior lobe contains principles which may be extracted from the acetone-dried gland with dilute acetic acid: pituitrin is a commercial extract of this type. It contains vasopressin (pitressin) which, on the one hand, affects the circulation, causing constriction of the capillaries leading to extreme pallor and a tendency to raise blood pressure, offset, however, by an unfavorable action on the heart (coronary constriction); and, on the other hand, checks the secretion of urine, especially by postponing or abolishing the diversis normally induced by administration of fluids. Oxytocin (pitocin) is also present in pituitrin but may be almost completely separated from pitressin; it causes contraction of the smooth muscle of the uterus (except in the presence of an active corpus luteum), and is used therapeutically in the late stages of labor. The extracts also affect the intestinal and bronchial musculature, and temporarily check the uptake of oxygen from the blood by the tissues; when introduced directly into the third ventricle they stimulate a "parasympathetic" center in the brain.

It is still uncertain how far these substances have physiological functions, for their absence does not seem to be significant when the whole gland is removed; but if the posterior lobe alone is extirpated, or if the nerve fibers which run into it from the nucleus supra-opticus are severed, there is a permanent increase in urine flow and in water consumption (diabetes insipidus). The posterior lobe principles arise in the pars nervosa and appear to be polypeptides; they are unstable in alkaline solution and inactive by mouth. There is evidence that, as ordinarily obtained, they are breakdown products of a much larger molecule possessing both pressor and oxytocic activity. The pars intermedia, which is embryologically part of the anterior lobe, produces a substance (intermedia) which causes expansion of pigment-cells (melanophores, erythrophores) in the skin of lower vertebrates. A frog from which the pituitary is removed is rendered permanently pale in color by contraction of the melano-

phores. It is uncertain whether this substance has any function in mammals.

EXPERIMENTS ON THE PITUITARY

- 1. Preparation of Anterior Lobe Extract: Method of Evans:²³ Bovine anterior lobes, as fresh as possible, are ground in a mortar with twice their weight of sand; 2 ml. of water are added for every g. of gland. The volume of the mixture is measured and three-eighths of this quantity of 0.2 N NaOH is added; the material is kept for 12 hours in the icebox, the supernatant fluid decanted off and neutralized to phenol-red with 0.2 N acetic acid. Crude extracts of this type contain maximal amounts of the several hormones, except that positive stimulation of the sex glands is not very readily obtainable with bovine material. The growth hormone may be precipitated from such an extract by adding 20 g. of anhydrous sodium sulfate per 100 ml. Special methods have been described for obtaining purer (but usually less potent) preparations of the various active principles.
- 2. Preparation of Chorionic Gonadotropin: Method of Katzman and Doisy:24 Human pregnancy urine (preserved with a little chloroform and kept at 1 to 5° C.) is made acid to methyl red-methylene blue (pH 4-5) with glacial acetic acid and filtered: 50 ml. of a saturated solution of benzoic acid in acetone are added to each liter of urine, with vigorous stirring, and the mixture is allowed to stand overnight. The precipitated benzoic acid, upon which the active material is adsorbed, is filtered off with suction and dissolved in a volume of acetone equal to the amount originally added. A small flocculent precipitate of acetone-insoluble material contains the active principle and is separated by decantation and centrifuging and thoroughly washed with acetone. Small additional quantities may be obtained by repeating the benzoic acid adsorption on the urine filtrate. The active principle is extracted from the combined precipitates by three treatments with distilled water, centrifuging after each extraction, and using not more than 25 ml. of water per liter of urine. The water-insoluble residue is discarded. Other useful methods involve adsorption upon Lloyd's reagent²⁵ or precipitation with tungstic acid.²⁶ All these methods may be used to concentrate the activity in urines other than those of pregnancy, when the gonadotropic substance is too dilute to be determined by direct biological assay of the urine.
- 3. Detection of Chorionic Gonadotropin (Prolan): Pregnancy Test of Aschheim and Zondek:27 Five infantile female mice, 6 to 8 g. in weight and 3 to 4 weeks old, are injected with the urine to be tested. This should be taken from the first sample passed in the morning, and toxic substances may be removed from it by shaking with ether. Each mouse is given six injections of 0.5 ml. of this urine, three doses on the first day and three on the second, and the animals are killed 96 hours after the beginning of the test. The reaction sought consists of three parts: (I) Formation of large ovarian follicles and precocious appearance of estrus; (II) hemorrhagic follicles, easily seen under a lens as deep, clear-red spots; (III) formation of corpora lutea, visible under a lens. Reaction I by itself is insufficient to establish a diagnosis of pregnancy. The dependability of the reaction is at least 98 per cent. It usually becomes positive a few days after the first missed menstrual period; in the ensuing month, the concentration of the active principle rises to a well-marked maximum. Very high concentrations occur in the presence of tumors of placental tissue (hydatid mole or chorionepithelioma).

4. Friedman Pregnancy Test: This test is more rapidly completed, is equally accurate, and probably more convenient where tests are made only occasionally. It is based on the fact that rabbits ovulate only when their ovaries are specifically stimulated, as they are after mating. A mature female rabbit, which must have been isolated in a cage by itself for at least three weeks previously, is given 10 ml. of urine to be tested by injection into the marginal ear vein. The ovaries are examined 24 hours later; a positive reaction is marked by reddish protrusions or by recent hemorrhage in the follicles. The abdomen may be opened and the ovaries inspected under anesthesia, so that the rabbit may be used again some weeks later, when the corpora lutea formed have disappeared.

THE KIDNEY

When the kidneys, or the arteries supplying them, are compressed, there follows a sustained rise in systemic blood pressure, resembling the clinical entity of essential hypertension; the phenomenon is independent of nervous connections, and of changes in excretory function. It is ascribed to the secretion into the blood of a globulin called "renin," which appears to be a proteolytic enzyme and to vary in composition from species to species. The substrate for renin is a fraction ("hypertensinogen" or "activator") of the serum globulins, and the product of the reaction a heat-stable, dialyzable vasoconstrictor, probably a polypeptide, called "hypertensin" or "angiotonin"; this in turn is slowly destroyed by a substance ("inhibitor," "angiotonase," or "hypertensinase") present in normal blood and tissues.²⁹

THE THYMUS AND PINEAL

Endocrine function has frequently been ascribed to these organs, but has not been established; extirpation, even in very young animals, has no specific systemic effects.³⁰

SECRETIN

The first hormone whose function was clearly established (by Bayliss and Starling in 1903) was secretin. This is a substance which is liberated from the walls of the duodenum when acid chyme enters the lumen; it is carried by the blood to the pancreas, where it stimulates the secretion of pancreatic juice. Tests on the most highly purified secretin show it to be a polypeptide.

Less well established are cholecystokinin, believed to arise in the same source and to stimulate contraction of the gallbladder; enterogastrone, believed to inhibit the secretory and motor activity of the stomach when fat is present in the intestine; and gastrin, which is possibly identical with histamine, and may evoke secretion of hydrochloric acid by the fundus of the stomach when the pyloric region is stimulated by the presence of partially digested food. Various hormone-like substances have been said to occur in the liver, the most important being one which by permitting

normal maturation of red blood corpuscles cures pernicious anemia; this substance is supposed to be formed by the reaction between an unidentified "extrinsic factor" supplied by the food with an enzyme-like "intrinsic factor" normally present in the gastric juice.

Urine: General Characteristics of Normal and Pathological Urine

Secretion of Urine. The problem of the mechanism of the formation of urine by the kidney has occupied the attention of investigators for many years, and has produced many conflicting theories. The filtration-reabsorption theory of Cushny has been the basis of the "modern theory," and the work of Starling, Marshall, Richards, and their collaborators and of other investigators has led to a more satisfactory conception of the processes involved.

Marshall has summarized the known facts relating to the formation of urine by the mammalian kidney in the following working hypothesis: "All of the non-colloid constituents of the plasma are eliminated by filtration

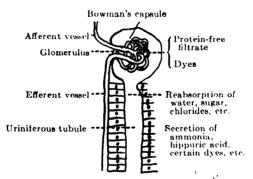

Fig. 223. Diagram illustrating the formation of urine.

through the glomerulus; water, chloride, bicarbonate, potassium (possibly phosphate, uric acid, and other bodies) are reabsorbed during the passage of the filtrate along the tubules; urea and sulfates are also reabsorbed to some extent under certain conditions but not as actively as chloride; ammonia, hippuric acid, and possibly other bodies are formed in the renal cells and secreted, while certain foreign substances when present in the organism (phenol red) and possibly substances occurring in small amounts in the organism are secreted after a preliminary concentration in the tubule cells. The amount of glomerular filtrate on this hypothesis is considered sufficient to account for all of the sulfate and urea eliminated but not sufficient to account for ammonia, certain dyes (phenol red, etc.) and other bodies which are concentrated to a much greater extent than sulfate by the kidney."

By direct catheterization of the glomerular urine of the frog, and comparison of its composition with simultaneously collected bladder urine, Wearn and Richards formulated a hypothesis illustrated diagrammatically in Fig. 223. It will be noted that the chief difference from Marshall's conception is in the site of dye secretion, these workers having found small amounts of dye in the glomerular filtrate although they admit much of the neutral red excretion is carried out by the tubules. They also found the polysaccharide inulin to be excreted by the glomerulus, indicating the presence of pores in the membrane, of considerable size.

Reabsorption of water which may be as high as 97 per cent appears to occur in both the proximal and distal tubules. Chloride is absorbed preferentially in the distal tubule, where also takes place the reabsorption of bicarbonate and acidification of the urine, probably through excretion of hydrogen ions. Reabsorption of glucose occurs in the proximal tubule, chiefly through esterification with phosphate. The substance phlorizin prevents this esterification and hence permits glucose to pass into the urine ("phlorizin diabetes"). Nitrogenous waste products appear in the urine either through failure of reabsorption from the glomerular filtrate or actual secretion by the tubular cells or both. Ammonia appears definitely to be secreted by the tubular cells, some urea may arise in this manner, and there is evidence for the tubular secretion of creatinine by man and Necturus but not by the frog. Thus species differences must be considered in interpreting kidney action.

Volume. The volume of urine excreted by normal individuals during any definite period fluctuates within very wide limits. The total volume of glomerular filtrate produced by normal adult kidneys may be 75 to 150 liters in 24 hours. However, after tubular reabsorption the average normal excretion of urine falls within the range of 1000 to 2000 ml. The volume-excretion is influenced greatly by the diet, particularly by the ingestion of fluids, and by the ambient temperature which affects not only fluid intake but also loss of water through perspiration. Strenuous physical exercise causes a diminished out put of urine.

Certain pathological conditions cause the output of urine for any definite period to depart very decidedly from the normal output. Among the pathological conditions in which the volume of urine is *increased* above normal are the following: diabetes mellitus, diabetes insipidus, certain diseases of the nervous system, contracted kidney, amyloid degeneration of the kidney, and in convalescence from acute diseases in general. Many drugs such as calomel, digitalis, acetates, and salicylates also increase the volume of the urine excreted. A decrease from the normal is observed in the following pathological conditions: acute nephritis, diseases of the heart and lungs, fevers, diarrhea, and vomiting.

Color. Normal urine ordinarily possesses an amber yellow tint, the depth of the color being dependent in part upon the density of the fluid. The color of normal urine is due principally to a pigment called urochrome. Traces of hematoporphyrin, urobilin, and urocrythrin have also been detected. Urochrome is believed to be a compound of urobilin and

¹ Pitte and Alexander: Am. J. Physiol., 144, 239 (1945).

urobilinogen with a peptide substance. The amount excreted per day by an adult man has been estimated at 7.3 mg., being very constant for a given individual. It seems to be a measure of basal metabolism, an increase being noted in fevers. The chemistry and significance of urochrome are, however, not fully established. Under pathological conditions or after the administration of various drugs or antiseptics, the color of the urine may vary in intensity from an extremely light yellow to a very dark

Color	Cause of Coloration	Pathological Condition	
Nearly colorless	Dilution, or diminution of normal pigments	Nervous conditions: hy- druria, diabetes insipidus, granular kidney	
Dark yellow to brown-red	Increase of normal, or oc- currence of pathological, pigments. Concentrated urine	Acute febrile diseases	
Milky	Fat globules	Chyluria	
	Pus corpuscles	Purulent diseases of the urinary tract	
Orange	Excreted drugs	Santonin, crysophanic acid	
Red or reddish	Hematoporphyrin; hemo- globin and myoglobin	Hemorrhages, hemoglobin- uria, trauma	
	Pigments in food (logweod, madder, bilberries, fuchsin)		
Brown to brown black	Hematin	Small hemorrhages	
	Methemoglobin	Methemoglobinuria	
	Melanin	Melanotic sarcoma	
	Hydroquinol and catechol	Phenol poisoning	
Greenish-yellow, greenish- brown, approaching black.	Bile pigments	Jaundice	
Dirty green* or blue	A dark blue scum on the surface, with a blue de- posit, due to an excess of indigo-forming substances	Cholera, typhus; seen espe- cially when the urine is putrefying	
Brown-yellow to red-brown, becoming blood-red upon adding alkalis.	Substances contained in senna, rhubarb, and cheli- donium which are intro- duced into the system		

^{*} This dirty green or blue color also occurs after the use of methylene blue in the organism.

brown or black or may even assume the color of the drugs or their degradation products. Vogel has constructed a color chart which is of some value for purposes of comparison. The nature and origin of the chief variations in the urinary color are set forth in tabular form by Halliburton. (See p. 715.)

Transparency. Normal urine is ordinarily perfectly clear and transparent when voided. On standing for a variable time, however, a cloud (nubecula) consisting principally of nucleoprotein or mucoid (see p. 742) and epithelial cells forms. A turbidity due to the precipitation of phosphates is normally noted in urine passed after a hearty meal. The urine obtained two to three hours after a meal or later is ordinarily free from turbidity. Permanently turbid urines ordinarily arise from pathological conditions.

Odor. The odor of normal urine is of a faint, aromatic type. The substances to which this odor is due are not well known, but it is claimed by some investigators to be due, at least in part, to the presence of minute amounts of certain volatile organic acids. Dehn and Hartman isolated from urine a neutral ill-smelling substance which they call urinod. Its empirical formula is C₂H₃O. Urinod occurs in urine to the extent of only one to two parts in 100,000 parts of urine. When the urine undergoes decomposition, e.g., in alkaline fermentation, a very unpleasant ammoniacal odor is evolved. All urines are subject to such decomposition if allowed to stand for a sufficiently long time. Under normal conditions the urine very often possesses a peculiar odor due to the ingestion of some certain drug or vegetable. For instance, cubebs, copaiba, myrtol, saffron, tolu, and turpentine each imparts a somewhat specific odor to the urine. After the ingestion of asparagus, the urine also possesses a typical odor attributed to methyl mercaptan (CH₃·SH) which may, however, exist in urine only as a precursor which yields the mercaptan on heating in acid solution.

Frequency of Urination. The frequency of urination varies greatly in different individuals, but in general is dependent upon the amount of fluid in the bladder. In pathological conditions an inflammatory affection of the urinary tract or any disturbance of the innervation of the bladder will influence the frequency. Affections of the spinal cord which lead to an increased irritability of the bladder or a weakening of the sphincter, or any condition lowering the residual capacity of the bladder, will result in increasing the frequency of urination.

Reaction. The mixed 24-hour urinary excretion of a normal individual ordinarily possesses an acid reaction to litmus. The actual hydrogen-ion concentration varies over a wide range (pH 4.8 to 8.0), the mean being about pH 6. The reaction of the urine represents an equilibrium between a large number of acid and basic constituents, both organic and inorganic, which it contains. Although organic acids and bases play a part in producing the normal reaction, this reaction is probably, in the main, dependent upon the relative amounts of the mono- and dibasic sodium and potassium phosphates present. The monobasic sodium phosphate (NaH₂PO₄) is acid in reaction, while the dibasic phosphate (Na₂HPO₄) is alkaline in reaction. The excretion of acid or alkaline phosphate by the kidneys is one

of the factors in the regulation of the neutrality of the blood and of the organism in general. The acidity of the urine as determined by titration runs in general parallel with the hydrogen-ion concentration and seems to be dependent upon the same factors, and in more acid urines mainly on the phosphate content. Van Slyke and Palmer have shown that normal men excrete organic acids equivalent to only about 6 ml. of 0.1 N acid per kilo in 24 hours. Strenuous physical exercise produces an increase in hydrogen-ion concentration and in acid and ammonia output. (For further discussion of acidity, see Chapter 32.)

The mean acidity in cardiorenal diseases is high—about pH 5.3 as compared with pH 6, the normal mean. In general the acidity tends to be increased in the greater number of pathological disorders.

The composition of the food is perhaps the most important factor in determining the reaction of the urine (see Chapter 34, Inorganic Metabolism, for the influence of base-forming and acid-forming foods). The reaction ordinarily varies considerably according to the time of day the urine is passed. For instance, for a variable length of time after a meal the urine may be neutral or even alkaline in reaction to litmus, owing to the claim

of the gastric juice upon the acidic radicals to further the formation of hydrochloric acid for use in carrying out the digestive secretory function. This hypothesis has been verified experimentally. This change in reaction is known as the alkaline tide and is common to perfectly healthy individuals. The urine may also become temporarily alkaline in reaction as the result of ingesting alkaline carbonates or certain salts of tartaric and citric acids which ultimately yield bicarbonate within the organism. Ingestion of acid fruits (oranges, lemons, peaches, etc.) causes the formation of alkaline urine. This is due to the fact that the ash of such fruits is alkaline

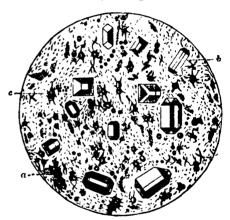

Fig. 224. Deposit in ammoniacal fermentation. (a) Acid ammonium urate, (b) ammonium magnesium phosphate, (c) bacteria.

and when the fruits are combusted in the body bicarbonate is formed. On the other hand, bread, cereals, meats, etc., yield an acid ash and an acid urine. Certain acid fruits, like cranberries and prunes, yield hippuric acid when metabolized.

Normal urine upon standing for some time becomes alkaline owing to the inception of alkaline or ammoniacal fermentation through the agency of microörganisms. This fermentation has no especial diagnostic value except in cases where the urine has undergone this change within the organism and is voided in the decomposed state. Ammoniacal fermentation is ordinarily due to cystitis or occurs as the result of infection in the process of catheterization. A microscopical examination of such urine

(Fig. 224) shows the presence of ammonium magnesium phosphate crystals, amorphous phosphates, and not infrequently ammonium urate.

Occasionally a urine which possesses a normal acidity when voided, upon standing instead of undergoing ammoniacal fermentation as above described, will become more strongly acid in reaction. Such a phenomenon is termed acid fermentation. Accompanying this increased acidity there is ordinarily a deepening of the tint of the urinary color. Such urines may contain acid urates, uric acid, fungi, and calcium oxalate (Fig. 225). On standing for a sufficiently long time any urine which exhibits acid fermentation will ultimately change in reaction, due to the inception of alkaline fermentation, and will show the microscopic deposits characteristic of such a urine.

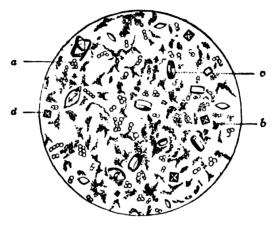

Fig. 225. Deposit in acid fermentation. (a) Fungus, (b) amorphous sodium urate, (c) uric acid, (d) calcium oxalate.

Specific Gravity. The specific gravity of the urine of normal individuals varies ordinarily between 1.015 and 1.025. This value is subject to wide fluctuations under various conditions. For instance, following copious water- or beer-drinking the specific gravity may fall to 1.003 or lower, whereas in cases of excessive perspiration it may rise as high as 1.040 or even higher. Where a very accurate determination of the specific gravity is desired, use is commonly made of the pycnometer or of the Westphal hydrostatic balance. These instruments, however, are not suited for clinical use. The clinical method of determining the specific gravity is by means of a urinometer (Fig. 226). This affords a very rapid method and at the same time is sufficiently accurate for clinical purposes. The urinometer is always calibrated for use at a specific temperature and the observations made at any other temperature must be subjected to a certain correction to obtain the true specific gravity. In making this correction one unit in the third decimal place is added to the observed specific gravity for every three degrees Centigrade above the normal temperature and subtracted for every three degrees below the normal temperature. For instance, if in using a urinometer calibrated for 15° C. the specific gravity of a urine having a temperature of 21° C. is determined as 1.018, it is necessary to add to the observed specific gravity 2×0.001 to obtain the real specific gravity of the urine. Therefore the specific gravity at 15°C. of a urine having a specific gravity of 1.018 at 21° C., would be 1.018 + 0.002 = 1.020.

Pathologically, the specific gravity may be subjected to very wide variations. This is especially true in diseases of the kidneys. In acute

nephritis ordinarily the urine is concentrated and of a high specific gravity, whereas in chronic nephritis the reverse conditions are more apt to prevail. In fact, under most conditions, whether physiological or pathological, the specific gravity of the urine is inversely proportional to the volume excreted. This is not true of diabetes mellitus, however, where the volume of urine is large and the specific gravity also is high, owing to the sugar contained in the urine.

The total solids normally excreted in the urine may be roughly calculated by means of Long's coefficient, i.e., 2.6. The solids content of 1000 ml. of urine is obtained by multiplying the last two figures of the specific gravity observed at 25° C. by 2.6. To determine the amount of solids excreted in 24 hours if the volume was 1120 ml. and the specific gravity was 1.018, the calculation would be as follows:

(a) $18 \times 2.6 = 46.8$ g. of solid matter in 1000 ml. of urine

(b)
$$\frac{46.8 \times 1120}{1000} = 52.4$$
 g. of solid matter in 1120 ml. of urine

FREEZING POINT. The freezing point of a solution depends upon the total number of dissolved molecules and ions. It is proportional to the osmotic pressure of the solution. Normally the freezing point of urine is

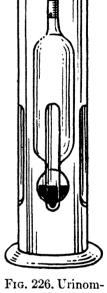

Fig. 226. Urinometer and cylinder.

usually from -1.3° to -2.3° C. The freezing point may be determined by means of a Beckmann-Heidenhain or some similar apparatus (see books on physical chemistry).

ELECTRICAL CONDUCTIVITY. The electrical conductivity of urine depends upon the total number of ions in solution and on the mobility of the ions (see Chapter 1). It runs closely parallel with the chloride of the urine. Normal variation of from 130 to 330·10⁻⁴ may occur.

Collection and Preservation of the Urine Sample. If any dependable data are desired regarding the quantitative composition of the urine, the examination of the mixed excretion for 24 hours is absolutely necessary. In collecting the urine the bladder may be emptied at a given hour, say 8 A.M., the urine discarded, and all the urine from that hour up to

and including that passed the next day at 8 A.M., saved, thoroughly mixed, and a sample taken for analysis.

Toluene is a very satisfactory preservative for urine. In using this preservative simply overlay the urine with a thin layer of the toluene. Formaldehyde (2 drops per 50 ml. of urine) or a bit of camphor or thymol are also satisfactory urine preservatives which do not interfere with the tests for the major urinary constituents.

According to Behre and Muhlberg, the most satisfactory preservative consists of a 3:2 mixture of hexamethylenetetramine (urotropin) and salicylic acid which is used in the proportion of 50 mg. per 10 ml. of urine. These substances produce formaldehyde in solution and it is claimed do not interfere with any of the usual tests.

In certain pathological conditions it is desirable to collect the urine passed during the day separately from that passed during the night. When this is done, the urine voided between 8 A.M. and 8 P.M. may be taken as the day sample and that voided between 8 P.M. and 8 A.M. as the night sample.

The qualitative testing of urine samples collected at random, except in a few specific instances, is of no particular value so far as giving us any accurate knowledge as to the exact urinary characteristics of the individual is concerned. In the great majority of cases the qualitative as well as the quantitative tests should be made upon the mixed excretion for a 24-hour period as well as upon a night sample as above described.

Urine: Physiological Constituents'

Normal urine varies widely in composition, being influenced by dict and other factors. The following table represents the composition of average normal urine.

Composition of a Typical Normal Urine (Daily Excretion)

)

Constituent	Amount (g.	
Water	1	200 0
(* 1. 1		60 0
Urea		30.0
Uric acid		0.7
Hippuric acid.		0.7
Creatinine		1.2

Neutral sulfur as S		0.12
Conjugated sulfates as S		0.08
Phosphate as P.		1.1
Ammonia		0.7

1. ORGANIC PHYSIOLOGICAL CONSTITUENTS

¹ It is impossible to make any absolute classification of the physiological and pathological constituents of the urine. A substance may be present in the urine in small amount physiologically and be sufficiently increased under certain conditions as to be termed a pathological constituent. Therefore it depends, in some instances upon the quantity of a constituent present whether it may be correctly termed a physiological or a pathological constituent.

Urea is the principal end-product of the metabolism of protein substances in mammals, amphibia, and elasmobranch fishes. About 80 to 90 per cent of the total nitrogen of human urine is present as urea. The distribution of the nitrogen of the urine among urea and the other nitrogencontaining compounds present depends upon the absolute amount of the total nitrogen excreted. A decrease in the total nitrogen excretion is always accompanied by a decrease in the percentage of the total nitrogen excreted as urea. By so reducing the protein content of the diet of a normal person as to cause the excretion of total nitrogen to be reduced to 3 to 4 g. in 24 hours, only about 60 per cent of this nitrogen appears in the urine as urea. Urea is the only one of the nitrogenous excretions which is, relatively as well as absolutely, decreased as a result of decreasing the amount of protein metabolized. Folin reported a hospital case in which only 14.7 per cent of the total nitrogen was present as urea and about 40 per cent was present as ammonia. Mörner had previously reported a case in which but 4.4 per cent of the total nitrogen of the urine was present as urea, and 26.7 per cent was present as ammonia.

Urea occurs most abundantly in the urine of man and carnivora and in somewhat smaller amount in the urine of herbivora; the urine of fishes, amphibians, and certain birds also contains a small amount of the substance. Urea is also found in nearly all the fluids and in many of the tissues and organs of mammals. The amount excreted under normal conditions by an adult man in 24 hours is about 30 g. The excretion is greatest in amount on a diet of meat, and least in amount on a diet consisting of non-nitrogenous foods; this is due to the fact that the urea output is regulated by the protein metabolism. A low-protein diet has a tendency to decrease the metabolism of the tissue proteins and thus the output of urea under these conditions may fall below that observed during starvation. The output of urea is also increased after copious water- or beer-drinking. The increase is probably due primarily to the washing out of the tissues of the urea previously formed, but which had not been removed in the normal processes, and secondarily to a stimulation of protein catabolism.

The formation of urea appears to be a property of the liver exclusively. This has been demonstrated by experiments in which there was complete cessation of urea formation after extirpation of the liver. Studies with isolated tissues, incubated in thin slices under physiological conditions, have also shown that only liver tissue is capable of synthesizing urea.

The mechanism of urea formation by the liver is still uncertain. Early views included formation from free NH₃, presumably liberated from amino acids by oxidative deamination, through the intermediate formation of ammonium carbonate, (NH₄)₂CO₃, or ammonium carbamate, NH₄·O·CO·NH₂. Attention has shifted to the role of certain amino acids in urea formation because of the studies of Krebs and Henseleit. These investigators, working with liver slices, showed that the liver could synthesize urea from ammonia and postulated the existence of a cyclic mechanism including ammonia, carbon dioxide, and the amino acids arginine, ornithine, and citrulline. The steps in the process, according to the "ornithine cycle" theory, are as follows:

Thus the primary source of urea according to this theory is the action of the enzyme arginase on the amino acid arginine, to produce urea and ornithine. The ornithine acts as a catalyst, being converted back to

arginine by the reactions shown, taking up ammonia and carbon dioxide in the process which ultimately appear as urea. This theory, while attractive, is not universally accepted (see Chapter 33). Points in its favor include the wellknown and powerful arginase activity of liver, and the fact that citrulline, first isolated from watermelon juice, is found in small amount in the blood, and its synthesis by liver tissue can be demonstrated. Opposed to it is the fact that the experimental demonstration of the "ornithine cycle" with liver slices requires the presence of

Fig. 227. Urea.

free ammonia in far higher concentration than is ever encountered in living tissue; even moderate amounts of free ammonia are not acted on at all by liver slices. Thus, if the theory is correct, the nitrogen would appear to enter the cycle in some other way than as free ammonia, and further evidence on the subject is clearly required.

Urea crystallizes in long, colorless, four- or six-sided, anhydrous, rhombic prisms (Fig. 227), which melt at 132° C. and are soluble in water or alcohol and insoluble in ether or chloroform. If urea is heated in a test tube, it melts and decomposes with the liberation of ammonia and the formation of biuret and cyanuric acid. According to the Werner hypothesis the changes are as follows:

The biuret may be dissolved in water and a reddish-violet color obtained by treating the aqueous solution with copper sulfate and potassium hydroxide (see Biuret Test, p. 156). Certain hypochlorites or hypobromites in alkaline solution decompose urea into nitrogen, carbon dioxide, and water. Sodium hypobromite brings about this decomposition as follows:

$$CO(NH_2)_2 + 3NaOBr \rightarrow NaBr + N_2 + CO_2 + 2H_2O$$

According to the Werner hypothesis, the urea is momentarily brominated and the resultant compound hydrolyzed by the alkali and oxidized by hypobromite. Sodium cyanate, sodium nitrate, hydrazine, and CO are formed as by-products, thus accounting for the low nitrogen values obtained in the clinical application of this method.

Soy beans, jack beans and watermelon seeds contain an enzyme called urease which has the power to decompose urea with the liberation of ammonia. This fact is made use of in the quantitative determination of urea (see Chapter 32). Urease action appears to involve the intermediate formation of ammonium carbamate and not of cyanate.

Urea forms crystalline compounds with certain acids; urea nitrate and urea oxalate are the most important. Urea nitrate, CO(NH₂)₂:HNO₂, crystallizes in colorless, rhombic or six-sided tiles (see Fig. 228), which are easily soluble in water. Urea oxalate, (CO(NH₂)₂)₂·H₂C₂O₄, crystallizes in the form of rhombic or six-sided prisms or plates (Fig. 229): the oxalate differs from the nitrate in being somewhat less soluble in water.

A decrease in the excretion of urea is observed in many diseases in which the diet is much reduced, in diseases associated with impaired liver function, in some disorders as a result of alterations in metabolism, e.g., myxedema, but most frequently as a result of diminished excretion, as in severe and advanced kidney disease. In fact, the determination of the ability of the kidneys to excrete urea (the "urea clearance" test, see Chapter 32) is perhaps the most valuable single clinical index of renal function. A pathological increase may result from tissue catabolism in febrile or wasting conditions. In marked acidosis it may be considerably decreased relative to the total nitrogen (see Ammonia, p. 745).

Strong solutions of urea have a remarkable solvent effect upon proteins, such as coagulated protein, and upon starch and other substances.

EXPERIMENTS ON UREA

- 1. Isolation from the Urine: Evaporate 200 ml. of urine in a casserole or evaporating dish over a free flame until the volume is reduced to about 25 ml. Transfer the container to a steam or water bath and continue the evaporation until the residue is semisolid, spreading the material over the sides of the dish to aid in removing as much water as possible. Add 50 ml. of acetone to the residue and stir thoroughly while the acetone is kept gently boiling on a previously heated water bath (with the flame turned out) or steam bath. Do not allow more than one-quarter of the acetone to boil off. Because of the inflammable and poisonous nature of acetone vapor, this and further operations should be conducted in the hood and in the absence of a free flame. Filter the hot extract quickly through a small dry filter into a dry 100-ml. beaker. Repeat the extraction of the residue once more with acetone, adding the filtrate to the first portion. Concentrate the combined extracts to a volume of 25 ml, on the steam bath or by placing the beaker in hot water. Chill the concentrated solution with cold water, cover, and allow to stand until crystallization occurs. Filter off the urea crystals, wash them with a little acetone, and allow to dry in air. Examine the crystals under the microscope and compare them with those shown in Fig. 227.
- 2. Melting Point: Determine the melting point of some urea crystals as follows: Into an ordinary melting-point tube, sealed at one end, introduce powdered urea. Fasten the tube to the bulb of a thermometer as shown in Fig. 40, and suspend the bulb and its attached tube in a small beaker containing sulfuric acid. Gently raise the temperature of the acid by means of a low flame, stirring the fluid continually, and note the temperature at which the urea begins to melt.
- 3. Crystalline Form: Dissolve a crystal of pure urea in a few drops of 95 per cent alcohol and place 1 to 2 drops of the alcoholic solution on a microscopical slide. Allow the alcohol to evaporate spontaneously, examine the crystals under the microscope, and compare them with those reproduced in Fig. 227. Recrystallize a little urea from water in the same way and compare the crystals with those obtained from the alcoholic solution.
- 4. Formation of Biuret: Place a small amount of urea in a dry test tube and heat carefully in a low flame. The urea melts at 132° C. and liberates ammonia. Continue heating until the fused mass begins to solidify. Cool the tube, dissolve the residue in dilute sodium hydroxide solution, and add very dilute copper sulfate solution (see p. 156). The purplish-violet color is due to the presence of biuret which has been formed from the urea through the application of heat as indicated. The chemistry of this reaction is shown on p. 724.
- 5. Urea Nitrate: Prepare a concentrated solution of urea by dissolving a little of the substance in a few drops of water. Place a drop of this solution on a microscopical slide, add a drop of concentrated nitric acid, and examine

under the microscope. Compare the crystals with those reproduced in Fig. 228.

- 6. Urea Oxalate: To a drop of a concentrated solution of urea, prepared as described in Exp. 5, add a drop of a saturated solution of oxalic acid. Examine under the microscope and compare the crystals with those shown in Fig. 229.
- 7. Decomposition by Sodium Hypobromite: Into a mixture of 3 ml. of concentrated sodium hydroxide solution and 2 ml. of bromine water in a test

Fig. 228. Urea nitrate.

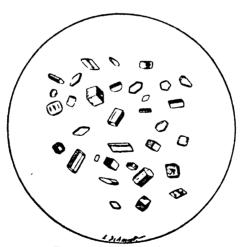

Fig. 229. Urea oxalate.

tube introduce a crystal of urea or a small amount of concentrated solution of urea. Through the influence of the sodium hypobromite, NaOBr, the urea is decomposed and carbon dioxide and nitrogen are liberated. The carbon dioxide is absorbed by the excess of sodium hydroxide, while the nitrogen is evolved and causes the marked effervescence observed. This property forms the basis for one of the methods in common use for the quantitative determination of urea. Write the equation showing the decomposition of urea by sodium hypobromite.

It is claimed that all ammonium compounds and all compounds containing the amino [—NH₂] group yield nitrogen when treated with hypobromite as in this test.

8. Decomposition by Urease: To 5 ml. of urea solution in a test tube add 1 ml. of urease solution or a little soy bean or jack bean powder. Allow the tube to stand for 10 minutes, heat the contents to boiling, holding moist red and blue litmus papers at the mouth of the tube. What do you observe? Note the odor. Explain.

URIC ACID

Uric acid is found in the urine normally to the extent of about 0.5 to 1.0 g. per 24 hours, but this amount is subject to wide variations, particularly under certain dietary and pathological conditions. On a purine-free diet the uric acid output may be 0.1–0.5 g. per day, whereas a high purine diet may yield a daily output of 2 g. Uric acid acts as a weak dibasic acid and forms two classes of salts, neutral and acid. The neutral potassium and lithium urates are the most easily soluble of the alkali salts; the ammonium urate is difficultly soluble. The acid salts are more insoluble and form the major portion of the sediment which separates upon cooling the concentrated urine; the alkaline earth urates are very insoluble. Ordinarily uric acid occurs in the urine in the form of urates and upon acidifying the liquid the uric acid is liberated and deposits in crystalline form.

Uric acid is closely related to the purine bases as may be seen from a comparison of its structural formula with those of the purine bases given on p. 191. According to the purine nomenclature, it is designated 2-6-8-trioxypurine. Uric acid forms the principal end-product of the nitrogenous metabolism of birds and scaly reptiles; in the human organism it occupies a position quantitatively inferior to urea, ammonia, and creatinine.

In man, uric acid probably results principally from the destruction of nuclear or other purine material, ingested as food or from the disintegrating cellular matter of the organism. The uric acid resulting from the diet is said to be of exogenous origin, whereas the product of cellular catabolism is said to be of endogenous origin. Folin demonstrated that, following a pronounced decrease in the amount of protein metabolized, the absolute quantity of uric acid is decreased, but that this decrease is relatively smaller than the decrease in the total nitrogen excretion and that the percentage of the uric acid nitrogen, in terms of the total nitrogen, is therefore decidedly increased. Foodstuffs may act to increase the endogenous uric acid output by stimulating the digestive glands to activity.

The enzymatic conversion of the purines adenine and guanine to the

intermediates hypoxanthine and xanthine, and of the latter to uric acid by means of xanthine oxidase, is discussed in Chapter 7, Nucleic Acids and Nucleoproteins. With the exception of man, the higher apes and the Dalmatian dog, mammalia carry the conversion one step farther; i.e., to allantoin, through the action of the enzyme uricase. Despite the absence of a typical uricase from human tissues, there is no question but that the human organism has considerable ability to destroy uric acid, by mechanisms not known. Thus uric acid excretion represents a balance between the rate of production and the rate of destruction. From experiments on dogs, Mann and associates drew the conclusion that the destruction of uric acid depends on the presence of the liver. The extirpation of the liver causes an accumulation of uric acid in the blood and tissues or an increased elimination in the urine if renal activity is maintained. These experiments also indicate that the liver is of considerable importance in the general metabolism of the purines.

In birds the formation of uric acid is analogous to the formation of urea in man. In these organisms it is derived principally from the protein material of the tissues and the food and is formed through a process of synthesis which occurs for the most part in the liver; a comparatively small fraction of the total uric acid excretion of birds may result from nuclear material.

When pure, uric acid may be obtained as a white, odorless, and tasteless powder, which is composed principally of small, transparent, crystalline, rhombic plates. Uric acid as it separates from the urine is invariably pigmented, and crystallizes in a large variety of characteristic forms, e.g., dumb-bells, wedges, rhombic prisms, irregular rectangular or hexagonal plates, whetstones, prismatic rosettes, etc. Uric acid is insoluble in alcohol and ether, soluble with difficulty in boiling water (1:1800) and practically insoluble in cold water (1:39,480, at 18° C.). It is soluble in alkalis, alkali carbonates, boiling glycerol, concentrated sulfuric acid, and in certain organic bases such as ethylamine and piperidine. It is claimed that the uric acid is held in solution in the urine by the urea and disodium hydrogen phosphate present. Uric acid possesses the power of reducing cupric hydroxide in alkaline solution and may thus lead to an erroneous conclusion in testing for sugar in the urine by means of Fchling's or Trommer's test. A white precipitate of cuprous urate is formed if only a small amount of cupric hydroxide is present, but if enough of the copper salt is present the characteristic red or brownish-red precipitate of cuprous oxide is obtained. Uric acid does not possess the power of reducing bismuth in alkaline solution and therefore does not interfere in testing for sugar in the urine by means of Boettger's or Nylander's tests.

In addition to being a constant urinary constituent uric acid is present in small amounts in normal human blood as well as in the blood of birds. It is also normally present in the brain, heart, liver, lungs, pancreas, and spleen.

Pathologically, the excretion of uric acid is subject to wide variations, but the experimental findings are rather contradictory. It may be stated with certainty, however, that in leukemia, because of the destruction of

PLATE V

URD ACID CRYSTALS, NORMAL COLORS, (From Purdy, after Peyer.)

nuclear material, the uric acid output is increased absolutely as well as relatively to the urea output; under these conditions the ratio between the uric acid and urea may be as low as 1:9, whereas the normal ratio, as we have seen, is 1:50 or higher. An actual output of 12 g. of uric acid per day has been reported in leukemia. In a study of the influence of x-rays on metabolism, Edsall and others found that the excretion of uric acid is usually increased and that in some conditions, particularly in leukemia, it may be greatly increased.

In gout the kidney is said to lose the power of properly eliminating uric acid and it collects in the blood in abnormally high concentration, although this is undoubtedly not the only factor concerned. The uric acid content of the urine in this disease is generally low preceding an attack and increases during the attack. Cinchophen and salicylates have been found to increase the uric acid output in gout, apparently due to increased kidney activity.

The uric acid content of the urine is of importance in relation to the formation of uric acid calculi. The administration of alkali carbonates and citrates, or the feeding of base-forming foods, by decreasing the acidity of the urine, increases its solvent power for uric acid and decreases the liability of formation of this type of calculus.

EXPERIMENTS ON URIC ACID

1. Isolation from the Urine: Place about 200 ml. of filtered urine in a beaker, render it acid with 2 to 10 ml. of concentrated hydrochloric acid, stir

Fig. 230. Pure uric acid.

thoroughly, and stand the vessel in a cold place for 24 hours. Examine the pigmented crystals of uric acid under the microscope and compare them with those shown in Fig. 230 and Plate V.

2. Crystalline Form of Pure Uric Acid: Place about 100 ml. of water in a small beaker, render it distinctly alkaline with potassium hydroxide solution, and add a small amount of pure uric acid, stirring continuously. Cool the solution, render it distinctly acid with hydrochloric acid, and allow it to stand in a cool place for crystallization. Examine the crystals under the microscope and compare them with those reproduced in Fig. 230.

3. Murexide Test: To a small amount of pure uric acid in a small evaporating dish add 2 to 3 drops of concentrated nitric acid. Carefully evaporate to dryness on a water bath or over a very low flame. A red or yellow residue remains which turns purplish-red after the dish has been cooled and a drop of very dilute ammonium hydroxide has been added. The color is due to the formation of murexide. If potassium hydroxide is used instead of ammonium hydroxide, a purplish-violet color due to the production of the potassium salt is obtained. The color disappears upon warming; with certain related compounds (purine bases) the color persists under these conditions. This is a valuable test for the detection of uric acid calculi.

In this reaction the uric acid is oxidized to dialuric acid and alloxan. These two substances condense to form alloxantin. This alloxantin reacts with ammonium hydroxide to form purpuric acid. The purple color is due to the formation of ammonium purpurate or murexide.

- 4. Phosphotungstic Acid Reaction (Folin): To 20 ml. of saturated sodium carbonate solution in a small beaker add a small amount of uric acid. Stir the solution until the uric acid has dissolved, then add 1 ml. of Folin's uric acid reagent (see p. 512). A blue color results.
- 5. Silver Reduction Test (Schiff): Dissolve a small amount of pure uric acid in sodium carbonate solution and transfer a drop of the resulting mixture to a strip of filter paper saturated with silver nitrate solution. A yellowish-brown or black coloration due to the formation of reduced silver is produced. It is claimed that chlorides interfere with this test.

CREATININE C=NH CREATINE C=NH

$$H_3C$$
—N— CH_2 II_3C —N— CH_2 COOH

Creatinine. Creatinine is the anhydride of creatine (methylguanidinoacetic acid) and is a constant constituent of normal human urine. Under normal conditions about 1 to 1.25 g. of creatinine are excreted by an adult man in 24 hours. The exact amount of creatinine excreted under ordinary circumstances depends in part upon the nature of the diet, since any creatinine in the diet is excreted unchanged in the urine. Foods such as meat and fish contain significant amounts of performed creatinine, particularly after cooking. Creatinine excretion decreases somewhat in starvation. The absolute amount of creatinine eliminated in the urine on a creatinine-free diet is practically a constant quantity for a given individual and is independent of quantitative changes in the total amount of nitrogen eliminated under these conditions. The "creatinine coefficient," which is the daily excretion of creatinine in mg. per kg. of body weight.2 is an index of this constancy of creatinine elimination. Endogenous creatinine is apparently the result of some special process of normal metabolism, which takes place at a constant rate and which almost certainly involves body creatine, since creatine can be converted in the body to creatinine, but of whose exact nature we are in ignorance at the present time. Until such time as this process is more clearly understood, the significance of a constant creatinine excretion would appear to be limited. The reversal of this process, i.e., the conversion of creatinine to creatine in the body, does not occur.

² Shaffer designates as the "creatinine coefficient" the excretion of creatinine nurogen in mg. per kg. of body weight.

Very little that is important is known regarding the excretion of creatinine under pathological conditions. The creatinine content of the urine is said to be increased in typhoid fever, typhus, tetanus, and pneumonia, and to be decreased in anemia, chlorosis, paralysis, muscular atrophy, advanced degeneration of the kidneys, and in leukemia (myelogenous, lymphatic and pseudo). The increase of creatinine found in diabetes was probably due to the creatinine content of the meat eaten. The greater part of the data, however, relating to the variation of the creatinine excretion under pathological conditions are not of much value since in nearly every instance the diet was not sufficiently controlled to permit the collection of reliable data. Shaffer has called attention to the fact that a low excretion of creatinine is found in the urine of a remarkably large number of pathological subjects, representing a variety of conditions, and that it is therefore evident that the excretion of an abnormally small amount of

Fig. 231. Creatinine.

this substance is by no means peculiar to any one disease. A considerable increase in the creatinine content of the blood is observed in uremia.

According to Mann and associates the changes in the blood creatinine after removal of the liver depend entirely on the kidneys. If the kidneys are active the blood creatinine does not change. If the kidneys are removed as well, or the animal becomes anuric, the creatinine increases in the blood at the same rate as when only the kidneys are removed. The creatine behaves in a similar manner. The liver would therefore appear to take no specific part in the creatinine-creatine relationship.

Creatinine crystallizes in colorless, glistening, monoclinic prisms (Fig. 231) which are soluble in about 12 parts of cold water; they are more soluble in warm water and in warm alcohol. It forms salts only with strong mineral acids. One of the most important and interesting of the compounds of creatinine is creatinine-zinc chloride, $(C_4H_7N_3O)_2ZnCl_2$, which is formed from an alcoholic solution of creatinine upon treatment with zinc chloride in acid solution. Creatinine has the power of reducing cupric hydroxide in alkaline solution and of forming an insoluble

cuprous-creatinine salt, and in this way may interfere with the determination of sugar in the urine. Creatinine does not reduce alkaline bismuth solutions and therefore does not interfere with Nylander's and Boettger's tests.

Creatine. Creatine occurs in very small amounts in the urine of normal adults but is found in larger amounts in that of children and of pregnant women. The amount is increased in fasting. Increased amounts have been found associated with malnutrition and disintegration of muscular tissue, in fever, and in carcinoma of the liver. The presence of readily detectable amounts of creatine in the urine is called *creatinuria*.

Creatine in the diet does not normally appear as either extra creatinine or creatine in the urine, being apparently incorporated by the body in its total supply of creatine where it undergoes metabolism at the same rate as that already present. The fact that ingestion of a gram or so of creatine does not normally lead to any change in urinary creatinine or creatine is used clinically in the so-called "creatine tolerance test"; in certain diseases involving muscular tissue chiefly, ingestion of creatine is followed by the appearance of extra creatine in the urine, i.e., the patient's "tolerance" for creatine is decreased. Creatine occurs in all tissues, but in much greater amount in the muscular tissues than elsewhere. The average adult human body contains about 100 g. of creatine, largely if not entirely in the form of phosphocreatine.

Creatine is synthesized in the animal body. The mechanism of this synthesis resisted elucidation for many years, finally yielding to the application of isotopes and the tissue slice technique, through the work of Schoenheimer, du Vigneaud, Borsook, and their collaborators. While other reactions may not be entirely excluded, these investigators have shown that the major processes in the biological synthesis of creatine are as follows:

Thus the synthesis involves the amino acids glycine and arginine in the reaction of transamidination, and a source of labile methyl groups in the transmethylation reaction; the latter may involve either the amino acid methionine or the substance choline. In this connection it is of interest that while glycine is readily synthesized by man, it cannot be synthesized by the chick and is ordinarily required in the diet but may be replaced there by creatine. Of interest also is the clinical observation that in myasthenia gravis the feeding of glycine leads to an increased excretion of creatine. The intermediate compound guanidino-acetic acid is found in normal urine to the extent of about 20 mg. per day.

Creatine is fairly soluble in water but the aqueous solution is unstable, the creatine being gradually transformed to its anhydride creatinine by ring closure after the splitting off of water. This process is accelerated by heat and acid, and this is the basis of the usual procedures for the detection or determination of creatine, the creatine being converted into creatinine and tested for as the latter compound. There is no satisfactory direct test reaction for creatine itself.

EXPERIMENTS ON CREATININE AND CREATINE

1. Preparation of Pure Creatinine from Urine (Folin-Benedict): To 10 liters of undecomposed urine in a large precipitating jar add with stirring a hot solution of 180 g. of picric acid in 450 ml. of boiling alcohol. Allow to stand overnight and syphon off the supernatant fluid. Pour the residue upon a large Buchner funnel, drain with suction, wash once or twice with cold saturated picric acid, and suck dry. Treat the dry or nearly dry picrate in a large mortar or evaporating dish with enough concentrated HCl to form a moderately thin paste (about 60 ml. of acid for each 100 g. of picrate) and stir the mixture thoroughly with the pestle for three to five minutes. Filter with suction on a hardened paper, and wash the residue twice with enough water to cover it, sucking as nearly dry as possible each time. Transfer the filtrate to a large flask and neutralize with an excess of solid magnesium oxide (the "heavy" variety is best). Add this oxide in small portions with cooling of the flask under running water between the additions. Neutralization of the acid will be indicated by a bright yellow color of the mixture, or litmus paper may be used to test it. Filter with suction. Wash the residue twice with water. Immediately add a few ml. of glacial acetic acid to the filtrate to make it strongly acid. Neglecting any precipitate that may form, dilute the solution with about 4 volumes of 95 per cent alcohol. After 15 minutes filter off the slight precipitate which forms. Treat the final filtrate with 30 to 40 ml. of 39 per cent zinc chloride. Stir and let stand overnight in a cool place. Pour off the supernatant liquid and collect the creatinine zinc chloride on a Buchner funnel, wash once with water, then thoroughly with 50 per cent alcohol, finally with 95 per cent alcohol and dry. A nearly white, light crystalline powder should be obtained. The yield should be 90 to 95 per cent of the original creatinine (usually about 1.5 to 1.8 g. of creatinine zinc chloride per liter of urine).

Recrystallize the creatinine zinc chloride by treating 10 g. with 100 mi. of water and about 60 ml. of normal sulfuric acid, heating the mixture until a clear solution is obtained. Add about 4 g. of purified animal charcoal, continue boiling for about a minute, filter with suction through a small Buchner funnel, pouring the filtrate back on the filter three or four times until it runs through perfectly colorless. Wash the residue with hot water and transfer the total filtrate to a beaker and while hot treat with a little atrong zinc chloride solution (3 ml.) and with about 7 g. of potassium acetate dissolved in a little water. After 10 minutes dilute with an equal volume of alcohol, and allow to stand in a cold place for some hours. Filter off the crystalline product and examine under a microscope (see Fig. 232).

To remove the small amount of potassium sulfate which it contains stir up with its weight of water, filter, wash with a little water and then with

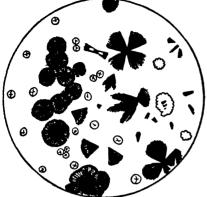

Fig. 232. Creatinine zinc chloride (Salkowski).

alcohol. The preparation should be snow white. Yield, 85 to 90 per cent.

For the decomposition of the creatinine zinc chloride Gaebler suggests the following modification of the original procedure. Place 32 g. creatinine zinc chloride in a pressure bottle (a citrate of magnesia bottle will serve) and add 225 to 250 ml. of concentrated ammonia. Close the bottle and heat in a water bath at 70° to 80°, shaking to effect solution. Cool quite rapidly to room temperature and then in a salt-ice bath. Pure creatinine crystallizes out. Filter. Wash with ice-cold ammonia, then with acetone and dry. The yield should be 75 per cent (15 g. of creatinine). The product is perfectly pure and can be used as a standard in the quantitative determination of creatine and creati-

nine. See the chapters on quantitative analysis of urine and blood.

- Nitroprusside Test (Weyl): Take 5 ml. of urine in a test tube, add a few drops of sodium nitroprusside, and render the solution alkaline with NaOH solution. A ruby-red color results which soon turns yellow. See Legal's test for acetone, Chapter 29.
- 3. Nitroprusside-Acetic Acid Test (Salkowski): To the yellow solution obtained in Weyl's test above, add an excess of acetic acid and apply heat. A green color results and is in turn displaced by a blue color. A precipitate of Prussian blue may form.
- 4. Picric Acid Reaction (Jaffe): Place 5 ml. of urine in a test tube, add an aqueous solution of picric acid, and render the mixture alkaline with NaOH solution. A red color is produced which turns yellow if the solution be acidified. Glucose gives a similar red color but only upon the application of heat. This color reaction observed when creatinine in alkaline solution is treated with picric acid is the basic principle of Folin's colorimetric method for the quantitative determination of creatinine (see Chapter 32) and is due to the formation of a red tautomer of creatinine picrate. The production of this tautomer is "dependent upon the formation of a salt, a keto-enol change within the creatinine molecule, and a change in the picric acid molecule involving the hydrogens in the meta positions and, probably, all three nitro groups."
- 5. Preparation of Creatine: Creatine may be prepared from creatinine zinc chloride by decomposition with calcium hydrate, the process being one of hydrolysis (Denedict).

100 g. of creatinine zinc chloride are treated with about 700 ml. of water in a large casserole and the mixture heated to boiling; 150 g. of pure powdered calcium hydrate are then added, with stirring, and the mixture boiled gently for 20 minutes (with occasional stirring). The hot mixture is then filtered with suction, the residue being washed with hot water. The filtrate is then treated with hydrogen sulfide gas for a few minutes and poured through a folded filter to remove the zinc. The filtrate is acidified by the addition of about 5 ml. of glacial acetic acid and boiled down rapidly to a volume of about 200 ml. This solution is allowed to stand overnight, preferably in a cool place. The next day the crystallized creatine is filtered off with suction, washed with a very little cold water, and then thoroughly washed with alcohol and dried. This product is then recrystallized by dissolving in about seven times its weight of boiling water and allowing the

solution to cool slowly and stand for some hours. This product should be perfectly pure creatine. If necessary it can be recrystallized with very little loss. The crystallized product should be filtered off, washed with alcohol and ether, and dried in air for about half an hour. Thus obtained, the creatine contains water of crystallization which it loses very readily upon exposure to air. To prepare creatine which can be weighed with absolute exactness it is necessary to dehydrate this product by heating for some hours at about 95°.

The yield in this process is about 18 g. of recrystallized creatine, and about 55 g. of creatinine zinc chloride recovered. Longer boiling with lime does not bring about a greater yield, as after the 20-minute point creatine is decomposed almost exactly as fast as it is formed.

Examine the crystals of creatine under the microscope and compare with illustration in Chapter 10, Muscular Tissue, in which may be found other creatine tests.

ETHEREAL SULFATES

The most common ethereal sulfates found in the urine are phenol-sulfuric acid, p-cresolsulfuric acid, indoxylsulfuric acid, and skatoxylsulfuric acid. Pyrocatecholsulfuric acid also occurs in traces in human urine. The total output of ethereal sulfuric acid (as S) varies ordinarily from 0.04 to 0.1 g. for 24 hours and comprises 5 to 15 per cent of the total sulfur. In health the ratio of ethereal sulfuric acid to inorganic sulfuric acid is about 1:10. These ethereal sulfuric acids originate in part from the phenol, cresol, indole, and skatole formed in the putrefaction of protein material in the intestine. The phenol passes to the liver where part of it is conjugated to form phenol potassium sulfate and appears in this form in the urine, whereas the indole and skatole undergo a preliminary oxidation to form indoxyl and skatoxyl respectively before their conjugation and elimination. (See Chapter 20.)

It was formerly generally considered that each of the ethereal sulfuric acids was formed principally in the putrefaction of protein material in the intestine and that therefore a determination of the total ethereal sulfuric acid content of the urine was an index of the extent to which these putrefactive processes were proceeding within the organism. Folin, however, showed that the ethereal sulfuric acid content of the urine did not afford an index of the extent of intestinal putrefaction, since these compounds arise only in part from putrefactive processes. He claimed that the ethereal sulfuric acid excretion represented a form of sulfur metabolism which is more in evidence when the diet contained little or no protein. The ethereal sulfuric acid content of the urine diminishes as the total sulfur content diminishes, but the percentage decrease is much less. Therefore, relative to the total sulfuric acid content, the ethereal sulfuric acid content is increased, although the total sulfuric acid content is diminished. The indoxylsulfuric acid (indican) content of the urine does not originate to any degree from the tissue catabolism of protein material but arises in great part from the action of intestinal putrefactive organisms on tryptophane (see Chapter 20). The excretion of indoxylsulfuric acid

which occurs in the urine as the potassium salt

may alone be taken as a rough index of the extent of putrefactive processes within the intestine and is clinically the most important of the ethereal sulfuric acids. Under normal conditions, from 4 to 20 mg. of indican are excreted per day. The variations are due mainly to diet, a high meat diet causing an increase and a carbohydrate diet a decrease. Pathologically, the greatest increases are found in disorders involving increased putrefaction and stagnation of intestinal contents. Bacterial decomposition of body protein as in gangrene, putrid pus formation, etc., gives rise to an increased indican excretion.

Phenols are excreted chiefly in the conjugated form. The phenol output tends to vary directly but not proportionally with the protein ingestion. The total phenol excretion of normal men on an ordinary mixed diet averages around 0.2 g. per day.

Tests for Indican³

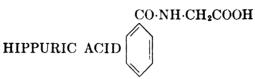

1. Jaffe's Test: Nearly fill a test tube with a mixture composed of equal volumes of concentrated HCl and the urine under examination. Add 2 to 3 ml. of chloroform and a few drops of a calcium hypochlorite solution, place the thumb over the end of the test tube and rock the tube back and forth, inverting at least 10 times. The chloroform is more or less colored, according to the amount of indican present. Ordinarily a blue color due to the formation of indigo-blue is produced; less frequently a red color due to indigo-red may be noted.

Repeat this test on some of this same urine to which formaldehyde has been added. Is there any variation in the reaction from what you previously obtained?

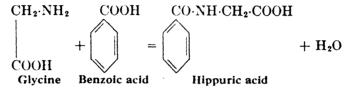

The following represents the reaction:

The urine should always be examined fresh if this is possible. In any event formaldehyde should never be used as a preservative for such urines as are to be examined for indican by means of any test involving hypochlorite or potassium permanganate. The formaldehyde through its reducing power lowers the oxidizing efficiency of the mixture. The formation of formic acid from the aldehyde may also interfere.

2. Obermayer's Test: Nearly fill a test tube with a mixture composed of equal volumes of Obermayer's reagent' and the urine under examination. Add 2 to 3 ml. of chloroform, place the thumb over the end of the test tube, and rock the tube back and forth, inverting at least 10 times. How does this compare with Jaffe's test?

This acid occurs normally in the urine of both carnivora and herbivora, but it is much more abundant in the urine of the latter. It is formed by the union of benzoic acid with glycine according to the following reaction:

In the dog this conjugation takes place exclusively in the kidneys, but in man and in the rabbit it is probable that the liver is the main site of this

Fig. 233. Hippuric acid.

synthesis. Clinically the ability of an individual to synthesize hippuric acid after administration of a test dose of benzoate is used as an index of liver function. Glycine is readily produced by the body from the hydrolysis of dietary or tissue protein, or may be synthesized from certain other amino acids, e.g., serine. Benzoic acid originates ordinarily either from intestinal putrefaction, i.e., from the abnormal metabolism of tyrosine and phenylalanine, or from the food. Many vegetables, fruits and grasses

⁴ See Appendix.

contain small quantities of preformed benzoic acid and larger amounts of quinic acid and other compounds which in the body are converted to benzoic acid. It has been found that approximately 2 g. of benzoic acid are excreted as hippuric acid after eating 250 g. of prunes. The average excretion of hippuric acid by an adult man for 24 hours under normal conditions is about 0.7 g. Hippuric acid crystallizes in needles or rhombic prisms (see Fig. 233), the particular form depending upon the rapidity of crystallization. Pure hippuric acid melts at 187° C. It is easily soluble in alcohol or hot water. It is sufficiently soluble in ether to allow its extraction from aqueous solution with this solvent. (For the quantitative determination of hippuric acid, see Chapter 32.)

EXPERIMENTS ON HIPPURIC ACID

1. Separation from the Urine: (See Chapter 32.)

2. Melting Point: Determine the melting point of the hippuric acid prepared

in the above experiment (see p. 725).

3. Formation of Nitrobenzene (Lücke's Reaction): To a little hippuric acid in a small porcelain dish add 1 to 2 ml. of concentrated HNO, and evaporate to dryness on a water bath. Transfer the residue to a dry test tube, apply heat, and note the odor of nitrobenzene (resembling that of oil of bitter almonds).

4. Sublimation: Place a few crystals of hippuric acid in a dry test tube and apply heat. The crystals are reduced to an oily fluid which solidifies in a crystalline mass upon cooling. When stronger heat is applied the liquid assumes a red color and finally yields a sublimate of benzoic acid and the odor of hydrocyanic acid.

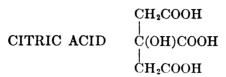

OXALIC ACID COOH

Oxalic acid is a constituent of normal urine, about 15 to 20 mg. being eliminated in 24 hours. It separates out from neutral or alkaline urine as the insoluble crystalline calcium oxalate, in the form of either dumbbells or octahedra, usually the latter (see Fig. 241). Many urinary calculi consist largely of calcium oxalate. The origin of the oxalic acid content of the urine is not well understood. When ingested it is eliminated, at least in part, unchanged. Since many common articles of diet, e.g., asparagus, apples, cabbage, grapes, lettuce, rhubarb, spinach, tomatoes, etc., contain oxalates (or precursors) it seems probable that they are responsible for most of the oxalic acid found in the urine. There is also experimental evidence that part of the oxalic acid of the urine is formed within the organism in the course of protein and fat metabolism. It has also been suggested that oxalic acid may arise from an incomplete combustion of carbohydrates, especially under certain abnormal conditions. In this connection it is of interest that oxalic acid is one of the end-products of in vitro oxidation of ascorbic acid. Pathologically, urinary oxalic acid is increased in diabetes mellitus, in organic diseases of the liver, and in various other conditions which are accompanied by a derangement of the oxidative mechanism. An abnormal increase in oxalic acid excretion is termed oxaluria and may be unaccompanied by any other apparent symptom.

Oxaluric acid (NH₂·CO·NH·CO·COOH) is occasionally found in traces in normal human urine. On hydrolysis it yields oxalic acid and urea.

EXPERIMENT ON OXALIC ACID

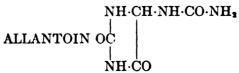

Precipitation of Calcium Oxalate: Place 200 to 250 ml. of urine in a beaker, add 5 ml. of a saturated solution of calcium chloride, make the urine slightly acid with acetic acid, and stand the beaker in a cool place for 24 hours. Examine the sediment under the microscope and compare the crystalline forms with those shown in Fig. 241, Chapter 30.

Citric acid occurs in normal urine, about 300-1500 mg. in 24 hours' excretion, being higher in women than in men. An enzyme, citrogenase, found in the kidney, heart, and liver can form citric acid by condensation of pyruvic and oxalacetic acids. A marked increase in citric acid excretion following hepatectomy denotes its function in intermediary metabolism. A rise in citric acid output occurs between menstrual periods paralleling a rise in urine calcium; a rise also follows administration of estrogens (Shorr). Measures to increase urinary citrate content have been applied clinically in treating urinary calculus formation from insoluble calcium salts since citrate forms a soluble complex with calcium.

NEUTRAL SULFUR COMPOUNDS

Under this head may be classed such substances as cystine, methyl mercaptan, ethyl sulfide, thiocyanates, taurine derivatives, etc. The sulfur content of the compounds just enumerated is generally termed unoxidized or neutral sulfur in order that it may not be confused with the acid or oxidized sulfur which occurs in the inorganic sulfuric acid and ethereal sulfuric acid forms, although this distinction is admittedly inexact. Ordinarily the neutral sulfur content of normal human urine is 5 to 25 per cent of the total sulfur content (see Partition of Urinary Sulfur, Chapter 32). The actual amount excreted may be 0.08 to 0.16 g. per day, calculated as S. Its origin is mainly endogenous. The excretion is fairly constant for any given individual in spite of dietary changes. In tuberculosis, cancer, cystinuria, etc., the amount may be relatively or absolutely increased. (See p. 153 for test for cystine and cysteine sulfur.)

Allantoin is found in the urine of practically all mammals including man. In human urine it occurs in very small amounts (5 to 15 mg. per day) whereas in all other mammals except anthropoid apes, and the Dalmatian

coach dog, it is the principal end-product of purine metabolism and may constitute 90 per cent or over of the total purine output. Allantoin is present in the urine of surgical maggots and appears to be partly responsible for the successful results in the healing of wounds by maggot treatment. Allantoin is formed upon oxidation of uric acid by the enzyme uricase and the output is increased by the feeding of thymus or pancreas to lower animals. The presence of only traces of allantoin in the urine of certain mammals may be due to the absence or inactivity of the uricase at the site of localization of urate ions. In the dog, according to Mann and associates, the liver is the sole seat of uric acid destruction. After hepatectomy the uric acid excretion is equivalent to the allantoin output of the normal animal. When pure, allantoin crystallizes in prisms (Fig. 234), and when impure in granules and knobs. Pathologically, it has been found increased in diabetes insipidus and in hysteria with convulsions (Pouchet).

EXPERIMENTS ON ALLANTOIN

1. Separation from the Urine: Meissner's Method: Precipitate the urine with baryta water. Neutralize the filtrate carefully with dilute sulfuric

Fig. 234. Allantoin, from cat's urine. (a and b) Forms in which it crystallized from the urine, (c) recrystallized allantoin.

acid, filter immediately, and evaporate the filtrate to incipient crystallization. Completely precipitate this warm fluid with 95 per cent alcohol (reserve the precipitate). Decant or filter and precipitate the solution by ether. Combine the ether and alcohol precipitates and extract with cold water or hot alcohol; aliantoin remains undissolved. Bring the aliantoin into solution in hot water and recrystallize.

 Preparation from Uric Acid: Dissolve 4 g. of uric acid in 100 ml. of water rendered alkaline with potassium hydroxide. Cool and carefully add 3 g. of potassium permanganate. Filter, immediately acidulate the filtrate with acetic acid, and allow it to stand in a cool place overnight. Filter off

The urine of the dog after thymus, pancreas, or uric acid feeding may be employed.

the crystals and wash them with water. Save the wash water and filtrate, unite them, and after concentrating to a small volume stand away for crystallization. Now combine all the crystals and recrystallize them from hot water. Use these crystals in the experiments which follow.

3. Microscopical Examination: Examine the crystals made in Exp. 2 and com-

pare them with those shown in Fig. 234.

4. Furfural Test (Schiff): Place a few crystals of allantoin on a test tablet or in a porcelain dish and add 1 to 2 drops of a concentrated aqueous solution of furfural and 1 to 2 drops of concentrated hydrochloric acid. Observe the formation of a yellow color, which turns to a light purple if allowed to stand. This test is given by urea but not by uric acid.

5. Murexide Test: Try this test according to the directions given on p. 730.

Note that allantoin fails to respond.

AMINO ACIDS

Certain of these acids are always present in normal urine. The excretion of total amino acid nitrogen by a normal adult averages 0.4 to 1.0 g. per day or about 2 to 6 per cent of the total nitrogen. Free amino acid nitrogen (for methods of estimation, see Chapter 32) is considerably less than this, and ordinarily constitutes 0.5 to 1 per cent of the total nitrogen. The amount may be largely increased in disorders associated with tissue waste, e.g., typhoid, acidosis, pronounced atrophy of the liver, etc. After extirpation of the liver urea formation ceases and amino acids accumulate in the blood or are excreted in the urine if renal activity is maintained. For tests on amino acids, see Chapter 4.

AROMATIC OXYACIDS

Two of the most important of the oxyacids are p-hydroxyphenylacetic acid, HOC₆H₄CH₂COOH and p-hydroxyphenylpropionic acid, HOC₆H₄-CH₂CH₂COOH. They are products of the putrefaction of protein material and tyrosine is an intermediate stage in their formation. Both these acids for the most part pass unchanged into the urine, where they occur normally in very small amount. The content may be increased in the same manner as the phenol content, in particular by acute phosphorus poisoning. A fraction of the total aromatic oxyacid content of the urine is in combination with sulfuric acid, but the greater part is present in the form of salts of sodium and potassium.

Levine has shown that the urine of premature infants fed cow milk regularly contains certain aromatic oxyacids, such as *p-hydroxyphenyl-pyruvic acid*. Administration of vitamin C abolishes this defect. A similar picture, likewise responding to Vitamin C, has been noted by Sealock in the case of scorbutic guinea pigs.

Homogentisic acid or 2,5-dihydroxyphenylacetic acid,

is another important oxyacid sometimes present in the urine. Under the name glycosuric acid it was first isolated from the urine by Marshall; subsequently Baumann isolated it and determined its chemical constitution. It occurs in cases of alcaptonuria and has also been found in the urine of the scorbutic guinea pig. A urine containing this oxyacid turns greenish-brown from the surface downward when treated with a little sodium hydroxide or ammonia. If the solution be stirred the color very soon becomes dark brown or even black. Homogentisic acid reduces alkaline copper solutions but not alkaline bismuth solutions.

Hydroxymandelic acid or p-hydroxyphenylglycolic acid, HOC₆H₄-CH(OH)·COOH has been detected in the urine in cases of yellow atrophy of the liver.

Kynurenic acid or γ -hydroxy- β -quinoline carboxylic acid is a product of the metabolism of tryptophane but it appears to be excreted only after the ingestion of this amino acid in excess of normal requirements.

Its presence after tryptophane administration in the urine of the dog, rat, rabbit, hyena, coyote, wolf, etc., and absence from that of the civet, cheetah, bear, racoon, etc. (Jackson) may have significance in the zoological classification of species.

EXPERIMENT ON KYNURENIC ACID

Isolation of Kynurenic Acid: Acidify the urine with hydrochloric acid in the proportion 1:25. From this acid fluid both the uric acid and the kynurenic acid separate in the course of 24 to 48 hours. Filter off the combined crystalline deposit of the two acids, dissolve the kynurenic acid in dilute ammonia (uric acid is insoluble), and reprecipitate it with hydrochloric acid. If a solution containing kynurenic acid be evaporated to dryness with hydrochloric acid and potassium chlorate, a reddish residue is obtained which becomes first brownish green and then emerald green on adding ammonia (Jaffé).

Kynurenic acid may be quantitatively determined by Capaldi's method.

PROTEIN

The nubecula of normal urine has been shown by one investigator to consist of a mucoid containing 12.7 per cent of nitrogen and 2.3 per cent of sulfur. This substance evidently originates in the urinary passages. It is probably slightly soluble in the urine. Some investigators believe that the material forming the nubecula of normal urine is nucleoprotein and not a mucin or mucoid. A discussion of nucleoprotein and related substances occurring in the urine under pathological conditions will be found in Chapter 29.

⁶ Capaldi: Z. physiol. Chem., 23, 92 (1897); Berg: J. Biol. Chem., 91, 513 (1931).

Normal urine contains a small amount of soluble protein (albumin, various enzymes (see below), etc.); the amount is too slight to be detected by any but the most delicate procedures. The significance of pathological proteinuria is discussed in Chapter 29.

CARBOHYDRATES

Normal human urine contains total reducing substances equivalent to about 0.05 to 0.15 per cent of glucose. Fermentable sugars make up about one-tenth of this or about 0.01 per cent. Whether all of the fermentable sugar is glucose is uncertain. Most of the sugar of normal urine is at any rate not glucose. The other sugars may include pentose, lactose, and altered carbohydrates formed by the baking of foods or through the action of bacteria in the intestinal tract. That glucose is not ordinarily excreted in more than traces is further indicated by the failure of glucose ingestion up to 1 g. per kg. of body weight to increase the fermentable urine sugar. In various types of nephritis the excretion of fermentable sugar is increased somewhat. Lactose may be found in the urine of pregnant women in appreciable amounts. In the rare conditions known as pentosuria and fructosuria these respective sugars may be present in readily detectable amount. Otherwise sugars are not normally found in sufficient amounts to give the ordinary sugar tests. Pathological glucosuria is discussed in Chapter 29.

ENZYMES

Various types of enzymes produced within the organism are excreted in both the feces and the urine. In this connection it is interesting to note that pepsin, trypsin, lipase, and an amylase have been positively identified in the urine. The amylase may be much increased in pancreatic disease.

VITAMINS

The normal path of elimination of the fat-soluble vitamins is the intestinal tract. The water-soluble vitamins thiamine, riboflavin, ascorbic acid, and others, are excreted in the urine under normal conditions of vitamin nutrition, the amounts of these vitamins in the 24-hour excretion being directly proportional to the intake. Nicotinamide is normally eliminated in the form of the metabolite N¹-methylnicotinamide. The urinary output of the water-soluble vitamins under controlled conditions forms the basis of clinical tests for vitamin deficiencies, since in such states the tissues are unsaturated and tend to retain the test doses of vitamins. Typical amounts of water-soluble vitamins excreted by normal adult males on an average American diet are shown below:

Thiamine	0.2-0.4 mg, per 24 hours
Riboflavin	0.5-0.8 mg. per 24 hours
Ascorbic acid	
Nicotinamide (in the form of N ¹ -methylnicotinamide)	3-7 mg, per 24 hours

¹ Dodds: Brit. J Exptl. Path., 3, 133 (1922).

VOLATILE FATTY ACIDS

Acetic, butyric, and formic acids have been found under normal conditions in the urine of man and of certain carnivora as well as in the urine of herbivora. Normally they arise principally from the fermentation of carbohydrates and the putrefaction of proteins. The acids containing the fewest carbon atoms (formic and acetic) are found to be present in larger percentage than those which contain a larger number of such atoms. The volatile fatty acids occur in normal urine in traces, the total output for 24 hours according to older investigators varying from 0.008 g. to 0.05 g. Formic acid excretion is increased in methyl alcohol poisoning.

LACTIC ACID

Lactic acid, CH₃·CHOH·COOH, is supposed to pass into the urine when the supply of oxygen in the organism is diminished through any cause, e.g., in pneumonia, eclampsia, acute yellow atrophy of the liver, carbon-monoxide poisoning, acute phosphorus poisoning, or epileptic attacks. This acid has also been found in the urine of healthy persons following the physical exercise incident to prolonged marching. Liljestrand and Wilson found the output of lactic acid to vary from 140 mg. to 1370 mg. after a few minutes of strenuous physical exercise (stair running). (See experiment, Chapter 33.) Lactic acid has been detected in the urine of birds after the removal of the liver.

PHOSPHORIZED COMPOUNDS

Phosphorus in organic combination has been found in the urine in such substances as glycerophosphoric acid, which may arise from the decomposition of lecithin, and phosphocarnic acid. It is claimed that on the average about 2.5 per cent of the total phosphorus elimination is in organic combination.

PIGMENTS

There are several pigments normally present in human urine, of which the most important are urochrome and urobilin.

Urochrome. Urochrome is the principal pigment of normal urine. Its chemical nature is not definitely established. It appears to be a compound of urobilin and urobilinogen with a peptide substance. It is a product of endogenous metabolism and is fairly constant in amount from day to day in the urine of normal individuals. Tryptophane and a metabolic derivative, kynurenine, are said to be precursors of urochrome. That its amount is proportional to the intensity of endogenous metabolism is indicated by the fact that there is an increase in hyperthyroidism, in fasting, and in fevers. It is increased by acid and decreased by alkali administration.

Urobilin. Urobilin is normally present in too small amount to give any appreciable color to the urine. It exists chiefly in the reduced form as the colorless urobilinogen which upon oxidation gives urobilin. (See Chapter 18.) It is derived from bile pigment by bacterial action in the bowel and most of it is excreted in the feces where the corresponding

and probably identical compounds are known as stercobilinogen and stercobilin, respectively. Of the small amount absorbed the larger part is excreted in the bile. In liver disease the excretion is often interfered with and the amount of urobilinogen in the urine is increased. This fact is of diagnostic importance. (For quantitative determination, see Chapter 32.) Urobilin is readily soluble in alcohol and slightly so in water. It gives a characteristic absorption spectrum.

EXPERIMENT ON URINARY PIGMENT

Ammoniacal Zinc Chloride Test: Render some of the urine ammoniacal by the addition of ammonium hydroxide, and after allowing it to stand a short time filter off the precipitate of phosphates and add a few drops of zinc chloride solution to the filtrate. Observe the production of a greenish fluorescence. Examine the fluid by means of the spectroscope and note the absorption band which occupies much the same position as the absorption band of urobilin in acid solution (see Absorption Spectra, Plate 1).

PURINE BASES

The purine bases found in human urine are adenine, epiguanine (7-methyl guanine), guanine, xanthine, heteroxanthine (7-methylxanthine), hypoxanthine, paraxanthine (1,7-dimethylxanthine), and 1-methylxanthine. The main bulk of the purine base content of the urine is made up of 7-methylxanthine, 1,7-dimethylxanthine, and 1-methylxanthine, which are derived for the most part from the caffeine, theobromine, and the ophylline of the food. The total purine base content is made up of the products of two distinct forms of metabolism, i.e., metabolism of ingested nucleoproteins and purines and metabolism of tissue nuclear material. Purine bases resulting from the first form of metabolism are said to be of exogenous origin, whereas those resulting from the second form of metabolism are said to be of endogenous origin. The daily output of purine bases by the urine is extremely small and varies greatly with the individual (16 to 60 mg.). The output is increased after the ingestion of nuclear material as well as after the increased destruction of leukocytes. A well-marked increase accompanies leukemia. The output of purine bases by the urine is increased as a result of x-ray treatment. The purine bases form a higher percentage of the total purine excretion in the case of the monkey, sheep, and goat than in man.

EXPERIMENT ON PURINE BASES

Formation of the Silver Salts: Add an excess of magnesia mixture⁵ to 25 ml. of urine. Filter off the precipitate and add ammoniacal silver solution to the filtrate. A precipitate composed of the silver salts of the various purine bases is produced. The purine bases may be determined quantitatively by Kruger and Schmidt's method or Welker's method (see Chapter 32).

2. INORGANIC PHYSIOLOGICAL CONSTITUENTS

AMMONIA

Next to urea, ammonia is quantitatively the most important of the nitrogenous end-products of protein metabolism. Ordinarily about 2.5

to 4.5 per cent of the total nitrogen of the urine is eliminated as ammonia, and on the average this would be about 0.7 g, per day. The significance of the ammonia content of the urine appears to be primarily if not entirely concerned with the mechanisms of acid-base balance in the body (see Chapter 24). If ammonia is fed in the form of oxidizable organic salts. such as ammonium acetate, ammonium lactate, etc., no extra ammonia appears in the urine. The organic portion of the salt is oxidized, and the ammonia portion is converted into urea and excreted in this form. If, however, a nonoxidizable salt such as ammonium chloride is administered. while the ammonia portion is probably also converted into urea for excretion, since there is no reason to suppose that the metabolism of the ammonium ion differs with different salts, the excretion of the extra chloride ions requires the simultaneous excretion of an equivalent amount of base. This base must be either sodium, potassium, or ammonium ions themselves, since these are the only forms of base available to the kidney. In the presence of abundant sodium or potassium ("fixed base"), the extra chloride is excreted largely as the sodium or potassium salt and no disturbance of acid-base balance results. If, however, the supply of fixed base is limited, its excretion results in the development of an acidosis due to the depletion of body base: in fact, the administration of a large dose of ammonium chloride is used clinically for the production of an acidosis. The kidney therefore synthesizes ammonia ("volatile base") to the limit of its capacity under these conditions to conserve body base, the extra ammonia is excreted in the urine, and the urinary ammonia content rises. Excretion of acid phosphate also occurs here (see p. 749). That the ingested ammonia of the ammonium chloride plays no important part in the increased excretion of ammonia is shown by the fact that exactly the same condition occurs if hydrochloric acid is administered instead of ammonium chloride; there is a rise of urinary ammonia accompanying the increased excretion of chloride. Acid-forming foods (see Chapter 34) also increase the ammonia output, whereas the administration of alkalies or of base-forming foods decreases the excretion of ammonia. Copious water drinking increases the ammonia output. This fact has been interpreted as indicating a stimulation of the gastric secretion.

The acids formed during the process of protein destruction within the body (i.e., sulfuric acid formed by oxidation of the sulfur of methionine and cystine) have an influence upon the excretion of ammonia similar to that exerted by acids which have been administered. Therefore a pathological increase in the output of ammonia is observed in such diseases as are accompanied by an increased and imperfect protein metabolism. Likewise in diabetes mellitus, where the excretion of excessive amounts of acetoacetic acid and β -hydroxybutyric acid as their salts also tends to deprive the body of fixed base, increased excretion of ammonia occurs.

As Nash and Benedict showed, the kidney is the source of urinary ammonia. This is indicated by the fact that following extirpation of the kidneys the blood ammonia does not increase. On removal of the liver blood ammonia increases but not urinary ammonia. This indicates

that the two have not the same origin. The blood ammonia appears to arise from the tissues, especially the muscles (probably from the deamination of adenylic acid) and to be converted so readily to urea that the blood ammonia remains too low to account for any appreciable part of the urinary ammonia. Ammonia is apparently formed by the cells of the tubules of the kidney. The precursor is believed to be an amide-nitrogen compound, probably glutamine, in blood plasma (Van Slyke). Deamination of amino acids by kidney tissue may also account for a small portion, possibly through the intermediate formation of glutamine. A decrease in the pH of the blood or of the kidney tissue seems to speed up the ammonia-producing mechanism.

The quantitative determination of ammonia must be made upon fresh or properly preserved urine, since upon standing normal urine will undergo ammoniacal fermentation (see p. 717).

EXPERIMENT ON AMMONIA

(See Exp. 2 under Phosphates, p. 751.)

SULFATES

Sulfur in combination is excreted in two forms in the urine: first, as unoxidized, loosely combined or neutral sulfur, and second, as oxidized or acid sulfur. The excretion of neutral sulfur has already been discussed (p. 739). The oxidized sulfur is eliminated chiefly in the form of the inorganic sulfate ion; a relatively small amount occurs in the form of ethereal sulfate; i.e., salts of sulfuric acid in combination with such aromatic substances as phenol, indole, skatole, cresol, pyrocatechol, and hydroquinol. This latter form of sulfuric acid is sometimes called conjugate sulfuric acid. The greater part of the total sulfur is eliminated in the oxidized form, but the absolute percentage of sulfur excreted in the various forms depends upon the total quantity of sulfur present; i.e., there is no definite ratio between the three forms of sulfur which will apply under all conditions. The preformed or inorganic sulfuric acid may be precipitated directly from acidified urine with BaCl₂, whereas the ethereal sulfuric acid must undergo a preliminary hydrolysis before it can be so precipitated.

The sulfuric acid excreted in the urine arises principally from the oxidation of the sulfur of protein within the body; a relatively small amount is due to ingested sulfates. Under normal conditions about 1.0 g. of total S is eliminated daily, about 75 to 95 per cent of this being in the form of sulfates. About 90 per cent of this sulfate excretion is in the form of inorganic sulfate and 10 per cent as ethereal sulfates.

The sulfate ion is excreted with greater difficulty than any other inorganic radical ordinarily present in normal blood. A retention of 30 times the normal blood value (0.5 to 1.0 mg. of S per 100 ml. of whole blood) has been observed. Sulfate ions are not readily absorbed by the tissues even when present in high concentration in the blood.

Pathologically, the excretion of sulfate by the urine is increased in acute fevers and in all other diseases marked by a stimulated metabolism,

whereas a decrease in the sulfate excretion is observed in those diseases which are accompanied by a loss of appetite and a diminished metabolic activity.

EXPERIMENTS ON SULFATES

- Detection of Inorganic Sulfuric Acid: Place about 10 ml. of urine in a test
 tube, acidify with acetic acid, and add some barium chloride solution. A
 white precipitate of barium sulfate forms.
- 2. Detection of Ethereal Sulfuric Acid: Filter off the barium sulfate precipitate formed in the above experiment, add 1 ml. of hydrochloric acid and a little barium chloride solution to the filtrate and heat the mixture to boiling for one to two minutes. Note the appearance of a turbidity due to the presence of sulfuric acid which has been hydrolyzed from the ethereal sulfates and has reacted with BaCl₂ to form BaSO₄.
- Detection of Unoxidized or Neutral Sulfur: Place about 10 ml. of urine in a test tube, introduce a small piece of zinc, add sufficient hydrochloric acid

Fig. 235. Calcium sulfate (Hensel and Weil).

to cause a gentle evolution of hydrogen, and over the mouth of the tube place a filter paper saturated with lead acetate solution. In a short time the portion of the paper in contact with the vapors within the test tube becomes blackened due to the formation of lead sulfide. The nascent hydrogen has reacted with the loosely combined or neutral sulfur to form hydrogen sulfide, and this gas coming in contact with the lead acetate paper has caused the production of the black lead sulfide. Sulfur in the form of inorganic or ethereal sulfuric acid does not respond to this test. (For discussion of neutral sulfur compounds, see p. 739.)

4. Calcium Sulfate Crystals: Place 10 ml. of urine in a test tube, add 10 drops of calcium chloride solution, and allow the tube to stand until crystals form. Examine the calcium sulfate crystals under the microscope and compare them with those shown in Fig. 235.

CHLORIDES

Next to urea, the various chlorides constitute the chief solid constituent of the urine. The excretion of chloride is dependent, in great part, upon the nature of the diet, but, on the average, the daily output is about 10 to 15 g. expressed as sodium chloride. Conditions which favor excessive perspiration, such as strenuous athletic or occupational activity especially in a hot environment, cause a diminution in urinary output of chlorides, the chloride leaving the body by other channels. Since copious water drinking tends to increase chloride excretion, the use of salt tablets in drinking water is widely practiced as a means of preventing muscular cramps resulting from salt deficiency. Because of their solubility, chlorides are never found in the urinary sediment.

The amount of chlorides excreted in the urine is related primarily to the chloride content of the food ingested. In cases of actual fasting the chloride content of the urine may be decreased to a slight trace which is derived from the body fluids and tissues. Under these conditions, however, an examination of the blood of the fasting subject will show the content of chloride in this fluid to be approximately normal. This forms a very

striking example of the care nature takes to maintain the normal composition of the blood. There is a limit to the power of the body to maintain this equilibrium, however, and if the fasting organism be subjected to the influence of diuretics for a time, a point is reached where the normal composition of the blood can no longer be maintained and a gradual decrease in its chloride content occurs which finally results in death. Since the excreted chloride must carry base (e.g., sodium) along with it, death results not so much from the loss of chloride alone as from the inability of the organism to maintain a normal osmotic pressure in its body fluids, which is a major function of the sodium and chloride ions. Potassium cannot substitute for sodium in this respect, thus the administration of potassium chloride under these conditions is of no value whatever.

Pathologically, the excretion of chlorides may be decreased in some fevers, chronic nephritis, croupous pneumonia, diarrhea, certain stomach disorders, and in acute articular rheumatism. Any condition accompanied by the formation of an exudate (e.g., pneumonia) will cause a diminished chloride output. In convalescence and with resolution of the exudate the chloride excretion rises again.

EXPERIMENT ON CHLORIDES

Detection of Chlorides in Urine: Place about 5 ml. of urine in a test tube, render it acid with nitric acid, and add a few drops of a solution of silver nitrate. A white precipitate, due to the formation of silver chloride, is produced. This precipitate is soluble in ammonium hydroxide.

PHOSPHATES

Of the various inorganic anions of urine, phosphate is ordinarily second only to chloride in amount present. The excretion of phosphate is extremely variable, depending in large measure upon the diet, but on the average the total output for 24 hours is about 1.1 g. expressed as P. The bulk of this is in the form of inorganic phosphate, the organic phosphorus of the urine constituting only about 1 to 4 per cent of the total phosphorus content. The greater part of the inorganic phosphate arises from the ingested food, either from phosphate already present as such or more especially from the metabolism of compounds containing phosphorus in organic combination, such as phosphoproteins, nucleoproteins and nucleotides, and phospholipids. The various phosphoruscontaining compounds of the body also contribute to the total output of this element. The phosphate content of the urine also depends to a considerable extent on conditions within the intestinal lumen; an increased alkalinity together with the presence of substances like calcium and magnesium which form insoluble phosphates tends to increase the proportion of phosphate excreted in the feces at the expense of the urinary phosphate content.

The phosphate ion is found in the urine in two forms, the acid phosphate ion, H₂PO₄, and the basic phosphate ion, HPO₄. The ratio of these two ions determines in large measure the pH of the urine, since they constitute

the major buffer system ordinarily present. In blood and in the glomerular ultrafiltrate of the kidney, these ions are present in a ratio corresponding to about 80 per cent basic phosphate and 20 per cent acid phosphate. If this ratio prevails in the urine, it will have the same pH as the blood, or approximately 7.4. Increased acidity of the urine is due to an increase in the amount of the acid phosphate relative to basic phosphate: at pH 6.6. which is approximately the pH of average urine, about 60 per cent of the total inorganic phosphate is in the acid form and 40 per cent appears as basic phosphate. The best available evidence indicates that the ability of the kidney to excrete a varying fraction of its total phosphate in either the acid or basic forms is an important part of the mechanism for the regulation of acid-base balance in the body; actually, the excretion of one equivalent of acid phosphate instead of basic phosphate corresponds to the excretion of one equivalent of hydrogen ion itself, and the simultaneous retention of one equivalent of base, as inspection of the formulas of these two salts will show. In combating acidosis. this mechanism appears to be of importance second only to the ability of the kidneys to replace sodium or potassium by ammonium. Available evidence indicates that the change from acid to basic phosphate and vice versa is brought about in the renal tubules, possibly by secretion of hydrogen ions (Pitts), since the total phosphate excretion does not vary with changes in the relative amounts of the acid and basic forms excreted.

If urine containing phosphate is rendered sufficiently alkaline, the so-called "alkaline earth" elements calcium and magnesium will precipitate, to the extent of their presence, as insoluble calcium and magnesium phosphates. This fraction of the total phosphate of urine was formerly called the "earthy phosphate" fraction as contrasted to the "alkaline phosphate" fraction composed of the soluble phosphates of sodium, potassium, and ammonium. It is doubtful whether this fractionation has any significance other than to indicate the amount of calcium and magnesium present relative to the total phosphate, and it should be abandoned.

The so-called "phosphaturia," the appearance of a copious crystalline precipitate which on examination proves to be magnesium ammonium phosphate ("triple phosphate"), ordinarily represents a decreased acidity of the urine and not an increased phosphate content. Such conditions may, however, be of significance in connection with a possible tendency to the formation of phosphate calculi. Measures designed to acidify the urine, and to decrease its phosphate content, have been of value in the treatment of this condition.

Pathologically the excretion of phosphoric acid is increased in such diseases of the bones as diffuse periostosis, osteomalacia, and rickets; according to some investigators, in the early stages of pulmonary tuberculosis, in acute yellow atrophy of the liver, in diseases which are accompanied by an extensive decomposition of nervous tissue, and after sleep induced by potassium bromide or chloral hydrate (Mendel). It is also increased after copious water drinking. A decrease in the excretion of phosphates is at times noted in febrile affections, such as the acute infec-

tious diseases, in pregnancy, in the period during which the fetal bones are forming, and in diseases of the kidneys, because of nonelimination.

EXPERIMENTS ON PHOSPHATES

1. Formation of "Triple Phosphate": Place some urine in a beaker, render it slightly alkaline with ammonium hydroxide, add a small amount of magnesium sulfate solution, and allow the beaker to stand in a cool place overnight. Crystals of ammonium magnesium phosphate, "triple phosphate," form under these conditions. Examine the crystalline sediment under the microscope and compare the forms of the crystals with those shown in Fig. 236. If possible, examine the crystals from a freshly passed specimen of cloudy urine, or from a sample of urine which on standing for a short while after voiding has become cloudy. How do they compare with those obtained in this experiment?

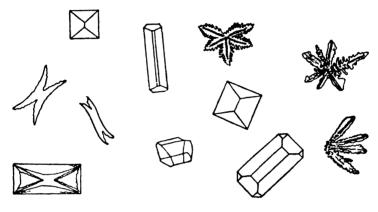

Fig. 236. Triple phosphate (Ogden).

- Ammoniacal Fermentation: Stand some urine aside in a beaker for several days. Ammoniacal fermentation will develop and "triple phosphate" crystals will form.
 - a. Examine the sediment under the microscope and compare the crystals with those shown in Fig. 236.
 - b. Hold a glass rod dipped in concentrated hydrochloric acid near the surface of the urine. Note the fumes of ammonium chloride.
 - c. Insert a strip of red litmus paper in the urine. Permit the paper to dry. Note the gradual restoration of red color, due to volatilization of ammonia (volatile alkali). Run a control test using 0.5 per cent Na₂CO₄ (fixed alkali).

SODIUM AND POTASSIUM

Sodium and potassium ions are always present in the urine. The amount of potassium excreted in 24 hours by an adult, subsisting upon a mixed diet, is on the average 1 to 3 g., whereas the amount of sodium under the same conditions is ordinarily 3 to 5 g. The ratio of K to Na is generally about 3:5. The absolute quantity of these elements excreted depends, of course, in large measure upon the nature of the diet. Because of the noningestion of NaCl and the accompanying destruction of potassium-containing body tissues, during fasting the urine contains more potassium than sodium.

Pathologically the output of potassium, in its relation to sodium, may be increased during fever; following the crisis, however, the output of this element may be decreased. It may also be increased in conditions associated with acidosis. In Addison's disease there is usually a relative retention of potassium and an increased excretion of sodium; the administration of cortical hormone preparations restores the normal relationship.

CALCIUM AND MAGNESIUM

The daily output of calcium in the urine, which depends principally upon the nature of the diet, is on the average about 0.1 to 0.3 g. per day. The percentage of calcium present in the urine at any one time (10 to 40 per cent of total calcium output) forms no dependable index as to the absorption of this element, since it may be again excreted into the intestine after absorption. Furthermore, as with phosphate (p. 749), the acidity or alkalinity of the intestinal lumen, and the presence of substances such as phosphate and fatty acids which form insoluble calcium salts, may determine to a considerable extent the relative output of calcium in the feces and the urine. Acidity promotes calcium absorption, alkalinity retards it. It is therefore impossible to draw any satisfactory conclusions regarding the excretion of calcium unless accurate analytical data from both the feces and the urine are obtained.

Myers and Fine⁹ have reported data showing a comparison of the kidney and intestine as excretory routes for various inorganic constituents. Their findings in this connection are summarized in the following table:

Number of Cases	Moisture Con- tent of Feces (Per Cent)	Fecal Output in Pcr Cent of Total in Urine and Feces							
		H ₂ O	N	8	Cl	P	Ca	Mg	K
5 9	76 84	6 16	10 15	10 19	3 9	36 33	90 89	72 68	18 27

The average findings in five cases with well-formed stools, 74 to 79 per cent moisture, and those with diarrheal stools, 79 to 89 per cent moisture, have been grouped separately in the table. It is not believed that the findings differed especially from the normal, except in that group of cases which suffered from intestinal diarrhea.

Very little is known positively regarding the actual course of the excretion of calcium under pathological conditions. An excess is found in some diseases of the bones, e.g., osteomalacia. In others, as in rickets, the urinary excretion may be very low.

The daily excretion of magnesium by way of the urine usually amounts to between 0.1 and 0.2 g. The amount depends mainly on the diet. About 65 per cent or more of the excreted magnesium is usually eliminated by

Myers and Fine: Proc. Soc. Exptl. Biol. Med., 16, 73 (1919).

the feces; the remainder passes out in the kidneys. There may be a retention of magnesium in certain bone disorders accompanying a loss of calcium; in osteomalacia for example. Thus the excretion of calcium and magnesium do not necessarily run parallel.

CARBONATES

Carbonate, in the form of the bicarbonate ion, HCO₃, generally occurs in small amount in the neutral or alkaline urine of man and carnivora, whereas much larger quantities are ordinarily present in the consistently alkaline urine of herbivora. The alkaline reaction of the urine of herbivora is due in great measure to the presence of bicarbonate. In general a urine containing bicarbonate in appreciable amount is turbid when passed or becomes so shortly after. This turbidity is due to the precipitation of insoluble calcium and magnesium salts. The carbonates of the alkaline earths are sometimes found in amorphous urinary sediments from quite alkaline urine.

IRON

Iron is present in small amount in normal urine. It probably occurs partly in inorganic and partly in organic combination. The iron contained in urinary pigments or chromogens is in organic combination. According to different investigators the iron content of normal urine probably averages not more than 1 to 5 mg. per day. After splenectomy there is an increased loss of iron from the body particularly by way of the feces.

EXPERIMENT ON IRON

Detection of Iron in Urine: Evaporate a convenient volume (10 to 15 ml.) of urine to dryness. Incinerate and dissolve the residue in a few drops of iron-free hydrochloric acid and dilute the acid solution with 5 ml. of water. Divide the acid solution into two parts and make the following tests: (a) To the first part add a solution of ammonium thiocyanate; a red color indicates the presence of iron. (b) To the second part of the solution add a little potassium ferrocyanide solution; a precipitate of Prussian blue forms upon standing.

FLUORIDES, NITRATES, AND SILICATES

These substances are all found in traces in human urine under normal conditions. Nitrates are undoubtedly introduced into the organism in the water and ingested food. The average excretion of nitrates is about 0.5 g. per day, the output being the largest upon a vegetable diet and smallest upon a meat diet. Nitrites are found only in urine which is undergoing decomposition and are formed from nitrates in the course of ammoniacal fermentation.

Urine: Pathological Constituents

Many of the subjected considered in this chapter as pathological constituents of uring represent in small amount in normal urine. Hence their pathological significance may be more a question of the amount present than of their actual presence in or absence from urine. It is generally true, however, that the usual qualitative tests for these substances are of such sensitivity as yield an essentially negative result when applied to normal urine, but to respond readily when unusual amounts are present. In this connection it is well to remember that a single specimen of urine may be sufficiently concentrated or otherwise influenced by dietary or other factors as to yield a positive result with a particular test, the significance of which disappears, however, when considered in the light of the total 24-hour excretion. Wherever possible, therefore, unless it is desired otherwise for special purposes, it is recommended that urine tests be carried out on a portion of the well-mixed and properly preserved 24-hour urine before interpreting results; if this is not feasible, the overnight sample collected before breakfast should be used.

GLUCOSE

Traces of this sugar may occur in normal urine, but the amount is ordinarily too small to be demonstrable by the common qualitative tests (see also Chapter 32). The presence of readily detectable amounts of glucose in urine is known as *glucosuria*; the term *glycosuria* is frequently used, but this latter expression more correctly refers to the presence of any sugar, not necessarily glucose, in the urine. Glucosuria may be either benign or pathological, and it is of importance to distinguish between these two types. Renal diabetes, in which the kidney threshold for glucose is below normal but the blood sugar level is normal, is an example of a benign glucosuria, as are the glucosurias associated with alimentary and emotional hyperglycemias. Pathological glucosurias include chiefly those of diabetes mellitus and other endocrine disorders, in which there is a marked elevation of the blood sugar, and usually an increased volume of urine (polyuria). The glucose content of the urine in diabetes mellitus may be as high as 10 per cent or more, but is usually around 3 to 5 per cent. The urine may be light in color and have a high specific gravity.

TESTS FOR GLUCOSE

The various tests for glucose in the urine which are embraced in the experiments given herewith are based upon one of the following properties of this sugar, as discussed in Chapter 2: (1) Its power to reduce the ions of certain metals in alkaline solution; (2) its power to rotate the plane of

polarized light; (3) its power to form a crystalline osazone with phenylhydrazine; and (4) its ability to ferment with ordinary yeast.

None of these tests by itself is specific for glucose. Positive evidence that the sugar is glucose may be obtained by demonstrating that the reducing power disappears after yeast fermentation and that the ical glucosazone is obtained in the absence of a positive test for ructose or mannes (see below). Quantitative measurement of optical rotation in relation to total reducing power is also of value.

The official test for glucose adopted by the Association of Life Insurance Medical Directors of America may be found in Caster 32.

1. Phenylhydrazine Reaction. Yellow crystamne compounds called osazones are formed from certain sugars by reaction with phenylhydrazine, in general each individual sugar giving rise to an osazone of a definite crystalline form which is typical for that sugar.

As applied to urine, however, it is frequently difficult to obtain characteristic crystals, even for glucose, since crystal form and growth may be influenced by other substances present. Better results are usually obtained if the usine is clarified first, as described below. Results are more significant if they are positive, i.e., if characteristic crystals are obtained, than if they are negative, but in any event the test should be regarded as a guide or confirmation, to be accompanied by more specific tests. Identification of the individual sugar osazones by their melting points is of little value.

In this connection it is important to remember that of the simple sugars of interest in physiological chemistry, glucose, fructose, and mannose give the same osazone. Fructose may be ruled out by the absence of a positive Selivanoff test (see p. 780); the presence of mannose will be indicated by the formation of a colorless crystalline hydrazone on treatment with phenylhydrazine in the cold, prior to the heating which produces the osazone.

Procedure: To a small amount of phenylhydrazine mixture¹ (about one-half inch in a small test tube), add 5 ml. of the urine, shake well, and heat on a boiling water bath for one-half to three-quarters of an hour. Allow the tube to cool slowly (not under the tap) and examine the crystals microscopically (see Plate II, Chapter 2). If the solution has become too concentrated in the boiling process it will be light red in color and no crystals will separate until it is diluted with water.

In case doubtful results are obtained by this test owing to the presence of interfering substances, the urine should be clarified and the test repeated. To clarify the urine introduce 10 ml. into a test tube, add 1 g. of pure blood charcoal, heat to boiling and allow to stand with occasional shaking for five minutes, then filter. Use the filtrate in the test.

2. Reduction Tests. It is to their potential aldehyde or ketone structure that many sugars owe the property of readily reducing alkaline solutions of metals like copper, bismuth, mercury, and iron; they also possess the property of reducing ammoniacal silver solutions with the separation of metallic silver. Upon this property of reduction the most widely used tests for sugars are based. A positive reduction test is not

¹ See Appendix.

specific for glucose, or even for reducing sugars in general; nonsugar reducing material is present in traces in normal urine and may be sufficiently augmented in amount, particularly in concentrated urines, to give a positive test. Other factors which may influence interpretation of results are discussed below. The chemistry of the various reduction tests and reagents is discussed in Chapter 2.

a. Fehling's Test: To about 1 ml. of Fehling's solution in a test tube add about 4 ml. of water, and boil.3 This is done to determine whether the solution will of itself cause the formation of a precipitate of brownish-red cuprous oxide. If such a precipitate forms, the Fehling's solution must not be used. Add urine to the hot Fehling's solution, a few drops at a time, and heat the mixture to boiling after each addition (never add more urine than the original volume of Fehling's solution). The production of yellow or brownish-red cuprous oxide indicates that reduction has taken place. The yellow precipitate is more likely to occur if the urine is added rapidly and in large amount, whereas with a less rapid addition of smaller amounts of urine the brownish-red precipitate is generally formed. The differences in color of the cuprous oxide precipitates under different conditions are apparently due to differences in the size of the particles, the more finely divided precipitates having a yellow color, while the coarser ones are red. In the presence of protective colloidal substances the vellow precipitate is usually formed.

This classical test is not entirely reliable when used to detect sugar in the urine, and has been largely replaced by Benedict's test (see below). Such compounds as conjugate glucuronates, uric acid, nucleoprotein, and homogentisic acid, when present in sufficient amount, may produce a result similar to that produced by sugar. Phosphates of the alkaline earths may be precipitated by the alkali of the Fehling's solution as a grayish-white precipitate which should not be mistaken for the cuprous oxide. Cupric hydroxide may also be reduced to cuprous oxide and this in turn form a soluble complex with creatinine, a normal urinary constituent. This will give the urine under examination a greenish tinge and may obscure the sugar reaction even when a considerable amount of sugar is present.

Conjugate glucuronates are present in normal urine in small amount (see p. 775) and are increased in amount after the ingestion of such substances as chloral hydrate, camphor, menthol, thymol, antipyrine, phenol, etc. The chloral hydrate is excreted in the urine as trichloroethylglucuronate. This compound reduces Fehling's solution and is levorotatory, whereas glucose also reduces but is dextrorotatory. Therefore by means of a polariscopic test we may differentiate between a "chloral urine" and a "sugar urine."

In testing urine preserved by chloroform a positive test may be obtained in the absence of sugar. This is due to the fact that the hot alkali produces a reducing substance from the chloroform.

* See Appendix.

In case doubtful results are obtained by this test owing to the presence of interfering substances the urine should be clarified with charcoal as described above, and the test repeated.

More dilute Fehling's solution should be used in testing urines containing small amounts of sugar. In case of urines containing a high concentration of sugar it may sometimes be desirable to use a larger volume of Fehling's solution.

Ammonium salts also interfere with Fehling's test preventing the precipitation of cuprous oxide. If present in excess the urine should be made alkaline with strong sodium carbonate, and boiled (or, better, aerated with a vigorous stream of air), to decompose and liberate the ammonia.

b. Benedict's Test: This is the most satisfactory of the copper reduction tests, and in laboratory practice has largely replaced Fehling's. The following is the procedure for the detection of glucose in the urine: To 5 ml. of the reagent⁵ in a test tube add exactly 8 drops of the urine to be examined. The fluid is then boiled vigorously for from one to two minutes and then allowed to cool spontaneously. (Do not hasten cooling by immersion in cold water.) The test may also be carried out by heating for five minutes in a boiling water bath, removing, and allowing to cool in the air. This procedure is recommended for serial tests. If a water bath is used, it is important that the urine and reagent be thoroughly mixed before placing in the water bath. In the presence of glucose the entire body of the solution will be filled with a colloidal precipitate, which may be green, yellow, or red in color, depending upon the amount of sugar present. In the presence of over 0.2 to 0.3 per cent of glucose, the precipitate will form quickly. If no glucose is present, the solution will either remain perfectly clear, or will show a very faint turbidity, due to precipitated urates.

Even very small quantities of glucose in urine (0.1 per cent) yield precipitates of surprising bulk with this reagent, and the positive reaction for glucose is the filling of the entire body of the solution with a precipitate, so that the solution becomes opaque. Since amount rather than color of the precipitate is made the basis of this test, it may be applied, even for the detection of small quantities of glucose, as readily in artificial light as in daylight. Chloroform does not interfere with this test nor does uric acid or creatinine interfere to such an extent as in the case of Fehling's test. It is common clinical practice to run this test under consistently uniform conditions (same amount of urine, heating time, etc.) and to indicate the intensity of the reaction by arbitrary signs (+, ++, +++, etc.) as an index of not only the presence of sugar but also its approximate relative concentration.

c. Bismuth Reduction Test (Nylander): To 5 ml. of urine in a test tube add one-tenth its volume of Nylander's reagent and heat for five minutes in a boiling water-bath. The mixture will darken if reducing sugar is present and upon standing for a few moments a black color will appear.

This color is due to the precipitation of bismuth.⁸ If the test is made on urine containing albumin this must be removed, by boiling and filtering,

See Appendix.

A simple modification of the copper reduction test for urine sugar is available commercially in the form of tablets containing copper sulfate, sodium hydroxide, and citric acid ("Clinitest" tablets, obtainable from the Ames Co., Inc., Elkhart, Indiana). In use, a little urine is diluted with 2 volumes of water and a tablet added to the mixture. Application of external heat is unnecessary. On standing for a few moments, the typical appearance of a positive copper reduction test is obtained if the urine contains reducing sugar.

⁷ Hammarsten suggests that the solution be boiled for two to five minutes (according to the sugar content) over a free flame and the tube then permitted to stand five minutes before drawing conclusions.

A dry powder containing the ingredients for a Nylander test is available commercially under the name of "Galatest" powder (obtainable from the Denver Chemical Mfg. Co., Inc., New York City). In use, a drop of urine is placed on a small amount of the powder. If reducing sugar is present, the powder turns gray or black.

before applying the test, since with albumin a similar change of color is produced. Glucose when present to the extent of 0.08 per cent or even lower may be easily detected by this reaction. Uric acid, creatinine, and homogeneisic acid which interfere with the Fehling test, do not interfere with the Nylander reaction.

Urine rich in indican, uroerythrin, urochrome, or hematoporphyrin, as well as urine excreted after the ingestion of large amounts of certain medicinal substances, may give a darkening of the Nylander's reagent similar to that of a true sugar reaction. It is a disputed point whether the urine after the administration of urotropin will reduce the Nylander reagent.

A positive bismuth reduction test is probably due to the following reactions:

(a)
$$Bi(OH)_2NO_3 + KOH \rightarrow Bi(OH)_3 + KNO_3$$

(b)
$$2Bi(OH)_3 - 3O \rightarrow Bi_2 + 3H_2O$$

Before testing the urine, Bohmansson treats 10 ml. with 2 ml. of 25 per cent hydrochloric acid and 4 to 5 g. of boneblack. This mixture is shaken one minute, then filtered, and the neutralized filtrate tested by Nylander's reaction. He claims that this procedure removes certain interfering substances, notably urochrome.

3. Fermentation Tests:

a. Saccharometer Method: Rub up in a mortar about 15 ml. of urine with a small piece of compressed yeast. Treat in the same way 15 ml. of urine known not to contain glucose and 15 ml. of urine to which glucose has been added. These are necessary controls. Transfer each mixture to a saccharometer (Fig. 17) and stand it aside in a warm place for about 12 hours. If glucose is present, alcoholic fermentation will occur and carbon dioxide will collect as a gas in the upper portion of the tube. On the completion of fermentation, fill the bulb portion of the saccharometer with 10 per cent sodium hydroxide solution, close the opening of the apparatus tightly with the thumb, mix the contents thoroughly, and restore the gas space to the limb of the saccharometer. Holding the apparatus at arm's length and with face averted (to avoid accidents) remove the thumb from the opening. Remembering that sodium hydroxide has the power to absorb carbon dioxide, how do you explain the result?

Ordinary baker's yeast, at least as obtained in the United States, will readily ferment glucose, fructose, mannose, maltose, and sucrose. Galactose, lactose, and the various pentoses are not fermentable, or, if so, at such a slow rate as to be of no practical significance in connection with the above test; yeast which readily ferments galactose may be obtained, however, by incubation and growth of ordinary baker's yeast on a medium rich in galactose. Thus the yeast fermentation test is of considerable practical value in distinguishing between glucosuria, lactosuria, and pentosuria, either simple or mixed, particularly when exhaustive yeast fermentation is used in connection with reduction tests before and after treatment with yeast, as in Mathews' procedure which follows.

b. Mathews' Modification for Distinguishing Fermentable Sugar (Glucose) from Nonfermentable Reducing Substances (Lactose, etc.): Mix 25 ml. of urine in a test tube with half a cake of compressed yeast, etirring

vigorously. Place at an angle of about 45° in a beaker of water and keep at 42° C. for 50 minutes, mixing occasionally. If 1 per cent or more of glucose is present, an evolution of gas bubbles will be observed after a few minutes and all glucose will be decomposed (up to 6 per cent) in 50 minutes. Filter and apply Benedict's test. A positive test indicates the possibility of lactose, but only if a control test using the same amount of yeast with urine containing added glucose demonstrates that the yeast is capable of removing all glucose under the experimental conditions. Reducing sugar may also be determined quantitatively before and after the fermentation.

4. Polariscopic Examination. For directions as to the use of the polariscope see Chapter 2, and for application to the quantitative analysis of urine. Chapter 32.

PROTEINS

Normal urine contains a trace of protein material, but the amount present is so slight as to escape detection by any of the simple tests in general use for the detection of protein urinary constituents. The following are the more important forms of protein material which have been detected in the urine under pathological conditions:

- 1. Serum albumin
- 2. Serum globulin

Proteoses and peptones

- 3. Non-blood proteins Proteins of Bence-Jones, Paton, and Hektoen, Kretschmer, and Welker
- 4. Nucleoprotein

ALBUMIN

Normal urine contains a trace of albumin which is too slight to be detected by the usual procedures. Albuminuria is the condition in which readily detectable amounts of the plasma proteins are found in the urine. The proteinuria is most commonly due to the presence of plasma albumin, since albumin is the most abundant of the plasma proteins, and has the smallest molecular size, thus permitting the greatest diffusion through damaged membranes. It is not uncommon, however, to find significant amounts of globulin material in so-called albuminuria if the proper tests are applied. There is some uncertainty as to whether or not the plasma proteins are altered from their normal state when found in the urine.

There are two distinct forms of albuminuria, viz., renal albuminuria and accidental albuminuria. Sometimes the terms "true" albuminuria and "false" albuminuria are substituted for those just given. In the renal type the albumin is excreted by the kidneys. This indicates a more serious condition and at the same time is more frequently encountered than the accidental type. In renal albuminuria we commonly find altered blood pressure or altered kidney structure. In the accidental form of albuminuria the albumin is not excreted by the kidneys as in the case in the renal form of the disorder, but arises from the blood, lymph, or some

albumin-containing exudate coming into contact with the urine at some point below the kidneys. It has been suggested that albuminurias may be classed as prerenal, renal, and postrenal. The prerenal type is illustrated by the albuminuria of heart disease, whereas the postrenal form corresponds to what we have called "accidental" albuminuria.

The determination of albumin may be of assistance in following the course of kidney disturbances, but the results can only be interpreted in the light of other clinical findings. Even in nephritis not every sample of urine will be abnormal if the specimens are obtained under ordinary conditions. It is nevertheless rare in this condition to fail to find albumin, casts, or excessive red cells and white cells in a concentrated urine obtained as a result of deliberate dehydration of the patient by feeding a dry diet for 12 to 24 hours. No diagnosis of the presence or absence of nephritis should be made until such a urine has been examined.

Benign proteinuria, which is usually transitory and in which there is no evidence of permanent kidney damage, may be due to such causes as severe exercise or cold baths. It is particularly common in young people. In the unusual condition known as orthostatic albuminuria, the proteinuria is apparently due to posture; urine formed while the patient is lying down is free from protein, while that formed when the upright position is assumed, particularly the position of military attention, contains protein. This condition is apparently harmless, although it has been used as a deterrent to military service, and may be due, in some instances at least, to mechanical pressure on the renal blood vessels due to a lumbar lordosis.

Foreign proteins injected into the blood stream are excreted by way of the urine, and lead to some excretion of blood proteins also. Pathological albuminuria may in some cases be due to the passage of an abnormal protein from the tissues into the blood.

TESTS FOR ALBUMIN

The urine should be filtered or centrifuged before performing these tests, and care should be taken against misinterpretation due to the presence of pus or bacteria. None of the tests described here is specific for albumin, since practically all of the proteins which have been found in urine at one time or another will respond to most of these tests. It is common clinical practice, however, to refer to a positive reaction as signifying the presence of "albumin" in the absence of specific information that some other protein (globulin, hemoglobin, Bence-Jones protein, etc.) is present, since in the vast majority of cases it appears to be really albumin which is concerned. A positive test for albumin would entail its characterization as a heat-coagulable protein, soluble in salt-free water (i.e., after dialysis), and requiring more than half-saturated ammonium sulfate for precipitation (see Chapter 6 for further discussion).

The official test for albumin adopted by the Association of Life Insurance Medical Directors of America may be found in Chapter 32.

1. Nitric Acid Ring Test (Heller): Place 5 ml. of concentrated HNO: in a test tube, incline the tube, and by means of a pipet allow the urine to flow

alowly down the side. The liquids should stratify with the formation of a white zone of precipitated protein at the point of juncture.

If the albumin is present in very small amount the white zone may not form until the tube has been allowed to stand for several minutes. If the urine is quite concentrated, a white zone, due to uric acid or urates, will form upon treatment with nitric acid as indicated. This ring may be easily differentiated from the albumin ring by repeating the test after diluting the urine with 3 or 4 volumes of water, whereupon the ring, if due to uric acid or urates, will not appear. It is ordinarily possible to differentiate between the albumin ring and the uric acid ring without diluting the urine, since the ring, when due to uric acid, has ordinarily a less sharply defined upper border, is generally broader than the albumin ring, and frequently is situated in the urine above the point of contact with the nitric acid. Concentrated urines also occasionally exhibit the formation, at the point of contact, of a crystalline ring with very sharply defined borders. This is urea nitrate and is easily distinguished from the "fluffy"

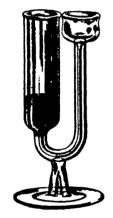

Fig. 237. Albumoscope.

ring of albumin. If there is any difficulty in differentiation, a simple dilution of the urine with water, as above described, will remove the difficulty. Various colored zones, due either to the presence of indican, bile pigments, or to the oxidation of other organic urinary constituents, may form in this test under certain conditions. These colored rings should never be confounded with the white ring which alone denotes the presence of albumin.

After the administration of certain drugs, a white precipitate of resin acids may form at the point of contact of the two fluids and may cause the observer to draw wrong conclusions. This ring, if composed of resin acids, will dissolve in alcohol, whereas the albumin ring will not dissolve in this solvent.

A ring closely resembling the albumin ring is often obtained in urines preserved for a considerable time

by thymol when subjected to the nitric acid test. The ring is due to the formation of nitrosothymol and possibly nitrothymol. If the thymol is removed from the urine by extraction with petroleum ether⁹ previous to adding nitric acid, the ring does not form.

An instrument called the albumoscope (horismascope) has been devised for use in this test and has met with considerable favor.

Use of the Albumoscope. This instrument is intended to facilitate the making of "ring" tests such as Heller's or Roberts'. In making a test about 5 ml. of the solution under examination is first introduced into the apparatus through the larger arm (see Fig. 237), and the reagent used in the particular test is then introduced through the capillary arm and allowed to flow down underneath the solution under examination. If a

^{*} Accomplished readily by gently agitating equal volumes of petroleum ether and the urine under examination for two minutes in a test tube before applying the test.

reasonable amount of care is taken there is no possibility of mixing the two solutions and a definitely defined white "ring" is easily obtained at the zone of contact.

Nitric Acid and Magnesium Sulfate Ring Test (Roberts): Place 5 ml. of Roberts' reagent¹⁰ in a test tube, incline the tube, and by means of a pipet allow the urine to flow slowly down the side. The liquids should stratify with the formation of a white zone of precipitated protein at the point of juncture.

This test is a modification of Heller's ring test and is rather more satisfactory than that test, since the colored rings never form and the consequent confusion is avoided. The albumoscope may also be used in making this test.

- 3. Sulfosalicylic Acid Test: To 1 volume of urine add 2 to 3 volumes of 3 per cent sulfosalicylic acid solution. A turbidity (compare against a control diluted with water) or precipitate denotes the presence of albumin or globulin (but not proteose). The precipitate may be intensified by warming.
- 4. Coagulation or Boiling Test: (a) Heat 5 ml. of urine to boiling in a test tube. (If the urine is not clear it should be filtered.) A precipitate forming at this point is due either to albumin (or globulin) or to phosphates. Acidify the urine slightly by the addition of 3 to 5 drops of very dilute acetic acid, adding the acid drop by drop to the hot solution. If the precipitate is due to phosphates it will disappear under these conditions, whereas if it is due to protein it will not only fail to disappear but will become more flocculent in character, since the reaction of a fluid must be acid to secure the complete precipitation of the protein by this coagulation process.

Too much acid should be avoided since it will cause the protein to go into solution. Certain *resin acids* may be precipitated by the acid, but the precipitate due to this cause may be easily differentiated from the protein precipitate by reason of its solubility in alcohol.

(b) A modification of this test in quite general use is as follows: Fill a test tube two-thirds full of urine and gently heat the upper half of the fluid to boiling, being careful that this fluid does not mix with the lower half, which serves as a control. A turbidity indicates protein or phosphates. Acidify the urine slightly by the addition of 3 to 5 drops of dilute acetic acid, when the turbidity, if due to phosphates, will disappear.

5. Osgood-Haskins Test for Urinary Protein: To 5 volumes of urine add 1 volume of 50 per cent acetic acid, followed by 3 volumes of saturated (30 per cent) sodium chloride. (The appearance of a precipitate after the addition of acetic acid, at room temperature, indicates the presence of bile salts, urates, resin acids, etc., whereas a precipitate after the addition of the salt solution suggests Bence-Jones protein (see p. 764), or globulin in excess of 0.38 g. per liter.) Heat the mixture gradually to boiling. As the temperature is raised the precipitate of Bence-Jones protein, if present, will go into solution; if albumin or globulin are present a precipitate will form. This test has the advantage of indicating the presence of Bence-Jones protein as well as albumin and globulin.

Many other reactions have been proposed for the detection of protein in urine, such as the use of acetic acid and potassium ferrocyanide,

molybdic¹¹ and phosphomolybdic acids, etc., but it is believed that those described here are the most satisfactory.

GLOBULIN

Serum globulin is not a constituent of normal urine but frequently occurs in the urine under pathological conditions and is ordinarily associated with serum albumin. In albuminuria globulin in varying amounts often accompanies the albumin, and the clinical significance of the two is very similar. Under certain conditions globulin may occur in the urine unaccompanied by albumin.

TESTS FOR GLOBULIN

Globulin will respond to all the tests outlined above under Albumin. If it is desirable to differentiate between albumin and globulin in any urine the following procedure may be employed:

Place 25 ml. of neutral urine in a small beaker and add an equal volume of a saturated solution of ammonium sulfate. Globulin, if present, will be precipitated. If no precipitate forms add ammonium sulfate in substance to the point of saturation. If albumin is present it will be precipitated upon saturation of the solution as just indicated. This method may also be used to separate globulin and albumin when they occur in the same urine.

Frequently in urine which contains a large amount of urates a precipitate of ammonium urate may occur when the ammonium sulfate solution is added to the urine. This urate precipitate should not be confounded with the precipitate due to globulin. The two precipitates may be differentiated by means of the fact that the urate precipitate ordinarily appears only after the lapse of several minutes whereas the globulin generally precipitates at once.

NON-BLOOD PROTEINS

Certain proteins are occasionally excreted by the kidneys which do not give the precipitin reactions for any of the normal blood proteins. These include proteoses, peptones, Bence-Jones protein, the Paton protein, and the protein of Hektoen, Kretschmer, and Welker.

Proteoses or substances giving similar precipitation reactions have frequently been found in the urine in cases of pneumonia, diphtheria, intestinal ulcer, carcinoma, dermatitis, osteomalacia, atrophy of the kidneys, and in conditions in which there is absorption of partially digested pus. Peptone occurs much less frequently if at all. In the many instances of peptonuria cited in the early literature the protein may have been proteose.

Bence-Jones protein is believed to be of diagnostic importance in cases of multiple myeloma and myelogenic osteosarcoma. It has been shown to be chemically and immunologically distinct from any of the blood proteins and has been obtained in crystalline form (see Fig. 238). It appears to be present normally in small amount in the bone marrow and in certain white blood cells. Its excretion in relatively large amount (30 to 50 g. per

¹¹ Tablets containing molybdic acid as a protein precipitant are available commercially under the name of "Albumintest," obtainable from the Ames Co. Inc., Elkhart, Indiana. In use, a tablet is dropped into a portion of the urine. A turbidity or precipitate indicates protein.

day in some instances) under pathological conditions is apparently due to either overproduction or decreased utilization; it is not known which is the true explanation. The presence of Bence-Jones protein in the blood plasma of patients with multiple myeloma has been shown by electrophoretic methods.

The protein of Hektoen, Kretschmer, and Welker resembles the Bence-Jones protein and certain proteoses in solubility and precipitation limits with ammonium sulfate (40 to 60 per cent). It is distinct from these, from

Fig. 238. Crystalline Bence-Jones protein. (Isolated by Prof. W. H. Summerson from the urine of a case of multiple myeloma.)

the Paton protein and from blood proteins in its precipitin reactions, its behavior with heat and in crystalline form.

The protein crystallized by Paton possesses globulin characteristics. In precipitin reactions it is distinct from blood proteins and from the other proteins mentioned.

TEST FOR NON-BLOOD PROTEINS

1. Schulte's Method: Acidify 50 ml. of urine with dilute acetic acid and filter off any precipitate of nucleoprotein which may form. Now test a few ml. of the urine for coagulable protein, by test 4 under Albumin, p. 763. If coagulable protein is present, remove it by coagulation and filtration before proceeding. Introduce 25 ml. of the urine, freed from coagulable protein, into 150 ml. of absolute alcohol and allow it to stand for 12 to 24 hours. Decant the supernatant fluid and dissolve the precipitate in a amail amount of hot water. Now filter this solution, and after testing

again for nucleoprotein with very dilute acetic acid, try the biuret test. If this test is positive the presence of proteose is indicated.¹²

Urobilin does not ordinarily interfere with this test since it is almost entirely dissolved by the absolute alcohol when the proteose is precipitated.

- 2. Boiling Test: Make the ordinary coagulation test according to the direction given under Albumin, p. 763. If no coagulable protein is found, allow the boiled urine to stand and note the gradual appearance, in the cooled fluid, of a flaky precipitate of proteose.
- 3. Detection of Bence-Jones' Protein: Heat the suspected urine very gently, carefully noting the temperature. At as low a temperature as 40° C. a turbidity may be observed, and as the temperature is raised to about 60° C. a flocculent precipitate forms and clings to the sides of the test tube. If the urine is now acidified very slightly with acetic acid and the temperature further raised to 100° C., the precipitate at least partly disappears. Filter while boiling hot. The precipitate returns on cooling the tube. The addition of a few drops of dilute (1 per cent) calcium chloride solution to the urine before testing frequently improves the response to this test.

This property of precipitating at so low a temperature and of dissolving at a higher temperature is typical of Bence-Jones' protein and may be used to differentiate it from all other forms of protein material occurring in the urine.

4. Osgood-Haskins Test for Bence-Jones Protein: See Exp. 5, p. 763.

NUCLEOPROTEIN

There has been considerable controversy as to the proper classification for the protein material which forms the "nubecula" of normal urine. By different investigators it has been called mucin, mucoid, phosphoprotein, nucleoalbumin, and nucleoprotein. Of course, according to the modern concept of the meanings of these terms, they cannot be synonymous. Mucin and mucoid are glycoproteins and hence contain no phosphorus (see p. 169), whereas phosphoproteins and nucleoproteins are phosphorized compounds. It may possibly be that both these forms of protein, i.e., the glycoprotein and the phosphorized type, occur in the urine under certain conditions (see p. 742). In this connection we will use the term nucleoprotein. The pathological conditions under which the content of nucleoprotein is increased include all affections of the urinary passages and in particular pyelitis, nephritis, and inflammation of the bladder.

TESTS FOR NUCLEOPROTEIN

'1. Detection of Nucleoprotein: Place 10 ml. of urine in a small beaker, dilute it with three volumes of water to prevent precipitation of urates, and make the reaction very strongly acid with acetic acid. If the urine becomes turbid it is an indication that nucleoprotein is present.

If the urine under examination contains albumin the greater portion of this substance should be removed by boiling the urine before testing it for the presence of pure contains

the presence of nucleoprotein.

2. Tannic Acid Precipitation Test (Ott): Mix 25 ml. of the urine with an equal volume of a saturated colution of sodium chloride and slowly add Almén's reagent.¹² In the pres nee of nucleoprotein a voluminous precipitate forms.

¹² If it is considered desirable to test for peptone the proteone may be removed by saturation with $(NH_4)_2SO_4$ according to the directions given on p. 182 and the filtrate tested for peptone by the biuret test.

¹³ See Appendix.

BLOOD

The pathological conditions in which blood occurs in the urine may be classified under the two divisions hematuria and hemoglobinuria. In hematuria we are able to detect not only the hemoglobin but the unruptured corpuscles as well, whereas in hemoglobinuria the pigment alone is present. Hematuria is brought about through blood passing into the urine because of some lesion of the kidney or of the urinary tract below the kidney. Hemoglobinuria is brought about through hemolysis, i.e., the rupturing of the stroma of the erythrocyte and the liberation of the hemoglobin. This may occur in scurvy, typhus, pyemia, purpura, and in other diseases. It may also occur as the result of a burn covering a considerable area of the body, or may be brought about through the action of certain poisons or by the injection of various substances having the power of dissolving the erythrocytes. Transfusion of blood may also cause hemoglobinuria.

Even in true hematuria the erythrocytes may escape detection if the urine is ammoniacal inasmuch as the cells disintegrate under these conditions.

TESTS FOR BLOOD

1. Benzidine Reaction. This is one of the most delicate of the reactions for the detection of blood. Different benzidine preparations vary greatly in their sensitiveness, however. Inasmuch as benzidine solutions change readily upon contact with light, it is essential that they be kept in a dark place.

The test is performed as follows: To 3 ml. of a saturated solution of benzidine in glacial acetic acid¹⁴ add 2 ml. of urine and 1 ml. of 3 per cent hydrogen peroxide. A blue or green color indicates a positive test. The following test is more delicate and specific.

Confirmatory Test: To 10 ml. of urine add 1 to 2 drops of glacial acetic acid and extract by shaking with 5 ml. of ether. The ur the ether extract into a small evaporating dish. Put on a hot water bath (with flame turned out) and evaporate to dryness. To the residue add a few drops of water, a drop of benzidine solution, and a drop of hydrogen peroxide. A blue or green color indicates blood.

Often when urines containing a small amount of blood are tested by the direct procedure, the mixture is rendered so turbid as to make it difficult to decide as to the presence of a faint green color. The sensitiveness of the benzidine reaction is greater when applied to aqueous solutions than when applied to the urine.

For modifications of this test and further discussion see page 437.

Gualac Test: Place 5 ml. of urine¹⁵ in a test tube and by means of a piper introduce a freshly prepared alcoholic solution of gualac (strength about 1:60) or the Lyle-Curtman gualac reagent (see p. 433) into the fluid until a

¹⁴ Glacial acetic acid is preferable, but, if it is not available, alcohol acidified with acetic acid may be used.

¹⁵ Alkaline urine should be made slightly acid with scetic acid as the blue end-reaction is very sensitive to alkali.

turbidity results, then add old turpentine or hydrogen peroxide, drop by drop, until a blue color is obtained.

This test is also much more delicate when applied to the acid-ether extract. The use of guaiaconic acid instead of the solution of guaiac has been recommended. The test is positive both before and after boiling the urine for 15 to 20 seconds. Pus does not respond after boiling. Old, partly putrefied pus gives the test even without the addition of hydrogen peroxide or old turpentine, whereas fresh pus responds upon the addition of hydrogen peroxide. See the discussion on p. 433 and the test on p. 437.

3. Ortho-Tolidin Test (Ruttan and Hardisty): To 1 ml. of a 4 per cent glacial acetic acid solution of o-tolidin in a test tube add 1 ml. of the solution under examination and 1 ml. of 3 per cent hydrogen peroxide. In the presence of blood a bluish color develops (sometimes rather slowly) and persists for some time (several hours in some instances).

This test is said to be as sensitive for the detection of occult blood in feces and stomach contents as is the benzidine reaction. It is also claimed to be more satisfactory for urine than any other blood test. The acetic acid solution may be kept for one month with no reduction in delicacy.

4. Spectroscopic Examination: Submit the urine to a spectroscopic examination according to the directions given on p. 444, looking especially for the absorption bands of oxyhemoglobin and methemoglobin (see Absorption Spectra, Plate I).

MYOGLOBIN

This heme pigment, derived from muscular tissue, is found in the urine after extensive destruction of muscular tissue, as from crushing injuries. Urine containing myoglobin resembles that containing blood; it may be smoky dark brown or red, and will give a positive benzidine test. Red cells, however, are notably absent, and the sediment may contain brown pigmented casts. By refined methods it is possible to distinguish the absorption spectrum of myoglobin from that of hemoglobin; for example, the peak of the broad band in the spectrum of oxymoglobin is at about 581 mµ, whereas that for oxyhemoglobin is at 578 mµ. Such distinction, however, cannot be made with the ordinary hand spectroscope. Myoglobin has a molecular weight only about one-fourth that of hemoglobin (see Chapter 22 for further discussion) which probably explains its ready diffusibility through the kidney membranes. The appearance of myoglobin in the urine is usually associated with concomitant kidney damage, both clinically and experimentally, but whether this has any direct connection with the presence of myoglobin is not known.

PUS

Pus may be present in the urine in inflammatory affections of various types. Such a condition is termed pyuria. Albumin always accompanies the pus. In catarrh of the bladder and in inflammation of the urethra or of the pelvis of the kidney pus is particularly apt to be present in the urine. If a urine of high pus concentration is voided it may indicate the rupturing

of an abscess in some part of the genitourinary tract. Pus may be detected by one of the procedures given below.

TESTS FOR PUS

1. Microscopical Detection of Pus: The characteristic form elements of pus are leukocytes. They may occur in very small number in normal urine. Examine the urine (centrifuged if necessary) under the microscope. Any considerable number of pus corpuscles indicates a pathological urine. In acid urine the pus corpuscles appear as round, colorless cells, composed of refractive, granular protoplasm. Sometimes they may exhibit ameboid movements, particularly if the slide containing them be warmed slightly. They are nucleated (one or more nuclei), the nuclei being clearly visible only upon treating the cells with water, acetic acid, or some other suitable reagent. In alkaline urine the pus corpuscles are often degenerated. They may occur as swollen, transparent cells, which exhibit no granular structure. If the degeneration has proceeded far enough the nuclei fade and the cell disintegrates and only debris remains.

Sometimes it is almost impossible to differentiate between pus corpuscles and certain types of epithelial cells. In such a case apply one of the following chemical tests

2. Guaiac Test: This test is not specific for pus, but is given by certain other substances and particularly by blood (see p. 767). Perform the test as follows: Acidify the urine (if alkaline) with acetic acid, filter and add tincture of guaiac or the Lyle-Curtman guaiac reagent (p. 433) to the sediment on the paper. If the pus is old and partly putrefied, it will give a blue color. If no blue color is secured, add old turpentine, or hydrogen peroxide, drop by drop A blue color formed only under these conditions indicates fresh pus.

As a control test boil some of the urine (or sediment) for 15 to 20 seconds and repeat the test. Pus does not respond after boiling. In the case of blood the test is positive both before and after boiling.

BILE

Both the pigments and the acids of the bile may be detected in the urine under certain pathological conditions. Of the pigments, bilirubin is the only one which has been positively identified in fresh urine; the other pigments, when present, are probably derived from the bilirubin. A urine containing bile may be yellowish-green to brown in color and when shaken foams readily. The staining of the various tissues of the body through the absorption of bile due to occlusion of the bile duct is a prominent symptom of the condition known as interus or jaundice. Bile is always present in the urine under such conditions unless the amount of bile reaching the tissues is extremely small.

TESTS FOR BILE PIGMENTS

Practically all of the tests for bile pigments are based on the oxidation of the pigment by a variety of reagents with the formation of a series of colored derivatives. For detailed chemistry of these tests see the chapter on Bile. A simple though satisfactory test for bile consists in shaking the urine in a test tube and observing the yellow foam.

1. Gmelin's Test: To about 5 ml. of concentrated nitric acid in a test tube add an equal volume of urine carefully so that the two fluids do not mix. At the point of contact note the various colored rings; green, blue, violet, red, and reddish-yellow. (Fuming yellow nitric a tree the best results.)

- Rosenbach's Modification of Gmelin's Test: Filter 5 ml. of urine through a small filter paper. Introduce a drop of concentrated nitric acid into the cone of the paper and observe the succession of colors as given in Gmelin's test.
- 3. Huppert's Test: To 10 ml. of urine add 5 ml. of mlk of lime 16 (a suspension of calcium hydroxide in water). Mix well and filter. The pigment is retained on the filter as a compound with the calcium hydroxide. Wash the residue on the filter thoroughly with water. Put a clean test tube under the funnel and to the residue on the filter add carefully about 10 drops of concentrated HCl so as to dissolve the calcium hydroxide as completely as possible and to set free the pigment. Pour 10 ml. of alcohol on the filter and let drain into the tube. Warm the filtrate in the test tube in a water bath. A green color in the solution indicates bile pigment.

TESTS FOR BILE ACIDS

1. Furfural-H₂SO₄ Test (Mylius): To 5 ml. of urine in a test tube add 3 drops of a very dilute (1: 1000) aqueous solution of furfural. Now incline the tube, run about 2 to 3 ml. of concentrated sulfuric acid carefully down the side, and note the red ring at the point of contact. Upon slightly agitating the contents of the tube the whole solution gradually assumes a reddish color. As the tube becomes warm, it should be cooled in running water in order that the temperature may not rise above 70° C.

It is claimed that this test is not satisfactory in the presence of protein and chromogenic substances which yield interfering colors with sulfuric acid.

2. Surface Tension Test (Hay): This test is based upon the principle that bile acids have the property of reducing the surface tension of fluids in which they are contained. The test is performed as follows: Cool about 10 ml. of fresh urine in a test tube to 17° C. or lower, and sprinkle a little finely pulverized sulfur upon the surface of the fluid. The presence of bile acids is indicated if the sulfur sinks to the bottom of the liquid, through the surface film. Compare with a control tube of normal urine known to be free from bile. Urines preserved with thymol may respond positively to this test.

THE ACETONE BODIES

The acetone (or ketone) bodies include the compounds acetoacetic (or diacetic) acid, β -hydroxybutyric acid, and acetone. The chemical relationship between these various acetone bodies is as indicated below; acetoacetic acid and β -hydroxybutyric acid are primary products, the latter probably being formed by reduction of the former. Acetone, however, is a decomposition product of acetoacetic acid and is probably not produced as such within the body, although it is invariably found there when the other two acetone bodies are present.

$$\begin{array}{c} \text{CH}_3\text{-}\text{CO}\text{-}\text{CH}_2\text{-}\text{COOH} \to \text{CH}_3\text{-}\text{CO}\text{-}\text{CH}_3 + \text{CO}_2\\ \cdot \text{ Acetoacetic acid} & \text{ Acetone} \\ & \downarrow \text{H (reduction)} \\ \\ \text{CH}_3\text{-}\text{CHOH}\text{-}\text{CH}_2\text{-}\text{COOH} \\ \cdot \\ \text{\emptyset-Hydroxybutyric acid} \end{array}$$

Acetoacetic acid and β -hydroxybutyric acid appear to be either intermediate products in the breakdown of fatty acid chains or secondary combinations of 2-carbon fragments formed in this breakdown or closely

16 A 1.5 per cent suspression of CaO in water. To be labeled: "Shake before using."

TESTS FOR ACETONE AND ACETOACETIC ACID

- 1. Isolation from the Urine: The tests for acetone are more satisfactory if the acetone is separated from the urine by distillation and the tests applied to the distillate. Introduce into a small distilling bulb 10 ml. (or more) of the urine to be tested, and acidify. Distil off about 2 ml. of liquid (containing most of the acetone) into a test tube. A condenser is not necessary but the tube should be kept cool. In the distillation any acetoacetic acid present is decomposed and the acetone from this source also passes into the distillate. Try either of the two following tests on the distillate.
- √ 2. Iodoform Test (Lieben): To 2 ml. of distillate add 3 to 5 drops of 10 per cent NaOH and then Lugol's iodine solution drop by drop to a faint yellow. Let stand at room temperature if necessary. A definite turbidity changing to a yellow precipitate of iodoform should be noted. The odor is characteristic as is also the crystalline form viewed under the microscope (see p. 60).

This test is given by alcohol which may be formed by fermentation in diabetic urines. Alcohol, however, reacts much more slowly. If ammonia is used, usually 5 to 10 drops, instead of NaOH (Gunning's test) the reaction is more specific for acetone but is less delicate.

- ∨ 3. Nitroprusside Test (Legal): Try this test on both the original urine and the distillate. To 2 ml. of liquid add a few drops of a freshly prepared 5 per cent aqueous solution of sodium nitroprusside. Make alkaline with NaOH. A red color indicates acetone. If the test is made directly on urine a red color is given by creatinine which, however, disappears on the addition of acetic acid. A modification of this test in quite general use is as follows: to a few ml. of urine add a few drops of the nitroprusside solution and mix. Add concentrated ammonium hydroxide carefully down the side of the tube so as to form a layer over the sample. A purple (not brown) ring at the zone of contact indicates the presence of acetone bodies.
 - 4. Nitroprusside Test (Rothera):17 Saturate 20 ml. of urine with ammonium sulfate by shaking with the crystals in a test tube. Add 2 to 3 drops of concentrated NH,0H and a few drops of a freshly prepared 5 per cent solution of sodium nitroprusside and shake. A positive test is indicated by the development of a permanganate tinge which gradually deepens. A brown color is not a positive test. A quick strong reaction indicates about 0.25 per cent acetoacetic acid while a slow weak reaction is given by 0.0005 per cent acetoacetic acid. A faint test has less significance than the ferric chloride test because of the delicacy of the reaction. The test is given by acetone also but is much less delicate for this substance.
 - 5. Salicylic Aldehyde Test (Behre): 19 In this test a previous distillation is unnecessary since the acetone, preformed and from acetoacetic acid, is distilled in the test tube onto the reagents. Place 3 ml. of urine in a clean test tube and 3 ml. of distilled water as a control in another tube, and add 1 drop of 1:1 sulfuric acid to each. Prepare two small thin squares of cotton and in the center of each place a drop of salicylic aldehyde (or of an alcoholic solution of salicylic aldehyde and two drops of a saturated solution of potassium hydroxide. These reagents solidify to form a yellow disk. When they have solidified, invert a cotton square over each test tube and push in slightly so that the spot of reagents faces down toward the fluid in

¹⁷ The dry ingredients of the Rothera test for acetone are available commercially as a powder ("Acetone Test," obtainable from the Denver Chemical Mfg. Co. Inc., New York City). In use, a few drops of urine are placed on a small amount of the powder. A purple color indicates acetone.

¹⁸ See Exp. 6.

¹⁹ Behre: J. Lab. Clin. Med., 13, 770 (1928). Also personal communication.

¹⁰ Eastman's technical grade or Eimer and Amend's Acid Salicylous, Synthetic, are usually satisfactory for use without dilution. If blackening appears on the cotton during the heating a solution of 1 part salicylic aldehyde in 1 part methyl or ethyl alcohol should be used.

the tube but does not touch the sides of the tube. Place both tubes upright in boiling water for eight minutes. Remove the cotton and examine the spots. The presence of acetone or acetoacetic acid in the urine is indicated by a pink to deep rose coloration of the spot, as compared with the yellow color of the blank test. The color from acetone bodies deepens on standing and in doubtful cases should be examined after a few minutes. Familiarity with the test makes it possible to estimate roughly the amount of total acetone present.

6. Ferric Chloride Test for Acetoacetic Acid²¹ (Gerhardt): To 5 ml. of urine in a test tube add ferric chloride solution, drop by drop, until no more precipitate forms. In the presence of acetoacetic acid, a Bordeaux-red color is produced; this color may be somewhat masked by the precipitate of ferric phosphate, in which case the fluid should be filtered.

A positive result from the above manipulation simply indicates the possible presence of acetoacetic acid. Before making a final decision regarding the presence of this substance make the two following control experiments:

- a. Place 5 ml. of urine in a test tube, small beaker, or Erlenmeyer flask and boil it vigorously for three to five minutes. Cool the vessel and, with the boiled urine, make the test as given above. Compare with the test on the unboiled sample. As has been already stated, acetoacetic acid yields acetone upon decomposition and acetone does not give a Bordeaux-red color with ferric chloride. By boiling as indicated above, therefore, any acetoacetic acid present would be decomposed into acetone and carbon dioxide and the test upon the resulting fluid would be negative. If positive, the color is due to the presence of substances other than acetoacetic acid.
- b. Place 5 ml. of urine in a test tube, acidify with H₂SO₄, to free aceto-acetic acid from its salts, and carefully extract the mixture with ether by shaking. If acetoacetic acid is present, it will be extracted by the ether. Now remove the ethereal solution, evaporate it to dryness, dissolve the residue in 1 to 2 ml. of water, and add 3 to 5 drops of 3 per cent ferric chloride. Acetoacetic acid is indicated by the production of the characteristic Bordeaux-red color.

This color disappears spontaneously in 24 to 48 hours. Such substances as antipyrine, kairin, phenacetin, salicylic acid, salicylates, sodium acetate, thiocyanates, and thallin yield a similar red color under these conditions, but when due to the presence of any of these substances the color does not disappear spontaneously but may remain permanent for days. Many of these disturbing substances are soluble in benzene or chloroform and may be removed from the urine by this means before extracting with ether as above. Acetoacetic acid is insoluble in benzene or chloroform.

TESTS FOR B-HYDROXYBUTYRIC ACID

1. Black's Reaction: Inasmuch as the urinary pigments as well as any contained sugar or acetoacetic acid will interfere with the delicacy of this test when applied to the urine directly, the following preliminary procedure is necessary: Concentrate 10 ml. of the urine under examination to one-third or one-fourth of its original volume in an evaporating dish at a gentle heat. Acidify the residue with a few drops of concentrated hydrochloric acid, add sufficient plaster of Paris to make a thick paste, and allow the mixture to stand until it begins to "set." It should now be stirred and broken up in the dish by means of a stirring rod with a blunt end. Extract the porous meal thus produced twice with ether by stirring and decantation. Any

²¹ To prepare a solution which may be added to urine, if urines containing this acid are not available for student work, proceed as follows: Treat 13 g. of ethyl acetoacetate with 500 ml. of 0.2 N sodium hydroxide. Allow to stand for 48 hours to hydrolyse the ester. In preparing urine for tests add 1 part of this solution to 10 parts of urine.

g-hydroxybutyric acid present will be extracted by the ether. Evaporate the ether extract spontaneously or on a water bath, dissolve the residue in water, and neutralize it with barium carbonate. To 5 to 10 ml. of this neutral fluid in a test tube add 2 to 3 drops of ordinary commercial acid hydrogen peroxide. Mix by shaking and add a few drops of Black's reagent. Permit the tube to stand and note the gradual development of a rose color which increases to its maximum intensity and then gradually fades. ²³

In carrying out the test care should be taken to see that the solution is cold and approximately neutral and that a large excess of hydrogen peroxide and Black's reagent are not added. In case but little β -hydroxybutyric acid is present the color will fail to appear or will be but transitory if the oxidizing agents are added in too great excess. It is preferable to add a few drops of the reagent and at intervals of a few minutes repeat the process until the color undergoes no further increase in intensity. One part of β -hydroxybutyric acid in 10,000 parts of the solution may be detected by this test.

2. Polariscopic Examination: Subject some of the urine (free from protein) to the ordinary fermentation test (see p. 759). This will remove glucose and fructose, which would interfere with the polariscopic test. Now examine the fermented fluid in the polariscope and if it is levorotatory the presence of β-hydroxybutyric acid is indicated. This test is not absolutely reliable, however, since conjugate glucuronates are also levorotatory and withstand fermentation.

GLUCURONIC ACID

Glucuronic acid, CHO·(CHOH) COOH, or

does not occur free in urine, but is found in combinations known as conjugate glucuronates or glucuronides with a wide variety of compounds under both normal and pathological conditions or after administration of such compounds for medicinal or experimental purposes. There are two general types of conjugate glucuronates, the glycoside type and the ester type, both of which involve linkage with glucuronic acid through the OH group on carbon atom number 1 of the cyclic structure. The glycoside type involves the OH group of aliphatic or aromatic alcohols, e.g., phenol, naphthol, borneol, etc., while the ester type involves reaction with the COOH group of such compounds as benzoic acid, phenylacetic acid, etc. Free glucuronic acid is as powerful a reducing substance as glucose, and its quantitative determination may be based upon this fact; ester-type glucuronides likewise show direct reducing properties, probably due to concomitant hydrolysis, while the glycoside type is nonreducing until hydrolyzed. Conjugate glucuronates may therefore interfere with the reducing tests for sugar in urine under certain conditions, but they may be readily distinguished from glucose because of their nonfermentability with yeast. While glucuronic acid is dextrorotatory, the

²³ Made by dissolving 5 g. of ferric chloride and 0.4 g. of ferrous chloride in 100 ml. of water.

³³ This disappearance of color is due to the further oxidation of the acetoacetic acid.

glucuronides as a class are levorotatory; this also serves for distinction from glucose in urine.

The total glucuronic acid content of normal urine appears to approximate 0.5 to 1.0 g, per day; earlier estimates were considerably lower than this, probably because the methods were based on the mistaken assumption that all conjugate glucuronates are soluble in ether. The glucuronides of normal urine include combinations with phenol, indoxyl, skatoxyl, and the estrogenic hormones. Urine glucuronide content may be greatly increased by the administration of a variety of compounds, such as antipyrine, acetylsalicylic acid (aspirin), borneol, camphor, chloral hydrate, menthol, morphine, phenolphthalein, turpentine, and practically all of the sulfonamides (except possibly sulfanilamide). Experimentally, certain carcinogenic substances or derivatives are ultimately excreted in part as glucuronides. Most of the common vitamin deficiencies produce a decrease in glucuronic acid excretion, at least in the rat; riboflavin deficiency apparently produces an increased excretion. Glucuronic acid formation and conjugation appear to take place in the liver. The origin of glucuronic acid is obscure; it appears doubtful that glucose itself is a direct precursor.

TESTS FOR GLUCURONATES

1. Naphthoresorcinol Reaction (Tollens): Introduce 5 ml. of urine in a test tube and add 0.5 to 1 ml. of a 1 per cent solution of naphthoresorcinol in 95 per cent alcohol, and 5 ml. of concentrated hydrochloric acid. Raise the temperature gradually to the boiling point and boil for one minute, shaking the tube continuously. Stand the tube aside four minutes, then cool under the tap. Extract with an equal volume of ether (preferably peroxidefree). Glucuronates are indicated by the ether extract assuming a violetred color. The spectroscope shows this extract to possess an absorption band in the green to yellow region of the spectrum. The peak absorption is at approximately 570 my.

2. Polariscopic Fermentation Test: If glucose is present in the urine tested for glucuronates the urine may first be subjected to a polariscopic examination, then fermented and a second polariscopic examination made. The sugar being dextrorotatory and fermentable and the glucuronides being levorotatory and nonfermentable, the second polariscopic test will show a

levorotation indicative of conjugate glucuronates.

3. Polariscopic Reduction Test: Test the urine by Benedict's test. If positive, try the resorcinol-HCl reaction for fructose. If negative, test the optical

activity. Levorotation indicates glucuronides.

4. Preparation of Glucuronic Acid: Method of Quick:²⁴ Give 5 g. of pulverized borneol daily to each of several dogs. Collect the urine, acidify with acetic acid, and add lead acetate. Most of the coloring matter is carried down. Filter, heat the filtrate to boiling, and add an excess of zinc acetate. Filter off the precipitate and wash with hot water until no more coloring matter is extracted. This is practically pure zinc borneol glucuronic acid. About 1 g. is obtained for each g. of borneol given.

Dissolve the finely powdered zinc salt in hot 3.5 N sulfuric acid, using about 140 ml. for each 100 g. of the salt. When completely dissolved, cool rapidly and put in an icebox for several hours. Filter off the crystals of borneol glucuronic acid, wash with a little cold water, and dry in the air.

Dissolve 100 g. of borneol glucuronic acid in 1,500 ml. of 0.2 N sulfuric acid and boil for three hours beneath a reflux condenser. Filter and treat the hot filtrate with sufficient barium hydroxide to precipitate the last traces

²⁴ Quick: J. Biol. Chem., 74, 331 (1927).

of sulfuric acid. Allow the mixture to settle. Siphon off the supernatant fluid, and complete the separation by centrifuging. Concentrate the solution under diminished pressure to a syrupy consistency, and let it stand to crystallize. Filter off the crystals and wash them with a small amount of alcohol to remove the pigment. This is a mixture of glucuronic acid and its lactone. Treat 4 g. of the product with 200 ml. of 95 per cent alcohol and set aside for 12 hours. Repeat twice, using 100-ml. portions of alcohol. The residue should be glucuronic acid of 99 per cent purity. To obtain the pure lactone, dissolve some of the mixture of acid and lactone in hot glacial acetic acid, allow the solution to cool, and recrystallize from hot water.

Glucuronic acid is a syrupy liquid, readily soluble in water and slightly soluble in alcohol. When the aqueous solution is boiled, evaporated, or even allowed to stand at the ordinary temperature, the acid loses the elements of water and yields the anhydride or lactone. It is a strong organic acid ($K > 1 \times 10^{-3}$).

Glucuronic anhydride, $C_6H_8O_6$, forms monoclinic tables or needles, having a sweet taste, and m.p. 160° when heat is gradually applied, or at 170° to 180° when heated rapidly. The anhydride is insoluble in alcohol, but dissolves readily in water to form a dextrorotatory solution, $[\alpha]_D = +19.25$ °. The solution prevents the precipitation of cupric ion by alkalies, and powerfully reduces Fehling's solution, the copper-reducing power being 98.8, compared with glucose as 100.

Glucuronic acid itself is dextrorotatory ($[\alpha]_D = +36^{\circ}$), but many of its compounds are levorotatory. It shows mutarotation with an initial value

of $[\alpha]_D^{20} = +16^\circ$. It reduces Fehling's solution on heating, and precipitates the metals from hot alkaline solutions of silver, mercury, and bismuth.

PENTOSES

There are two distinct types of pentosuria, viz., (1) alimentary pentosuria, resulting from the ingestion of large quantities of pentose-rich fruits such as prunes, cherries, grapes, or plums, and fruit juices, in which condition the pentoses appear only temporarily in the urine; and (2) the chronic form of pentosuria, in which the output of pentoses bears no relation whatever to the quantity and nature of the pentose content of the food eaten. Pentosuria is

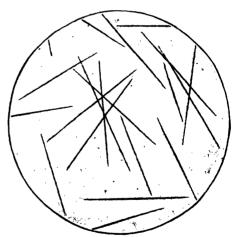

Fig. 239. Pentosazone crystals. Isolated and purified in the senior author's laboratory by Dr. B. L. Fleming. For color of crystals see Plate II, opposite p. 55.

apparently a harmless abnormality; it is definitely known that pentosuria bears no relation to diabetes mellitus and there is no generally accepted theory to account for the occurrence of the chronic form of pentosuria. The pentose detected most frequently in the urine in chronic pentosuria is p-xyloketose. L-Arabinose has been found in cases of alimentary pentosuria. For pentosazone crystals, see Fig. 239.

TESTS FOR PENTOSE

1. Tauber's Test:25 To 0.1 ml. of the urine in a test tube, add 0.5 ml. of a 4 per cent solution of benzidine in glacial acetic acid. Heat to vigorous boiling, cool under the cold water tap, and add 1 ml. of water. The presence of pentose is indicated by the immediate appearance of a pink to red color. If pentoses are absent, the mixture has a yellowish-brown color.

This test is highly specific for pentoses, either free or in the form of nucleotides (nucleic acid, riboflavin, etc.) but does not respond to gum arabic because the pentosan is not hydrolyzed. Normal and abnormal constituents of urine do not interfere. Too large amounts of protein may be removed from pathological urine by mixing with an equal volume of 10 per cent trichloroacetic acid solution, warming to 95°, and filtering. The test is applied to the filtrate. This test has been found to be extremely satisfactory for the detection of pentosuria. The 4 per cent benzidine solution is stable for four days.

2. Orcinol-Hydrochloric Acid Reaction (Bial): To 5 ml. of Bial's reagent¹⁶ in a test tube add 2 to 3 ml. of urine and heat the mixture gently until the first bubbles rise to the surface.²⁷ Immediately or upon cooling the solution becomes green and a flocculent precipitate of the same color may form.

This test is believed to be more accurate than the original orcinol test. It is claimed that urines containing menthol, kreosotal, etc., respond to the old orcinol reaction, but not to Bial's. If so desired the osazone of the pentose (see Fig. 239) may be formed, then distilled with hydrochloric acid and the distillate tested by Bial's test (Jolles).

3. Phloroglucinol-Hydrochloric Acid Reaction (Tollens): To equal volumes of urine and hydrochloric acid (sp. gr. 1.09) add a little phloroglucinol and heat the mixture on a boiling water bath. Pentose, galactose, or glucuronic acid will be indicated by the appearance of a red color. To differentiate between these compounds examine by the spectroscope and look for the absorption band in the yellow region of the spectrum given by pentoses and glucuronic acid, and then differentiate between the two latter compounds by the melting points of their osazones.

LACTOSE

Lactose is rarely found in the urine except when excreted by women during pregnancy, during the nursing period, or soon after weaning, i.e., when the mammary glands are actively functioning. Lactosuria has no pathological significance, representing as it does simply the excretion of a sugar which has found its way into the blood stream by some means and which is not utilizable as such by the organism.²⁸ It is nevertheless important to be able to identify the condition of lactosuria and to distinguish it from glucosuria, otherwise serious misinterpretation of laboratory data may result. Lactose in urine is readily distinguished from glucose by its lack of fermentability with ordinary yeast; qualitative or better quantitative determination of reducing power before and after exhaustive treatment with yeast is of value in this connection, particularly for the

²⁵ Tauber: Proc. Soc. Exptl. Biol. Med., 37, 600 (1937).

²⁴ See Appendix.

²⁷ The test may also be performed by adding the urine to the *kot* reagent. No further heating should be necessary if pentose is present.

²⁶ If any lactore is excreted into the intestinal tract and there hydrolyzed into glucose and galactore, these products are capable of absorption and utilization by the body.

detection of a concomitant glucosuria. The characterization of lactose as its typical osazone is not ordinarily attended with much success in urine; better results may be obtained by adsorption of the lactose on charcoal prior to testing, as described below. The mucic acid test, which is specific for lactose and galactose, may be used to identify lactose in urine, but interpretation of results may be obscured by the presence of other insoluble crystalline substances.

TESTS FOR LACTOSE

- 1. Fermentation Test: Ferment the urine as in Exp. 3(a) or 3(b), p. 759. If non-fermentable reducing sugar is found it is very probably lactose, especially if the patient be pregnant or lactating. In rare cases it may be pentose. Lactose may be distinguished from pentose by proper application of Tauber's test (p. 778), the mucic acid test, or the osazone test.
- 2. Osazone Test (According to Cole): Shake 25 ml. of urine with 1 g. of Merck's medicinal charcoal, boil a few seconds, cool thoroughly, and shake at intervals for 10 minutes. Filter through a small paper or use a filter pump. Let drain completely. Transfer the charcoal to a dish containing 10 ml. of water and 1 ml. of glacial acetic acid. Boil for about 10 seconds and filter hot into a tube containing as much phenylhydrazine hydrochloride as will lie on a quarter and twice as much sodium acetate. Mix and heat on a boiling water bath for 45 minutes. Remove and let stand for at least an hour. Look for "hedgehog crystals" of lactosazone. Glucose, if present in significant amount, will be adsorbed by the charcoal to some extent and come through along with the lactose to give glucosazone crystals. The value of the charcoal separation is chiefly to increase the concentration of lactose relative to glucose and to facilitate the obtaining of characteristic lactosazone crystals.
- 3. Mucic Acid Test: Transfer 50 ml. of urine to a 150-ml. beaker and add 12 ml. of concentrated HNO₃. Heat on a boiling water bath until the volume is reduced to about 10 ml. Cool. Add 10 ml. of water and let stand overnight. A fine white precipitate of mucic acid will form if lactose or galactose is present. Examine the crystals under the microscope (see Fig. 21). Other reducing sugars do not give this test. Lactose and galactose may be differentiated by Tollens' test (see tests for pentose).

GALACTOSE

Galactose has occasionally been detected in the urine, and in particular in that of nursing infants afflicted with a deranged digestive function. It may be present in significant amount in liver disease after the administration of large doses of galactose, as in the "galactose tolerance test" (analogous to the glucose tolerance test) for liver function. Lactose and galactose may be differentiated from other reducing sugars which may be present in the urine by means of the mucic acid test. For a description of the mucic acid test, see the experiments on lactose above. To differentiate galactose, use Tollens' reaction (see the section on pentose above). The red solution given by galactose shows no absorption bands. Galactose is fermentable very slowly or not at all by ordinary bakers' yeast.

FRUCTOSE

The occurrence of fructose in the urine is relatively rare. In essential fructosuria small amounts of fructose are constantly excreted regardless of the fructose content of the diet, although it is curious that, if the diet

is carbohydrate-free, the excretion of fructose ceases. No satisfactory explanation has as yet been offered for the condition of essential fructosuria, which is apparently a harmless metabolic abnormality. In diabetes mellitus, fructose may at times be excreted along with glucose (never by itself); the significance of this is not known, although it may be recalled that fructose diphosphate is an intermediate in carbohydrate metabolism (see Chapter 33). Fructose is levorotatory while glucose is dextrorotatory; the detection of fructose in the urine by polariscopic methods is generally unsatisfactory, however, because other levorotatory compounds (conjugate glucuronates, β -hydroxybutyric acid) may also be present.

TESTS FOR FRUCTOSE

1. Borchardt's Reaction: To about 5 ml. of urine in a test tube add an equal volume of 25 per cent hydrochloric acid and a few crystals of resorcinol. Heat to boiling and after the production of a red color, cool the tube under running water and transfer to an evaporating dish or beaker. Make the mixture slightly alkaline with solid potassium hydroxide, return it to a test tube, add 2 to 3 ml. of ethyl acetate, and shake the tube vigorously. In the presence of fructose the ethyl acetate is colored yellow.

The only urinary constituents which interfere with the test are nitrites and indican, and these interfere only when they are simultaneously present. Under these conditions, the urine should be acidified with acetic acid and heated to boiling for one minute to remove the nitrites. In case the indican content is very large, it will impart a blue color to the ethyl acetate, thus masking the yellow color due to fructose. When such urines are to be examined, the indican should first be removed by Obermayer's test (see p. 737). The chloroform should then be discarded, the acid-urine mixture diluted with one-third its volume of water, and the test applied as described above. The urine of patients who have ingested santonin or rhubarb responds to the test. The test will serve to detect fructose when present in a dilution of 1:2000—i.e., 0.05 per cent.

2. Resorcinol-Hydrochloric Acid Reaction (Selivanoff): To 5 ml. of Selivanoff's reagent²⁹ in a test tube add a few drops of the urine under examination and heat the mixture to boiling, or place in a boiling water bath. The presence of fructose is indicated by the production of a red color which may or may not lead ultimately to the separation of a red precipitate. The latter if formed may be filtered off and dissolved in alcohol to which it will impart a striking red color.

If the boiling be prolonged, a similar reaction may be obtained with urine containing glucose. The precautions necessary for a positive test for fructose are as follows: The concentration of the hydrochloric acid must not be more than 12 per cent; the reaction (red color) and the precipitate must be observed after not more than 20-30 seconds of boiling; glucose must not be present in amounts exceeding 2 per cent; the precipitate must be soluble in alcohol with a bright red color.

Phenylhydrazine Test: Make the test according to directions under Glucose, Exp. 1, p. 756. With methylphenylhydrazine fructose gives crystals differing from those given by glucose in their rate of formation (p. 64).
 See Appendix.

4. Polariscopic Examination: A simple polariscopic examination, when taken in connection with other ordinary tests, will furnish the requisite data regarding the presence of fructose, provided fructose is not accompanied by other levorotatory substances, such as conjugate glucuronates and §-hydroxybutyric acid.

ARSENIC

When any soluble form of arsenic is introduced into the body in any way, it is quickly absorbed and distributed by the blood and lymph. The absorption is influenced by the quantity and character of food in the stomach, and the activity of the circulation of the part in contact with the poison. Some of the absorbed arsenic may be returned to the alimentary canal by way of the bile and gastrointestinal mucous membrane. After absorption it may be deposited in the liver, kidneys, brain, bone, muscles, and walls of the stomach and intestines. It is eliminated in all of the excretions, but chiefly by the kidneys and through the feces. It does not appear very promptly in the urine but continues to be excreted in the urine over a long period of time, in some cases for several months. The urine may be examined for arsenic by the following classical methods.

1. Marsh and Marsh-Berzelius Method: This method has the advantage of serving as a qualitative and quantitative determination, and is a very

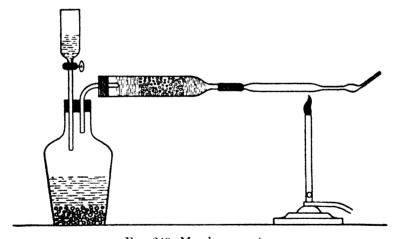

Fig. 240. Marsh apparatus.

delicate test; it is, however, long and tedious. The various steps in the analysis are: (1) The destruction of the organic matter in the urine; (2) treatment with sulfuric acid to drive off excess nitric acid and break up nitro-compounds; and (3) application of independent test to the resultant solution. Proceed as follows: The urine, to which is added one-third its volume of nitric acid, is placed in a casserole or evaporating dish and evaporated at 65° to 70° C. to a syrupy consistency. The mass is then allowed to cool and 5 ml. of concentrated sulfuric acid added, and gentle heat applied. The heating must be done cautiously, or deflagration takes place and some of the arsenic is sure to be lost. The mass will liquefy and finally darken, indicating organic matter. Cool and add concentrated nitric acid, 1 ml., and apply very gentle heat; copious reddish-brown fumes are evolved.

Gradually raise the temperature until darkening of the solution occurs, then cool, add 1 ml. of concentrated nitric acid, and again apply gentle heat, and repeat the process until the solution fails to darken. Now raise the temperature until white fumes begin to come off. At this temperature excess nitric acid will have been removed and all nitro-compounds broken up. The solution at this point is clear and at most a pale straw color. Cool and add a mixture of 10 ml. of concentrated sulfuric acid and 40 ml. of water, and test for arsenic using a Marsh apparatus (Fig. 240), which consists of a wide-mouth flask—250 ml. capacity—fitted with a two-hole stopper. Through one hole is passed the stem of a separatory funnel of 50 to 60 ml. capacity. Through the other hole a piece of glass tube bent at right angles, which is fitted to a calcium chloride tube, and this in turn to a narrow quartz tube, the distal end of which is drawn to a fine bore and bent up almost at a right angle. All joints must be air-tight.

Introduce 30 to 40 g. of arsenic-free granulated zinc into the flask, insert the stopper, and through the funnel introduce 50 ml. of dilute sulfuric acid (1 part to 4 parts water). After a few minutes collect a test tube of gas by inverting a test tube over the end of the quartz tube, and test it by igniting. When the gas in the test tube ignites quietly, light the gas issuing from the quartz tube.

Hold a clean porcelain crucible lid in the flame and note whether any deposit occurs. This precaution must be taken to insure that the chemicals and apparatus are not contaminated with arsenic.

Now introduce the prepared urine solution into the funnel and adjust the flow so that 6 to 8 drops are introduced into the flask per minute. Immediately hold a clean porcelain crucible lid in the flame, and, at the first evidence of a dark deposit, apply heat, using a wing-top burner, to the quartz tube. The arsenic if present will deposit in the quartz tube beyond the flame. Now test the spot on the lid to see if it is arsenic; it should dissolve readily in sodium hypochlorite solution. Continue the operation for two hours, remove the Bunsen burner and again hold the lid in the flame. If no more deposits on the lid, the arsenic has all come over and is deposited in the quartz tube; if deposition occurs, apply the Bunsen burner again and repeat.

When complete, remove the quartz tube, weigh it after cooling, then dissolve out the arsenic with nitric acid, wash, dry, and weigh again. The difference in weight is the weight of metallic arsenic in the volume of urine taken.

2. Reinsch's Test: This test is very much simpler, but not so delicate. It has the advantage of application in the presence of organic matter. The test is performed as follows: The urine, acidified with one-fifth its volume of pure hydrochloric acid, is placed in a beaker. A piece of bright copper foil free from arsenic is then introduced, and the urine heated almost to the boiling point. It is then set aside for six to eight hours. The arsenic is deposited on the copper foil, giving it a bluish-gray color. The foil is then removed, washed successively in pure water, alcohol, ether, and dried without heat. The foil is then rolled into a scroll and inserted into a 3-mm.-bore glass tube 4 inches long, about 1 inch from the end. The tube is then held in the Bunsen flame at an angle of 20 to 25 degrees, heat being applied where the copper foil is situated. The arsenic volatilizes and is oxidized, and deposits as octahedral crystals of arsenic trioxide on the cooler part of the tube. The crystals can readily be recognized by the microscope and sometimes with a simple magnifying lens.

MERCURY

The rapidity of absorption of mercury depends upon a number of conditions such as mode of administration, the nature of the compound and

its physical state, the state and condition of the stomach and intestines, the quantity and quality of the food in the stomach, and the state of the circulation of the portal of entrance. There is no definite knowledge as to the form in which it is absorbed. Elimination depends upon the state of the excretory organs. It is eliminated in all the excretions of the body—urine, feces, saliva, sweat, tears, and milk. Elimination begins about two hours after introduction. Depending upon the amount introduced and absorbed, and the extent of renal injury, the time required for its complete elimination varies from 24 hours to many weeks. Mercury may be detected in the urine by the following methods.

- 1. Reinsch's Test: The procedure is carried out in the same manner as for arsenic (see above). A piece of arsenic-free copper foil is introduced into the urine acidified with one-fifth its volume of pure hydrochloric acid. The urine is, however, not heated to boiling, but warmed to 50° or 60° and set aside for 12 or preferably 24 hours. Metallic mercury is deposited on the foil as a bright lustrous mirror. The foil is then washed with pure water, alcohol, ether, and dried without heat, rolled into a scroll, inserted into a glass tube and heated in the same manner as under Arsenic. The mercury is deposited in the metallic state in the form of globules readily distinguishable with the microscope.
- 2. Amalgamation Test: A more rapid method than the above is by amalgamation with zinc. Add 5 g. of zinc dust to the urine and heat for 15 minutes, stirring continuously. Allow the amalgamated zinc to settle and decant the urine. Then wash by decantation several times with pure water, then with alcohol, and finally with ether and dry in air. Now introduce the dry zinc into a narrow dry glass tube sealed at one end. With the Bunsen burner soften the tube about 2 inches above the zinc and constrict the tube by pulling the ends apart. Introduce a small bit of glass wool or asbestos sufficient to support a small piece of iodine. Introduce the iodine supported by the asbestos at the constriction. Apply heat to the zinc amalgam, and then gently to the region holding the iodine to gently volatilize it, and immediately reapply heat to the zinc. The mercury volatilizes and meeting the iodine vapor unites with it, and is deposited as the red iodide of mercury.

LEAD

Lead may be found to the extent of 0.05 mg. or so per liter in the urine of healthy individuals and may be estimated by the method of Fairhall.³⁰ It is increased in lead poisoning.

INOSITOL

Inositol, C₆H₆(OH)₆, occasionally occurs in the urine in albuminuria, diabetes mellitus, and diabetes insipidus. It is claimed also that copious water drinking causes this substance to appear in the urine. For further discussion, see Chap. 35.

TEST FOR INOSITOL

1. Detection of Inositol (Scherer): Acidify the urine with concentrated nitric acid and evaporate nearly to dryness. Add a few drops of ammonium hydroxide and a little calcium chloride solution to the moist residue and

¹⁰ Fairhall: J. Biol. Chem., 60, 485 (1924); Aub, Fairhall, Minot, and Resnikoff: Medicine, 4, 1 (1925); Millet: J. Biol. Chem., 83, 265 (1929). See also Chapters 23 and 32.

evaporate the mixture to dryness. In the presence of inositol (0.001 g.) a bright red color is obtained.

For a more satisfactory test, which, however, is more time-consuming, see Salkowski's modification of Scherer's test.

FAT

When fat finds its way into the urine through a lesion which brings some portion of the urinary passages into communication with the lymphatic system, a condition known as chyluria is established. The turbid or milky appearance of such urine is due to its content of chyle. This disease is encountered most frequently in tropical countries, but is not entirely unknown in more temperate climates. Albumin is a constant constituent of the urine in chyluria. Upon shaking a chylous urine with ether, the fat is dissolved by the ether and the urine become less turbid or entirely clear.

MELANINS

These pigments never occur normally in the urine, but are present under certain pathological conditions, their presence being especially associated with melanotic tumors. Ordinarily the freshly passed urine is clear, but upon exposure to the air the color deepens and may at last be very dark brown or black in color. The pigment is probably present in the form of a chromogen or melanogen and upon coming into contact with the air oxidation occurs, causing the transformation of the melanogen into melanin and consequently the darkening of the urine.

It is claimed that melanuria is proof of the formation of a visceral melanotic growth. In many instances, without doubt, urines rich in indican have been wrongly taken as diagnostic proof of melanuria. The pigment melanin is sometimes mistaken for indigo and melanogen for indican. It is comparatively easy to differentiate between indigo and melanin through the solubility of the former in chloroform.

In rare cases melanin is found in urinary sediment in the form of fine amorphous granules.

TESTS FOR MELANIN

1. Ferric Chloride Reaction (von Jaksch-Pollak): Add a few drops of ferric chloride solution to 10 ml. of urine in a test tube and note the formation of a gray color. Upon the further addition of the chloride a dark precipitate forms, consisting of phosphates and adhering melanin. An excess of ferric chloride causes the precipitate to dissolve.

This is the most satisfactory test for the identification of melanin in the urine.

 Bromine Test (Zeller): To 50 ml. of urine in a small beaker add an equal volume of bromine water. In the presence of melanin a yellow precipitate will form and will gradually darken in color, ultimately becoming black.

UROROSEIN

Urorosein is a urinary pigment which does not occur preformed in the urine, but is present in the form of a chromogen, which is transformed into the pigment upon treatment with a mineral acid. Herter showed this chromogen to be indoleacetic acid,

⁸¹ Salkowaki: Z. physiol. Chem., 69, 478 (1910).

Indoleacetic acid may be found in urine free or as a compound with glycine. Normal urine responds to the uroresein reaction (see below) if nitrites are present. Pathologically, a positive urorosein reaction is obtained in a variety of diseases, such as pulmonary tuberculosis, typhoid fever, nephritis, stomach disorders, and pellagra. The reaction in the urine of pellagra has attracted considerable interest because of its possible metabolic and diagnostic significance.³²

TEST FOR UROROSEIN

Nitrite-Hydrochloric Acid Test (Urorosein Reaction): To 10 ml. of urine in a test tube add 2 ml. of concentrated hydrochloric acid and a few drops of a 1 per cent solution of potassium nitrite. A rose-red color indicates urorosein. The chromogen (indoleacetic acid) has been changed to urorosein by oxidation.

HEMATOPORPHYRIN

Urine containing this compound is occasionally met with in various diseases, but more frequently after the use of quinine, tetronal, trional, and especially sulfonal. Such urines ordinarily possess a reddish tint, the depth of color varying greatly under different conditions.

The porphyrin found in the urine normally as an absorbed intestinal product and which may also be increased in disease, is coproporphyrin $C_{20}H_6N_4(CH_2CH_2COOH)_4$. In congenital porphyrinuria, uroporphyrin, $C_{20}H_6N_4(CH_2COOH)_4(CH_2CH_2COOH)_4$ is found.

TESTS FOR HEMATOPORPHYRIN

- 1. Spectroscopic Examination: To 100 ml. of urine add about 20 ml. of a 10 per cent solution of potassium hydroxide or ammonium hydroxide. The precipitate which forms consists principally of earthy phosphates to which the hematoporphyrin adheres and is carried down. Filte: off the precipitate, wash it and transfer to a flask and warm with alcohol acidified with hydrochloric acid. By this process the hematoporphyrin is dissolved and on filtering will be found in the filtrate and may be identified by means of the spectroscope (see p. 447, and Absorption Spectra, Plate I).
- 2. Acetic Acid Test: To 100 ml. of urine add 5 ml. of glacial acetic acid and allow the mixture to stand 48 hours. Hematoporphyrin deposits in the form of a precipitate.

UROCHROMOGEN

Urochromogen is a substance of unknown composition whose relation to the urinary pigments is uncertain. It has been claimed that the urochromogen reaction of the urine is an aid to prognosis and diagnosis of pulmonary tuberculosis. Urochromogen is not present in normal urine. Its presence in pathological urine is due probably to faulty oxidation.

¹³ See Watson: Proc. Soc. Exptl. Biol. Med., 41, 591 (1939); Watson and Layne: Ann. Int. Med., 19, 183 (1943).

Urochromogen may be detected by oxidizing it to a yellow pigment by means of potassium permanganate. In this process a certain antecedent of urochromogen also is oxidized. Whereas the diazo reaction (see below) is also given by urines containing urochromogen, it is claimed that the diazo reaction does not show the presence of the precursor of urochromogen. Hence the urochromogen reaction is said to be more constant and uniform in its appearance.

TEST FOR UROCHROMOGEN

Urochromogen Reaction (Weisz): Fill a test tube a little less than one-third full of urine, dilute it with 2 volumes of distilled water, and mix thoroughly. Pour one-half the diluted urine into another tube and to one of the tubes add 3 drops of a 1 per cent solution of potassium permanganate. Shake the tube thoroughly. In the presence of urochromogen a yellow tint will appear in the tube to which permanganate was added.

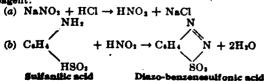

The reaction is due to the oxidation of urochromogen. The presence of sugar, albumin, or urobilin in low concentration does not interfere with the test. The test often runs parallel with the diazo reaction (see below). The test is supposed to be positive when the focus of the lung is so active or extensive as to flood the blood with toxins or to break down the defensive forces of the body. It is claimed, therefore, that this test will differentiate the cases in which the tuberculosis is beyond help by the use of tuberculin from those in which the body is liable to respond favorably to its action. Some investigators claim the test is not specific and that a positive reaction may be obtained in many disorders other than tuberculosis.

UNKNOWN SUBSTANCES

Ehrlich's Diazo Reaction: Place equal volumes of urine and Ehrlich's diazobenzenesulfonic acid reagent³³ in a test tube, mix thoroughly by shaking, and quickly add ammonium hydroxide in excess. The test is positive if both the fluid and the foam assume a red color. If the tube is allowed to stand, a precipitate forms, the upper portion of which exhibits a blue, green, greenish-black, or violet color. Normal urine gives a brownish-yellow reaction with the above procedure.

The exact nature of the substance or substances upon whose presence in the urine this reaction depends is not well understood. The reaction may be taken as a symptom of certain metabolic disorders, which is of value diagnostically *only* when taken in connection with the other symptoms. The reaction appears principally in the urine in febrile disorders and in particular in the urine in typhoid fever, tuberculosis, and measles. The reaction has also been obtained in the urine in various other disorders such as carcinoma, chronic rheumatism, diphtheria, erysipelas,

33 See Appendix. The following chemical reactions take place in preparing Ehrlich's reagent:

pleurisy, pneumonia, scarlet fever, syphilis, typhus, etc. The administration of alcohol, chrysarobin, creosote, cresol, dionin, guiacol, heroin, morphine, naphthalene, opium, phenol, tannic acid, etc., will also cause the urine to give a positive reaction.

Hunter describes two types of diazo reaction in alkaline solution—Type A and Type B. Type A reaction is characterized by a gradual development of color until a relatively stable maximum is reached. Type B is characterized by an *immediate* development and a very rapid disappearance of color. All urines give some form of type A reaction and the substances responsible are imidazoles, phenols, purines, and probably other unknown chromogens. Type B is given only by pathological urines, especially those from *typhoid* and *measles*. Urochromogen may be responsible for this reaction.

Urine: Organized and Unorganized Sediments

The sedimentary constituents of the urine may be divided into two classes, viz., organized and unorganized. The sediment is collected by centrifuging the urine at low speed or by allowing it to stand for some time in a conical vessel.

UNORGANIZED SEDIMENTS

The more common unorganized sediments consist of ammonium magnesium phosphate ("triple phosphate"), calcium oxalate, calcium phosphate, uric acid, and sodium and ammonium urates. Less commonly observed are calcium carbonate, calcium sulfate, magnesium phosphate, cystine, leucine, tyrosine, hippuric acid, bilirubin, indigo, xanthine, and melanin.

The separation as sediments depends upon the degree of saturation of the urine for these substances, which in turn is influenced by the reaction of the urine. Uric acid most commonly separates out from strongly acid urines, sodium urate from less acid urines. Calcium phosphate comes out most commonly in urines more alkaline than pH 6, while calcium oxalate is found in acid, alkaline, and neutral urines. All of these substances are found as sediments in normal urines, and the majority of normal urines show one or more of these separating out on standing. Ammonium magnesium phosphate, ammonium urate, and calcium carbonate precipitate from urines which have undergone ammoniacal fermentation due to an infection in the urmary tract, and which are hence alkaline in reaction. Maslow studied the sediments forming on long standing in carefully preserved specimens of the urines of normal young men. Sediments were found in 93 per cent of the urines. Uric acid was found in 17 per cent of cases at an average pH of 5.5 and sodium urate in a similar number of cases at an average pH of 5.8. Calcium phosphate was found in 46 per cent of cases with an average pH of 6.2 and calcium oxalate was found in 71 per cent of cases and at all reactions.

Ammonium Magnesium Phosphate ("Triple Phosphate"). Crystals of "triple phosphate" are a characteristic constituent of the sediment when alkaline fermentation of the urine has taken place either before or after being voided. They may even be detected in neutral or slightly acid urine provided the ammonium salts are present in large enough quantity. This substance may occur in the sediment in two forms, viz., prisms and the feathery type. The prismatic form of crystals is the one most commonly observed in the sediment; the feathery form predominates when the urine is made ammoniacal with ammonia (see Fig. 236).

The sediment of the urine in such disorders as are accompanied by a retention of urine in the lower urinary tract contains "triple phosphate" crystals as a charac-

-teristic constituent. The crystals are frequently abundant in the sediment during paraplegia, chronic cystitis, enlarged prostate, and chronic pyelitis.

Calcium Oxalate. Calcium oxalate is found in the urine in the form of at least two distinct types of crystals, viz., the dumbbell type and the octahedral type (Fig. 241). Either form may occur in the sediment of neutral, alkaline, or acid urine, but both forms are found most frequently in urine having an acid reaction. Occasionally, in alkaline urine, the octahedral form is confounded with "triple phosphate" crystals.

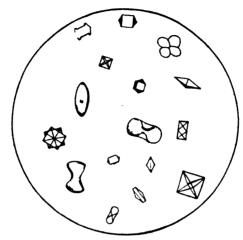

Fig. 241. Calcium oxalate (Ogden).

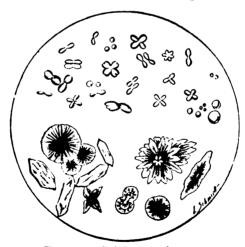

Fig. 242. Calcium carbonate.

They may be differentiated from the phosphate crystals by the fact that they are insoluble in acetic acid.

The presence of calcium oxalate in the urine is not of itself a sign of any abnormality, since it is a constituent of normal urine. It is increased above the normal, however, in such pathological conditions as diabetes mellitus, in organic diseases of the liver, and in various other conditions which are accompanied by a derangement of digestion or of the oxidation mechanism, such as occurs in certain diseases of the heart and lungs.

Calcium Carbonate. Calcium carbonate crystals form a typical constituent of the urine of herbivorous animals. They occur less frequently in human urine. The reac-

tion of urine containing these crystals is nearly always alkaline, although they may occur in neutral or in slightly acid urine. It generally crystallizes in the form of granules, spherules, or dumbbells (Fig. 242). The crystals of calcium carbonate may be differentiated from calcium oxalate by the fact that they dissolve in acetic acid with the evolution of carbon dioxide gas.

Calcium Phosphate (Stellar Phosphate). Calcium phosphate may occur in the urine in three forms, viz., amorphous, granular, or crystalline. The crystals of calcium phosphate are ordinarily pointed, wedge-shaped formations which may occur as individual crystals or grouped together in more or less regularly formed rosettes (see Fig. 71). Acid sodium urate crystals (Fig. 244) are often mistaken for crystals of calcium phosphate. We may differentiate between these two crystalline forms by the fact that acetic acid will readily dissolve the phosphate, whereas the urate is much less soluble and when finally brought into solution and recrystallized one is

Fig. 243. Various forms of uric acid. (1) Rhombic plates; (2) whetstone forms; (3, 3) quadrate forms; (4, 5) prolonged into points; (6, 8) rosettes; (7) pointed bundles; (9) barrel forms precipitated by adding hydrochloric acid to urine.

frequently enabled to identify uric acid crystals which have been formed from the acid urate solution. The clinical significance of the occurrence of calcium phosphate crystals in the urinary sediment is similar to that of "triple phosphate" (see p. 788).

Calcium Sulfate. Crystals of calcium sulfate are of quite rare occurrence in the sediment of urine. Their presence seems to be limited in general to urines which are of a decided acid reaction. Ordinarily it crystallizes in the form of long, thin, colorless needles or prisms (Fig. 235) which may be mistaken for calcium phosphate crystals. There need be no confusion in this respect, however, since the sulfate crystals are insoluble in acetic acid, which reagent readily dissolves the phosphate. As far as is known, their occurrence as a constituent of urinary sediment is of very little clinical significance.

Uric Acid. Uric acid forms a very common constituent of the sediment of urines which are acid in reaction. It occurs in more varied forms than any of the other crystalline sediments (see Plate V, and Fig. 243), some of the more common varieties of crystals being rhombic prisms, wedges, dumbbells, whetstones, prismatic rosettes, irregular or hexagonal plates, etc. Crystals of pure uric acid are always colorless (see Fig. 230), but the form occurring in urinary sediments is impure and under the

microscope appears pigmented, the depth of color varying from yellow to a dark reddish-brown according to the size and form of the crystal.

The presence of a considerable uric acid sediment does not, of necessity, indicate a pathological condition or a urine of increased uric acid content, since this substance very often occurs as a sediment in urines whose uric acid content is diminished from the normal merely as a result of changes in reaction, etc. Pathologically, uric acid sediments occur in gout, acute febrile conditions, chronic interstitial nephritis, etc. If the microscopical examination is not conclusive, uric acid may be differentiated from other crystalline urinary sediments from the fact that it is soluble in alkalies, alkali carbonates, boiling glycerol, concentrated sulfuric acid, and in certain organic bases such as ethylamine and piperidin. It also responds to the murexide test (see p. 730), Schiff's reaction (see p. 730), and to Folin's phosphotungstic acid reaction (see p. 730).

Urates. The urate sediment may consist of a mixture of the urates of ammonium, calcium, magnesium, potassium, and sodium. The ammonium urate may occur in neutral, alkaline, or acid urine, whereas the other forms of urates are confined to the sediments of acid urines. Sodium urate occurs in sediments more abundantly than the other urates. There are two sodium urates, the mono- and the di-, which may be expressed thus:

$$Na^+$$
 $C_bH_2N_4O_1^-$ and Na^+
 $C_bH_2N_4O_2^-$

The so-called quadriurate or hemiurate have no existence as chemical units. The urates of calcium, magnesium, and potassium are amorphous in character, whereas

Fig. 244. Acid sodium urate.

the urate of ammonium is crystalline. Sodium urate may be either amorphous or crystalline. When crystalline it forms groups of fan-shaped clusters or colorless, prismatic needles (Fig. 244). Ammonium urate is ordinarily present in the sediment in the burrlike form of the "thorn-apple" crystal, i.e., yellow or reddish-brown spheres, covered with sharp spicules or prisms (Fig. 245). The urates are all soluble in hydrochloric acid or acetic acid and their acid solutions yield crystals of uric acid upon standing. They also respond to the murexide test. The clinical significance of urate sediments is very similar to that of uric acid. A considerable sediment of amorphous urates does not necessarily indicate a high uric acid content, but ordinarily signifies a concentrated urine having a very strong acidity.

Cystine. Cystine is one of the rarer of the crystalline urinary sediments. It has been claimed that it occurs more often in the urine of men than of women. Cystine crystallizes in the form of thin, colorless, hexagonal plates (see Fig. 48), which are insoluble in water, alcohol, and acetic acid, and soluble in mineral acids, alkalies. and especially in ammonia. Cystine may be identified by burning it upon platinum foil, under which condition it does not melt but yields a bluish-green flame. For the preparation of cystine, see p. 128.

Cholesterol. Cholesterol crystals have been but rarely detected in urinary sediments. When present they probably arise from a pathological condition of some portion of the urinary tract. Crystals of cholesterol have been found in the sediment in cystitis, pyelitis, chyluria, and nephritis. Ordinarily they occur as large regular and irregular colorless, transparent plates, some of which possess notched corners (see Fig. 112). Frequently, instead of occurring in the sediment, cholesterol is found in a film on the surface of the urine.

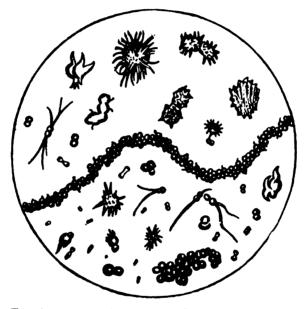

Fig. 245. Ammonium urates, showing spherules and thorn-apple-shaped crystals. (After Peyer.)

Hippuric Acid. This is one of the rare sediments of human urine. It deposits under conditions similar to those which govern the formation of uric acid sediments. The crystals, which are colorless needles or prisms (see Fig. 233) when pure, are invariably pigmented in a manner similar to the uric acid crystals when observed in urinary sediment and because of this fact are frequently confounded with the rarer forms of uric acid. Hippuric acid may be differentiated from uric acid from the fact that it does not respond to the murexide test and is much more soluble in water and in ether. The detection of crystals of hippuric acid in the urine has very little clinical significance, since its presence in the sediment depends in most instances very greatly upon the nature of the diet. It is particularly prone to occur in the sediment after the ingestion of certain fruits as well as after the ingestion of benzoic acid (see p. 737).

Leucine and Tyrosine. Leucine and tyrosine have frequently been detected in the urine, either in solution or as a sediment. Neither of them occurs in the urine ordinarily except in association with the others, i.e., whenever leucine is detected it is more than probable that tyrosine accompanies it. They have been found pathologically in the urine in acute yellow atrophy of the liver, in acute phosphorus poison-

ing, in cirrhosis of the liver, in severe cases of typhoid fever and smallpox, and in leukemia. In urinary sediments leucine ordinarily crystallizes in characteristic spherical masses which show both radial and concentric striations and are highly refractive (Fig. 246). Some investigators claim that these crystals which are ordinarily called

leucine are, in reality, generally urates. For the crystalline form of pure leucine obtained as a decomposition product of protein, see Fig. 45. Tyrosine crystallizes in urinary sediments in the well-known sheaf or tuft formation (Fig. 47). For other tests on leucine and tyrosine, see pp. 122 and 126.

Bilirubin. Bilirubin crystallizes in the form of tufts of small needles or in the form of small plates which are ordinarily yellowish-red in color (Fig. 111). Pathologically, typical crystals of bilirubin have been found in the urinary sediment in jaundice, acute yellow atrophy of the liver, carcinoma of the liver, cirrhosis of the liver, and in phosphorus poisoning, typhoid feyer, and scarlatina.

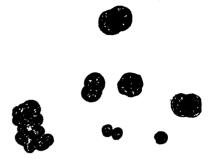

Fig. 246. Crystals of impure leucine (Ogden).

Magnesium Phosphate. Magnesium phosphate crystals occur rather infrequently in the sediment of urine which is neutral, alkaline, or feebly acid in reaction. It ordinarily crystallizes in clongated, highly refractive, rhombic plates which are soluble in acetic acid.

Indigo. Indigo crystals are frequently found in urine which has undergone alkaline fermentation. They result from the breaking down of indoxyl sulfates or indoxyl-glycuronates. Ordinarily indigo deposits as dark blue stellate needles or occurs as amorphous particles or broken fragments. These crystalline or amorphous forms may occur in the sediment or may form a blue film on the surface of the urine. Indigo crystals generally occur in urine which is alkaline in reaction, but they have been detected in acid urine.

Xanthine. Nanthine is a constituent of normal urine but is found in the sediment in crystalline form very infrequently, and then only in pathological urine. When present in the sediment xanthine generally occurs in the form of whetstone-shaped crystals somewhat similar in form to the whetstone variety of uric acid crystal. They may be differentiated from uric acid by the great ease with which they may be brought into solution in dilute ammonia and on applying heat. Xanthine may also form urinary calculi. The clinical significance of xanthine in urinary sediment is not well understood.

Melanin. Melanin is an extremely rare constituent of urinary sediments. Ordinarily in melanuria the melanin remains in solution; if it separates it is generally held in suspension as fine amorphous granules.

Sulfonamides. After administration of the sulfonamides (see p. 601 for discussion of chemical nature), crystalline deposits of the free drug or of its acetylated derivative may be found in the urine. Sulfonamide crystals may be recognized by their characteristic appearance (Fig. 247). If the crystals form in the renal tubules during the formation of urine, kidney damage accompanied by hematuria may result. Since the compounds producing the crystals are much more soluble in the form of their alkali salts, the maintenance of an alkaline urine during sulfonamide therapy will prevent the deposition of the crystals.

ORGANIZED SEDIMENTS

Among the more important organized sediments are casts of different types, epithelial cells, pus cells, erythrocytes, and microörganisms. Cylindroids, spermatozoa, urethral filaments, tissue debris, animal parasites, fibrin, and foreign substances due to contamination, are also observed.

Epithelial Cells. The detection of a certain number of these cells in urinary sediment is not, of itself, a pathological sign, since they occur in normal urine. However, in certain pathological conditions they are greatly increased in number, and since

different areas of the urinary tract are lined with different forms of epithelial cells. it becomes necessary, when examining urinary sediments, to note not only the relative number of such cells, but at the same time to observe carefully the shape of the various individuals in order to determine, as far as possible, from what portion of the tract they have been derived. Since the different layers of the epithelial lining are composed of cells different in form from those of the associated layers, it is evident that a careful microscopical examination of these cells may indicate which particular

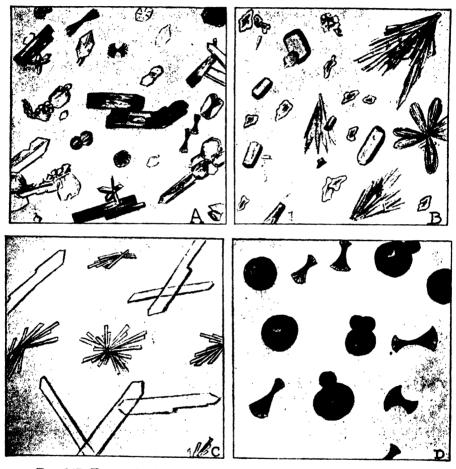

Fig. 247. Types of urinary crystals of the sulfonamide compounds. (A) Sulfathiazole, (B) sulfapyridine, (C) sulfanilamide, (D) sulfadiazine. (Courtesy, Kolmer: "Clinical Diagnosis by Laboratory Examinations," D. Appleton-Century Co.)

layer is being desquamated. It is frequently a most difficult undertaking, however, to make a clear differentiation between the various forms of epithelial cells present in the sediment. If skillfully done, such a microscopical differentiation may prove to be of very great diagnostic aid.

The principal forms of epithelial cells met with in urinary sediments are shown in Fig. 248.

Pus Cells. Pus corpuscles or leukocytes are present in extremely small numbers in normal urine. Any considerable increase in the number, however, ordinarily denotes

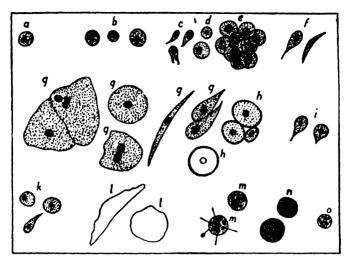

Fig. 248. Epithelium from different areas of the urinary tract. (a) Leukocyte (for comparison); (b) renal cells; (c) superficial pelvic cells; (d) deep pelvic cells; (e) cells from calices; (f) cells from ureter; (g, g, g, g, g) squamous epithelium from the bladder; (h, h) neck-of-bladder cells; (i) epithelium from prostatic urethra; (k) urethral cells; (l, l) scaly epithelium; (m, m) cells from seminal passages; (n) compound granule cells; (a) fatty renal cell (Ogden).

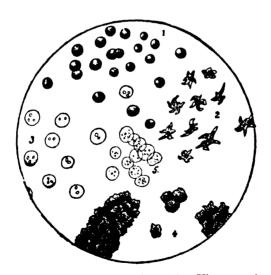

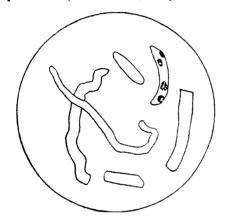

Fig. 249. Pus corpuscles. (After Ultzmann.) (1) Normal; (2) showing ameboid movements; (3) nuclei rendered distinct by acetic acid; (4) as observed in chronic pyelitis; (5) swollen by ammonium carbonate.

a pathological condition, generally an acute or chronic inflammatory condition of some portion of the urinary tract. The sudden appearance of a large amount of pus in a sediment denotes the opening of an abscess into the urinary tract. Other form elements, such as epithelial cells, casts, etc., ordinarily accompany pus corpuscles in urinary sediment and a careful examination of these associated elements is necessary in order to form a correct diagnosis as to the origin of the pus. Protein is always present in urine which contains pus.

The appearance which pus corpuscles exhibit under the microscope depends greatly upon the reaction of the urine containing them. In acid urine they generally present the appearance of round, colorless cells composed of refractive, granular protoplasm, and may frequently exhibit ameboid movements, especially if the slide containing them be warmed slightly. They are nucleated (one or more nuclei), the nuclei being clearly visible only upon treating the cells with water, acetic acid, or some other suitable reagent. In urine which has a decided alkaline reaction, on the other hand, the pus corpuscles are often greatly degenerated. They may be seen as swollen, transparent cells, which exhibit no granular structure and as the process of degeneration

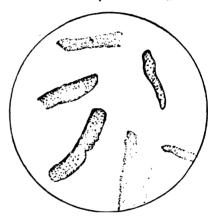

Fig. 250. Hyaline casts. One cast is impregnated with four renal cells.

Fig. 251. Granular casts. (After Peyer.)

continues the cell outline ceases to be visible, the nuclei fade, and finally only a mass of debris containing isolated nuclei and an occasional cell remain (see Fig. 249).

It is frequently rather difficult to make a differentiation between pus corpuscles and certain types of epithelial cells which are similar in form. Such confusion may be avoided by the addition of iodine solution (I in KI), a reagent which stains the pus corpuscles a deep mahogany-brown and transmits to the epithelial cells a light yellow tint. The test proposed by Vitali often gives very satisfactory results. This simply consists in acidifying the urine (if alkaline) with acetic acid, then filtering, and treating the sediment on the filter paper with freshly prepared tincture of guaiac. The presence of pus in the sediment is indicated if a blue color is observed. Large numbers of pus corpuscles are present in the urinary sediment in gonorrhea, leukorrhea, chronic pyelitis, and in abscess of the kidney.

Casts. These are cylindrical formations, which originate in the uriniferous tubules and are forced out by the pressure of the urine. They vary greatly in size, but in nearly every instance they possess parallel sides and rounded ends. The finding of casts in the urine is very important because of the fact that they generally indicate some kidney disorder; if albumin accompanies the casts the indication is much accentuated. Casts have been classified according to their microscopical characteristics as follows: (a) hyaline, (b) granular, (c) epithelial, (d) blood, (e) fatty, (f) waxy, (g) pus.

a. HYALINE CASTS. These are composed of a basic material which is transparent, homogeneous, and very light in color (Fig. 250). In fact, chiefly because of these

physical properties, they are the most difficult form of renal casts to detect under the microscope. Frequently such casts are impregnated with deposits of various forms, such as erythrocytes, epithelial cells, fat globules, etc., thus rendering the form of the cast more plainly visible. Staining is often resorted to in order to render the shape and character of the cast more easily determined. Ordinary iodine solution (I in KI) may be used in this connection; many of the aniline dyes are also in common use for this purpose, e.g., gentian violet, Bismarck brown, methylene blue, fuchsin, and cosin. Generally, but not always, albumin is present in urine containing hyaline casts. Hyaline casts are common to all kidney disorders, but occur particularly in the earliest and recovering stages of parenchymatous nephritis and interstitial nephritis.

b. Granular Casts. The common hyaline material is ordinarily the basic substance of this form of cast. The granular material generally consists of albumin, epithelial cells, fat, or disintegrated erythrocytes or leukocytes, the character of the cast varying according to the nature and size of the granules (Fig. 251). Thus we have casts of this general type classified as finely granular and coarsely granular casts.

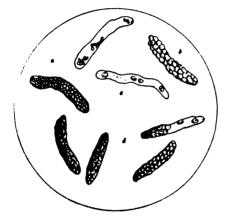

Fig. 252. Blood, pus, hyaline, and epithelial casts. (a) Blood casts; (b) pus cast; (c) hyaline cast impregnated with renal cells; (d) epithelial casts.

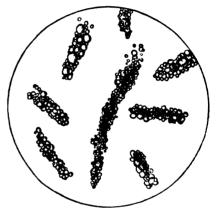

Fig. 253. Fatty casts. (After Peyer.)

Granular casts, and in particular the finely granular types, occur in the sediment in practically every kidney disorder but are probably especially characteristic of the sediment in inflammatory disorders.

- c EPITHELIAL CASTS. These are casts bearing upon their surface epithelial cells from the lining of the urimiferous tubules. The basic material of this form of cast may be hyaline or granular in nature. Epithelial casts are particularly abundant in the urinary sediment in acute nephritis.
- d. Blood Casts. Casts of this type may consist of erythrocytes borne upon a hyaline or a fibrinous basis (Fig. 252). The occurrence of such casts in the urinary sediment denotes renal hemorrhage and they are considered to be especially characteristic of acute diffuse nephritis and acute congestion of the kidney.
- e. FATTY CASTS. Fatty casts may be formed by the deposition of fat globules or crystals of fatty acid upon the surface of a hyaline or granular cast (Fig. 253). In order to constitute a true fatty cast the deposited material must cover the greater part of the surface area of the cast. The presence of fatty casts in urinary sediment indicates fatty degeneration of the kidney, such casts are particularly characteristic of subacute and chronic inflammation of the kidney.
- f. WAXY CASTS. These casts possess a basic substance similar to that which enters into the foundation of the hyaline form of cast. In common with the hyaline type,

they are colorless, refractive bodies, but differ from this form of cast in being, in general, of greater length and diameter and possessing sharper outlines and a light yellow color (see Fig. 254). Such casts occur in several forms of nephritis, but do not appear to characterize any particular type of the disorder except amyloid disease, in which they are rather common.

g. Pus Casts. Casts whose surface is covered with pus cells or leukocytes are termed pus casts (Fig. 252). They are frequently mistaken for epithelial casts. The

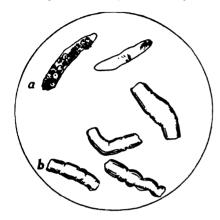

Fig. 254. (a) Fatty and (b) waxy casts.

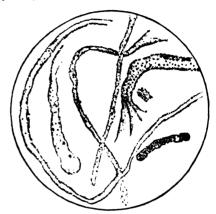

Fig. 255. Cylindroids. (After Pever.)

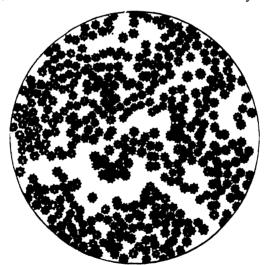

Fig. 256. Crenated erythrocytes.

differentiation between these two types is made very simple, however, by treating the cast with acetic acid which causes the nuclei of the leukocytes to become plainly visible. The true pus cast is quite rare and indicates renal suppuration.

Cylindroids. These formations may occur in normal or pathological urine and have no particular clinical significance. They are frequently mistaken for true casts, especially the hyaline type, but they are ordinarily flat in structure with a rather smaller diameter than casts, may possess forked or branching ends, and are not composed of homogeneous material as are the hyaline casts. Such "false casts" may

become coated with urates, in which event they appear granular in structure. The basic substance of cylindroids is often the nucleoprotein of the urine (Fig. 255).

Erythrocytes. These form elements are present in the urinary sediment in various diseases. They appear as the normal biconcave, yellow erythrocyte (see Plate IV) or may exhibit certain modifications in form, such as the crenated type (Fig. 256) which is often seen in concentrated urine. Under different conditions they may become swellen sufficiently to entirely erase the biconcave appearance and may even occur in the form of colorless spheres having a smaller diameter than the original disk-shaped corpuscles. Erythrocytes are found in urinary sediment in hemorrhage of the kidney or of the urinary tract, in traumatic hemorrhage, hemorrhage from congestion, and in hemorrhagic diathesis.

Spermatozoa. Spermatozoa may be detected in the urinary sediment in diseases of the genital organs, as well as after coitus, nocturnal emissions, epileptic, and other convulsive attacks, and sometimes in severe febrile disorders, especially in typhoid fever. In form they consist of an oval body, to which is attached a long, delicate tail (Fig. 257). Upon examination they may show motility or may be motionless.

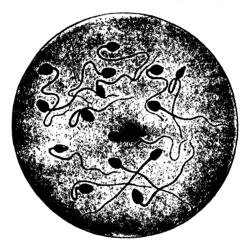

Fig. 257. Human spermatozoa.

Urethral Filaments. These are peculiar threadlike bodies which are sometimes found in urinary sediment. They may occasionally be detected in formal urine and pathologically are found in the sediment in acute and chronic gonorrhea and in urethrorrhea. The ground substance of these urethral filaments is, in part at least, similar to that of the cylindroids (see p. 798). The urine first voided in the morning is best adapted for the examination for filaments. These filaments may ordinarily be removed by a pipet since they are generally macroscopic.

Tissue Debris. Masses of cells or fragments of tissue are frequently found in the urinary sediment. They may be found in the sediment in tubercular affections of the kidney and urinary tract or in tumors of these organs. Ordinarily it is necessary to make a histological examination of such tissue fragments before coming to a final decision as to their origin.

Animal Parasites. The cysts, hooklets, and membrane shreds of echinococci are sometimes found in the urinary sediments. Other animal organisms which are more rafely met with in the urine are embryos of the *Filaria sanguinis* and eggs of the *Distoma haematobium* and *Ascarides*. Animal parasites in general occur most frequently in the urine in tropical countries.

Microorganisms. Bacteria as well as yeasts and molds are frequently detected in the urine. Both the pathogenic and nonpathogenic forms of bacteria may occur. The nonpathogenic forms most frequently observed are Micrococcus ureae, Bacillus ureae, and Staphylococcus ureae liquefaciens. Of the pathogenic forms many have been

observed, e.g., Escherichia coli, typhoid bacillus, tubercle bacillus, gonococcus, Bacillus pyocyaneus, and Proteus vulgaris. Yeasts and molds are most frequently met with in diabetic urine.

Fibrin. Following hematuria, fibrin clots are occasionally observed in the urinary sediment. They are generally of a semigelatinous consistency and of a very light color, and when examined under the microscope they are seen to be composed of bundles of highly refractive fibers which run parallel.

Foreign Substances Due to Contamination. Such foreign substances as fibers of silk, linen, or wool; starch granules, hair, fat, and sputum, as well as muscle fibers, vegetable cells, and food particles, are often found in the urine. Care should be taken that these foreign substances are not mistaken for any of the true sedimentary constituents already mentioned.

Urine: Calculi

Urinary calculi, also called concretions or concrements, are solid masses of urinary sediment formed in some part of the urinary tract. They vary in shape and size according to their location, the smaller calculi, termed sand or gravel, in general arising from the kidney or the pelvic portion of the kidney, whereas the large calculi are ordinarily formed in the bladder. There are two general classes of calculi as regards composition, viz., simple and compound. The simple form is made up of but a single constituent, whereas the compound type contains two or more individual constituents. The structural plan of most calculi consists of an arrangement of concentric rings about a central nucleus, the number of rings frequently being dependent upon the number of individual constituents which enter into the structure of the calculus. However, layers quite different in macroscopical appearance may be almost identical in composition.

In India and China urinary calculi are most frequently found in children. Up to the middle of the nineteenth century this was true for Europe and America also. But with improvement in diet of more recent years, vesical calculus in children has become rare in this country and is now primarily a disease of old age, more than half of persons admitted for operation being between the ages of 50 and 70. Calculi have been found in Egyptian tombs dating as far back as 4800 B.C.

The etiology of stone in man is still obscure. In rats urinary lithiasis can be regularly produced by diets low in vitamin A. It may be secondary to the epithelial degeneration in the bladder which occurs in vitamin-A deficiency. The calculi contain ammonium magnesium phosphate, calcium carbonate, and calcium hydroxide. The greater frequency of lithiasis in earlier times and be prevalence of stone in children in the Orient may very probably be related to dictary deficiency. Whether vitamin A or other dietary deficiency bears any important relationship to the etiology of calculus disease in this country at the present time is uncertain.

Urinary calculi base frequently been noted in patients with a variety of bone disorders. Lertain of these, associated with hyperparathyroidism, the calculus formation may be related to the markedly increased excretion of calcium in the urine. Immobilization of the patient may also be a factor.

Stone formation appears often to be secondary to infection in the urinary tract. Clumps of bacteria and epithelial and pus cells may act as foreign-body nuclei for stone formation and the alkaline fermentation frequently associated with infection is favorable to the precipitation of calcium and ammonium magnesium phosphates, which are the most common constituents of secondary calculi. The majority of stones appear,

however, to arise in aseptic urines. That stone formation is not commonly due to any metabolic defect is indicated by the fact that most stones are not composed of any one substance but are of a mixed type.

Attempts have been made to account for the greater solubility of uric acid and other substances in the urine than in pure water, on the basis of the presence, in the urine, of protective colloids which hinder precipitation. According to this view stone formation may occur when this colloid is altered or diminished in quantity. In support of this view it is stated that the crystal form of calcium oxalate in calculi is not that noted to form in pure solutions, but is similar to that produced when precipitation occurs in colloidal solutions. It is possible that precipitation of colloidal material with the crystalloids does conduce to the formation of a concrement rather than a mere precipitate of the latter.

According to the investigation of Meyer, however, the growth of a concrement depends solely on the degree of saturation of the urine for the crystalline constituents and such precipitation of the "crystalline" constituents occurs in just the same way in urine as in pure aqueous salt solutions. In determining the nature of the sediment or calculus formed the pH is a controlling factor. Uric acid tends to precipitate out of normal urines of average composition when the acidity becomes high (in the neighborhood of pH 5). At pH 6 mixed calculi of uric acid, sodium urate, and calcium oxalate and phosphate will tend to form. At pH 7 calcium phosphate calculi would tend to form and between pH 7 and 8 with the urine ammoniacal mixed calculi of calcium phosphate, magnesium ammonium phosphate, and ammonium urate may form which may be firm if precipitation occurs slowly. At pH values above 8 the rapid precipitation would tend to produce soft stones containing calcium carbonate, ammonium magnesium phosphate, and ammonium urate.

Aside from the question of protective colloids, certain of the stone-forming constituents may, under certain conditions, themselves exist in part in colloidal solution. Thus Hammarsten found that lithium and potassium urates gave the solutions at 37°. Sodium and ammonium urates in saturated solution are present partly in colloidal form. At the average chloride concentration of the three the solubility follows of the latter may be increased 300 per cent. Urates and uric at the presence of urates thus have a strong tendency to form supersaturated solutions.

According to Stillman, out of 510 urinary calculi submitted for routine examination over a period of five to six years at the New York Hospital, about 44 per cent consisted largely of calcium can hat, calcium phosphate, or "triple phosphate," either alone or in maxture; about 49 per cent were largely calcium oxalate, with some instances of admixture with phosphate and carbonate; and about 6 per cent were largely uric acid. Cystine calculi occurred to the extent of 0.8 per cent. These examinations refer to the principal constituent of the calculus; no attempt was made to isolate a "nucleus" and analyze it. Ultzmann has reported that, in

¹ Personal communication.

545 cases of urinary calculus, uric acid and urates formed the "nucleus" in about 81 per cent of the cases; earthy phosphates in about 9 per cent; calcium oxalate in about 6 per cent; cystine in a little over 1 per cent, and some foreign body in about 3 per cent.

In the chemical examination of urinary calculi the most valuable data are obtained by subjecting each of the concentric layers of the calculus to a separate analysis. Material for examination may be conveniently obtained by sawing the calculus carefully through the nucleus, then separating the various layers, or by scraping off from each layer (without separating the layers) enough powder to conduct the examination as outlined in the scheme (see p. 805).

VARIETIES OF CALCULI

Uric Acid and Urate Calculi. Uric acid and urates constitute the nuclei of a large proportion of urinary concretions, but stones which consist chiefly of uric acid or urates are found in less than 1 out of 10 cases. Such stones are always colored, the tint varying from a pale yellow to a brownish-red. The surface of such calculi is generally smooth but it may be rough and uneven.

Phosphatic Calculi. Ordinarily these concretions consist principally of "triple phosphate" and other phosphates of the alkaline earths, with very frequent admixtures of urates and oxalates. The surface of such calculi is generally rough but may occasionally be rather smooth. The calculi are somewhat variable in color, exhibiting gray, white, or yellow tints under different conditions. When composed of earthy phosphates the calculi are characterized by their friability.

Calcium Oxalate Calculi. These calculi are quite hard and are rather difficult to crush. They ordinarily occur in two general forms, viz., the small, smooth concretion which is characterized as the hemp-seed calculus, and the medium-sized or large stone possessing an extremely uneven surface, which is generally classed as a mulberry calculus. This roughened surface of the latter form of calculus is due, in many instances, to protruding calcium oxalate crystals of the octahedral type.

Calcium Carbonate Calculi. Calcium carbonate concretions are quite common in herbivorous animals, but of exceedingly rare occurrence in man. They are generally small, white, or grayish calculi, spherical in form, and possess a hard, smooth surface. These considerations apply to stones consisting largely if not entirely of calcium carbonate. Mixed calculi which contain smaller but readily demonstrable amounts of calcium carbonate are rather common in man.

Cystine Calculi. Cystine calculi are of very rare occurrence, the incidence being usually less than 1 per cent. Ordinarily they occur as small, smooth, oval, or cylindrical concretions which are white or yellow in color and of a rather soft consistency.

Xanthine Calculi. This form of calculus is somewhat more rare than the cystine type. The color may vary from white to brownish-yellow. Very often uric acid and urates are associated with xanthine in this type of calculus. Upon rubbing a xanthine calculus it has the property of assuming a wax-like appearance.

Urostealith Calculi. This form of calculus is extremely rare. Such concretions are composed principally of fat and fatty acid. When moist they are soft and elastic, but when dried they become brittle. Urostealiths are generally light in color.

Fibrin Calculi. Fibrin calculi are produced in the process of blood coagulation within the urinary tract. They frequently occur as nuclei of other forms of calculus. They are rarely found.

Cholesterol Calculi. This is an extremely rare form of calculus somewhat resembling the cystine type.

Indigo Calculi. Indigo calculi are extremely rare.

The scheme proposed by Heller and given on p. 805 will be found of much assistance in the chemical examination of urinary calculi,

Urine: Quantitative Analysis

In analyzing a normal or pathological urine quantitatively for any of its constituents, it is particularly necessary that the complete and exact 24-hour sample be obtained. For directions with regard to the collection and preservation of urine for analysis, see Chapter 27 on General Characteristics of Normal and Pathological Urine. Methods for the determination of the specific gravity of the urine are also there described. Before any urine is taken for analysis its total volume should be measured, using a large graduated cylinder, and this volume is thereafter taken as a basis for the calculations of the daily output of the individual constituents determined. If the urine be pathological, it is of course necessary to precede its quantitative analysis by qualitative tests for the pathological constituents.

PREPARATION OF STANDARD ACID AND ALKALI SOLUTIONS

Principle. Many of the quantitative methods used in physiological chemistry are volumetric or titration procedures. For these methods solutions of accurately known strength called standard solutions are needed. Their strength is usually expressed in terms of normality. A normal solution is one which in 1000 ml. contains 1 g. of replaceable hydrogen or its equivalent. Thus, to make 1000 ml. of a normal solution of hydrochloric acid (HCl), we would need 36.5 g. of this acid containing 1 g. of replaceable hydrogen. This we derive from the fact that the atomic weight of Cl is 35.5 and of H is 1, so that the molecular weight of HCl is 36.5, and each 36.5 g. of this acid contain 1 g. of replaceable hydrogen. Sulfuric acid (H₂SO₄) has a molecular weight of 2 + 32 + 64 = 98, but 98 g. of sulfuric acid contain 2 g. of replaceable hydrogen. Therefore, to prepare a normal solution of this acid, we must use one-half of 98 or 49 g. of sulfuric acid (containing 1 g. of hydrogen) for 1000 ml. of normal solution. Oxalic acid (H₂C₂O₄ + 2H₂O) has a molecular weight of 2+24+64+36=126. It also is a dibasic acid so we must use only one-half of 126 or 63 g. of oxalic acid in making a liter of normal solution.

A normal alkali solution is exactly equivalent to a normal acid solution, i.e., 1 liter of the alkali will neutralize 1 liter of the acid. According to the reaction of neutralization, therefore, the 36.5 g. of HCl in a liter of this normal acid will require 40.0 g. of sodium hydroxide to neutralize it, and 1 liter of normal sodium hydroxide must contain 40.0 g. of the alkali.

$$HCl + NaOH \rightarrow NaCl + H_2O$$
 (36.5) (40.0) (58.5) (18)

¹ See table of atomic weights, Appendix.

Having prepared solutions of acid and alkali of definitely known strength, it is then possible to determine the strength of any unknown acid or alkali by finding out how much of these standard solutions is required to neutralize a definite volume of the unknown solution.

In order to tell when the unknown solution has been exactly neutralized, we titrate in the presence of a small amount of one of a class of substances called indicators. An indicator is a substance which undergoes a sharp color change at a particular range of hydrogen-ion concentration, and this color change indicates the end-point of the titration.

When strong acids (as HCl) are being titrated with strong alkalies (as NaOH), almost any one of the common indicators is satisfactory. If weak acids (acetic acid) or weak bases (as ammonia) are being titrated, it is necessary to be very careful in the choice of an indicator as all indicators are not equally satisfactory in these instances.²

Preparation of 0.1 N Oxalic Acid Solution: Weigh accurately a watch glass or a piece of glazed paper. Then add to the weights on the balance pan 3.1512 g. With a spatula transfer to the watch glass enough pure oxalic acid in the form of clear crystals to counterbalance exactly the weights in the opposite pan. Transfer completely to a 250-ml. beaker, using a little water for rinsing purposes. Add about 150 ml. of distilled water and stir with a glass rod until dissolved, warming gently if necessary. Transfer every particle of this solution to a clean 500-ml. volumetric flask, rinsing rod and beaker several times with distilled water. Hold under the tap until cooled to room temperature. Then add distilled water until the bottom of the meniscus is level with the mark on the neck of the flask (the lower mark if there are two). Insert a stopper and mix thoroughly by inverting the flask again and again. Transfer to a clean dry bottle. Label. This solution will not keep indefinitely and is to be used only in the standardization of 0.1 N alkali. Preparation of 0.1 N Sodium Hydroxide Solution:

- a. Preparation of Concentrated Carbonate-free Sodium Hydroxide Solution: Shake up about 110 g. of best quality NaOH with 100 ml. of distilled water in a 300-ml. Erlenmeyer flask (pyrex) to make a saturated solution. Stopper and allow to stand for a couple of days or until the sodium carbonate settles to the bottom, leaving a clear solution of NaOH practically free from carbonate.
- b. Preparation of a Standard Sodium Hydroxide Solution: Measure out 6.3 ml. of the saturated NaOH solution from a buret into a 1-liter flask. Add 750 ml. of distilled water and mix thoroughly. Clean a buret by allowing it to stand filled with cleaning mixture (sodium dichromate and sulfuric acid) for a few minutes or longer if necessary. Empty, rinse several times with tap water, finally with distilled water, and allow to drain. Introduce a few ml. of the NaOH solution, and invert a couple of times to rinse the buret, discarding this NaOH. Repeat this process at least twice more. Then fill the buret with the alkali solution, making sure that the tip contains no air bubbles, and run out solution until the bottom of the meniscus is exactly at 0.

Into a clean Erlenmeyer flask (150 to 250 ml.) now introduce 25 ml. of 0.1 N oxalic acid solution measured from an accurate, clean pipet, previously rinsed by means of a little of the acid solution drawn up into it. Allow the pipet to drain about 15 seconds against the side of the flask. Add 2 to 3 drops of a 1 per cent alcoholic solution of phenolphthalein.

Now run in NaOH solution from the buret, rotating the flask. Ten ml. can be added quite rapidly; then add more slowly, and finally drop by drop

² For further consideration of indicators see pp. 28 and 334.

until the last drop changes the color of the solution permanently throughout to a definite pink. Take the buret reading, estimating as closely as possible to the second decimal place. Repeat the titration until two closely agreeing duplicate readings are obtained, then average the two readings for calculation.

Calculate the strength of the NaOH solution. Divide 25 (the number of ml. of 0.1 N oxalic acid used) by the buret reading to obtain the strength of the NaOH in terms of 0.1 N solution. Then multiply by 0.1 to obtain the normality. For example, if 15.67 ml. were required: $25 \div 15.67 = 1.595 \times 0.1 = 0.1595$ N.

c. Preparation of the 0.1 N NaOH Solution: Calculate how much of the standard NaOH solution just prepared will be required to make 1 liter of 0.1 N solution. To do this divide 1000 ml. by the strength of the NaOH in terms of 0.1 N solution. Thus in the example cited above: 1000 ÷ 1.595 = 626.9 ml. required. Measure out the exact amount of alkali required (using the buret, pipet, and volumetric flasks) into a 1000-ml. flask. Dilute with distilled water exactly to the mark. Mix very thoroughly and transfer to a clean, dry bottle with a rubber (not glass) stopper. Check the strength of the solution by again titrating 25-ml. portions of oxalic acid solution.

Preparation of 0.1 N Hydrochloric Acid: Concentrated hydrochloric acid is about 12 N or 44 per cent HCl weight in volume. Approximately 0.1 N HCl may, therefore, be prepared by diluting 9 ml. of the concentrated acid to 1 liter in a volumetric flask. This must be standardized by titration with 0.1 N alkali, using alizarin red or methyl red as an indicator.

Or introduce into a 1-liter flask 12 ml. of concentrated HCl and 750 ml. of distilled water. Mix well and titrate 10, 15, or 25 ml. portions of the acid solution with 0.1 N NaOH, using alizarin as an indicator. Dividing the number of ml. of 0.1 N NaOH required by the number of ml. of acid used gives the strength of the HCl in terms of 0.1 N solution. Dividing 1000 by this quotient gives the number of ml. of HCl solution to be measured into a volumetric flask and made up to 1000 ml.

This diluted solution will be 0.1 N HCl. It should be mixed thoroughly and 25-ml. portions of it checked by titration with the 0.1 N NaOH.

Standard acid and alkali solutions are best kept in paraffin-lined bottles. The acid solution is the more permanent of the two; and standard sulfuric acid solutions are more permanent than hydrochloric acid solutions. Alkali solutions must be protected from the carbonic acid of the air, the solution being best drawn over into the buret by means of a siphon tube leading from the top of the buret to the interior of the alkali bottle. The air inlet through the stopper of the bottle should be guarded by a tube containing soda lime.

Preparation of Standard Hydrochloric Acid from a Constant Boiling Solution: Method of Hulett and Bonner: Procedure: Make up by hydrometer about 200 ml. of HCl of specific gravity about 1.10. Distil off about threefourths of the liquid and discard. Then collect about 25 ml. of the constant boiling distillate. Weigh 18.017 g. of distillate using a capillary pipet

² If a very high degree of accuracy is desired, the alkali may be checked against pure acid potassium phthalate (mol. wt. 204.139). Dodge: J. Ind. Eng. Chem., 7, 29 (1915); J. Am. Chem. Soc., 42, 1655 (1920).

⁴ The acid solution may be standardized directly in the following manner: Introduce a platinum dish containing very pure sodium bicarbonate or the highest grade anhydrous sodium carbonate into a hot air oven previously heated to 200° C. Raise the temperature to 270° to 280°, but not above 300° C. Heat for half an hour, allow to cool in a desiccator, but while still a little warm, transfer to a glass-stoppered weighing bottle. Weigh out rapidly 0.1- to 0.2-g. portions of the sodium carbonate, dissolve in about 50 ml. of water in an Erlenmeyer flask, and titrate, using methyl orange as an indicator. One hundred ml. of 0.1 N acid are equivalent to 0.530 g. of dried sodium carbonate.

for final adjustment (or measure out 16.442 ml. at 25° C.). Dilute to 1 liter. This is a 0.1 N solution of HCl. The figures given are for a barometric pressure of 760 mm. At 770 mm. use 18.039 g.; at 750 mm. use 17.996 g.; at 740 mm. use 17.975 g. and at 730 mm. use 17.953 g. The composition of the distillate should not vary more than 1 part in 10,000 from the figures given.

TITRATABLE ACIDITY OF URINE

Introduction. The titratable acidity of the urine, as determined by the Folin method described here, is expressed in terms of the amount of standard alkali necessary to bring the urine from its original pH to the phenolphthalein end-point, around pH 8.5 or 9. In normal urine, the "acid" titrated consists almost entirely of the acid phosphate ion, $H_2PO_4^-$, the reaction being as follows:

$$H_2PO_4^- + OH^- = HPO_4^- + H_2O$$

Small amounts of titratable acidity may be contributed normally by acid organic salts (acid urate, acid oxalate, etc.). In certain conditions, such as severe ketosis, significant amounts of free β -hydroxybutyric acid, for example, may be present in the urine and contribute to the titratable acidity. In general, however, monobasic organic acids are found in the urine largely if not entirely as their salts, and in this form contribute little or nothing to the total titratable acidity. To evaluate the significance of the excretion of organic acids on acid-base balance, they may be determined as such (see determination of organic acids, p. 810) or the urinary ammonia content determined as an index of base replacement (see p. 828).

The Folin method is theoretically unsound as an exact measure of acid excretion relative to the normal acid-base balance in the body, and cannot be used for such purposes. A more correct picture is obtained if the urine is titrated back to the pH of the blood (pH 7.4) rather than to pH 9, since it is the difference between the pH of blood and urine which reflects the excretion of acid or base in excess of the amounts normally required for acid-base balance. A method for determining titratable acidity by titrating urine to pH 7.4 against a color standard is described by Henderson and Palmer; a pH meter may also be used. In the Folin method, even urines more alkaline than the blood may show a positive "titratable acidity," the quantitative significance of which is obscure. Despite these limitations, the method is simple and has been widely used, especially for comparative purposes and in conjunction with the determination of urinary ammonia as an aid in estimating the severity of acidosis, as described on p. 634.

Folin's Method: Principle. The urine is titrated with standard sodium hydroxide solution, using phenolphthalein as an indicator. Potassium oxalate is added to precipitate the calcium which would otherwise interfere with the end-point due to the precipitation of calcium phosphate on neutralization of the urine.

⁴ Henderson and Palmer: J. Biol. Chem., 17, 305 (1914).

Procedure: Place 25 ml. of urine in a 200-ml. Erlenmeyer flask and add 5 grams of finely pulverized potassium oxalate and 1 to 2 drops of a 1 per cent phenolphthalein solution to the fluid. Shake the mixture vigorously for one to two minutes and titrate it immediately with 0.1 N sodium hydroxide until a faint but unmistakable pink remains permanent on further shaking. For more accurate results, particularly with deeply colored urine, compare during the titration against a control sample of urine plus oxalate, until there is a distinct difference in color in the titrated sample. The control sample may then be used for a duplicate estimation, titrating it to color match against the first sample. Take the buret reading and calculate the titratable acidity of the urine under examination.

Calculation. If y represents the number of milliliters of 0.1 N sodium hydroxide used and y' represents the volume of urine excreted in 24 hours, the total acidity of the 24-hour urine specimen may be calculated by means of the following proportion:

25: y: y': x (titratable acidity of 24-hour urine expressed in ml. of 0.1 N sodium hydroxide)

Interpretation.⁶ The titratable acidity of the urine, expressed in ml. of 0.1 N alkali required to neutralize the 24-hour output by the method described, varies ordinarily from 200 to 500 under normal conditions with an average of perhaps 350. It is dependent almost entirely upon the diet, being low on a vegetable (base-forming) diet and high on a diet containing much meat, milk, cheese, rice, whole wheat products, etc. (acid-forming foods). On the administration of 15 g. of sodium bicarbonate it may go down to 100; the ingestion of much acid-forming food may increase it to 600. In fasting it may rise in a few days to 800. Acidities of less than 250 usually indicate a true alkalinity of the urine inasmuch as phenolphthalein changes at a pH significantly more alkaline than that of the blood, as discussed above. Samples of urine collected shortly after a meal may be alkaline due to the so-called "alkaline tide."

Bacterial decomposition of the urea of the urine occurring in the urinary tract will increase the amount of ammonia and decrease the acidity of the urine. The same change usually occurs in urine left in contact with the air. The acidity of the urine is increased in acidosis and cardiorenal and certain other disorders. The acidity of the urine may be somewhat increased by administration of mineral acids, acid phosphates, or ammonium chloride, but it is much more difficult to increase than to decrease this acidity.

Determination of Organic Acids: Method of Van Slyke and Palmer: Principle. Carbonates and phosphates are precipitated and the filtrate titrated with acid from pH 8 to pH 2.7. In the procedure described, the indicators phenolphthalein and tropcolin OO are used to define the pH range; a pH meter may also be used. In diabetes this titra-

Van Slyke and Palmer: J. Biol. Chem., 41, 567 (1920). According to Widmark and Ljungberg (Biochem. Z., 216, 1 (1929)) the CaO used in this method carries down from 7 to 10 per cent of the ether-soluble acids of urine and thus gives slightly low results.

^{&#}x27;Under the heading "Interpretation" there will be found, in connection with the various quantitative methods which follow, brief notes as to the possible significance of the results obtained. For further discussion see the chapters on the Normal and Pathological Constituents of Urine; on Inorganic Metabolism, and on Protein, Carbohydrate, and Fat Metabolism. General references will be found listed at the end of the chapter, particularly with reference to clinical aspects.

tion approximates closely the amount of β -hydroxybutyric and aceto-acetic acids in the urine and may be substituted for the determination of these substances for clinical purposes.

Procedure: Mix 100 ml. of urine with 2 g. of finely powdered calcium hydroxide and stir occasionally for 15 minutes. Filter. Carbonates and phosphates are removed. Transfer 25 ml. of filtrate to a 125 to 150-ml. test tube, add 0.5 ml. of 1 per cent phenolphthalein and 0.2 N HCl from a buret until pink color just disappears. This amount need not be measured. The pH is now about 8. Add 5 ml. of 0.02 per cent tropeolin OO little by little with stirring to prevent precipitation of the dye. Titrate with 0.2 N HCl until the red color is that of a standard (pH 2.7) made from 0.6 ml. 0.2 N HCl, 5 ml. of tropeolin OO solution and water to make 60 ml. When the end-point is nearly reached dilute unknown to 60 ml. before completing the titration. Calculation. Subtract from ml. 0.2 N HCl the amount (usually 0.7 ml.) of the acid required to titrate a control tube of water between the same limits. Multiply the difference by 2 to get results in terms of 0.1 N acid (the usual basis) and by 1000/25 to get the value for 1000 ml. of urine.

Interpretation. The titration includes organic acids, creatine, creatinine, and a small amount of amino acids. Normally the excretion for 24 hours corresponds to 400 to 750 ml. of 0.1 N HCl or about 8 ml. per kg. of body weight. In diabetic acidosis values from 20 to 180 ml. per kg. have been observed.

HYDROGEN-ION CONCENTRATION OR TRUE ACIDITY

Colorimetric Method: Principle. The reaction of the urine is determined by matching the colors produced when pH indicators are added respectively to the diluted urine and to standard solutions of known reaction. This method is subject to salt and dilution errors but is sufficiently accurate for most clinical purposes.

Procedure: Preparation of Standard Buffer Solutions: The Sørensen phosphate buffer standards, together with the Walpole acetate standards, cover satisfactorily the range of pH of urine. The acetate buffers are prepared by mixing 0.1 N acetic acid and 0.1 N sodium acetate in the following proportions:

pH	0.1 N acetic acid (ml.)	0.1 N sodium acetate (ml.)		
3.6	185	15		
3.8	176	24		
4.0	164	36		
4.2	147	53		
4.4	126	74		
4.6	102	98		
4.8	80	120		
5.0	59	141		
5.2	42	158		
5.4	29	171		
5.6	19	181		

The phosphate buffers are prepared by mixing M/15 disodium phosphate and M/15 potassium acid phosphate in the proportions given in the table below.

If it is desired to use the Clark and Lubs standard buffer mixtures these may be prepared as described on p. 25, et seq.

Choice of Indicator: The selection of indicators depends on the pH range. See the table on p. 336. For urine, bromcresol green (pH 4.0 to 5.6), bromcresol purple (pH 5.4 to 7.0) and phenol red (pH 6.6 to 8.2) may be used. Methyl red (pH 4.4 to 6.0) may be substituted for bromcresol green, but is not so stable. Aqueous solutions of 0.04 per cent strength are used. 10 drops (or 0.5 ml.) of these indicators are added to 10-ml. portions of the standard buffer solutions covering the effective pH range of the particular indicator. For preparation of indicator solutions, see p. 29.

pH	M/15 Na ₂ HPO ₄ (ml.)	M/15 KH ₂ PO ₄ (ml.)		
5.4	3.0	97.0		
5.6	5.0	95.0		
5.8	7.8	92 . 2		
6.0	12.0	88.0		
6.2	18.5	81.5		
6.4	26.5	73.5		
6.6	37.5	62.5		
6 8	50.0	50.0		
7.0	61.1	38.9		
7.2	71.5	28.5		
7.4	80.4	19.6		
7.6	86.8	13.2		
7.8	91.4	8.6		
8.0	94.5	5.5		

Determination: The urine is collected and kept under mineral oil. Into a test tube of the same diameter as those used to contain the indicator standards, introduce 8 ml. of recently boiled distilled water and 10 drops (or 0.5 ml.) of a particular indicator solution, say bromcresol purple. To this diluted indicator solution now add a layer of mineral oil and then introduce, without exposure to air, 2 ml. of urine. Stir gently and match with indicator standards in a comparator block. A control tube containing the urine diluted 1:5 should be used in making the comparison, as described in the hydrogen-ion determination of blood (see p. 635).

If the urine is too acid or alkaline to come within the range of the indicator selected, repeat using a more suitable indicator, until a satisfactory one is found.

Calculation. The colorimetric reading made on the diluted urine at room temperature may be approximately corrected to give the actual pH at 38° C., by subtracting 0.2 pH. The latter factor is, however, not constant. Hastings, Sendroy, and Robson warm the diluted urine to 38° before reading, and correct only for the dilution by subtracting 0.1 pH. This gives results which are claimed to be within 0.05 pH of the electrometric pH of the undiluted urine at 38°.

^{*} Interpolated from the data of Sørenson. For the preparation of the M/15 solutions see p. 23.

Interpretation. The pH of urine may vary over the extreme range of pH 4.8 to 8.0; normal pH values lie between about 5.5 and 8.0, with a mean value of about 6.0. In most pathological conditions the mean pH is lowered (increased acidity). The factors influencing urinary pH are similar to those influencing the titratable acidity of the urine (diets containing acid- and base-forming foods; the administration of acid or alkali); the two are not necessarily related quantitatively, however. Thus a dilute urine and a concentrated urine may have the same pH, but quite different titratable acidities. The pH may be considered as an intensity factor. while the titratable acidity is a *capacity* factor. The determination of urinary pH is of importance clinically largely in relation to the precipitation of insoluble material from the urine and the possible formation of urinary calculi. For example, in acid urine, urates and the sulfonamides may precipitate out; prophylaxis entails the maintenance of an alkaline urine, where these substances are more soluble. The reverse is true for phosphate calculi, which form in alkaline urine but are soluble in acid urine. Urinary pH may be altered by the administration of ammonium chloride (acidifying) or sodium bicarbonate (akalinizing).

Electrometric Method. The colorimetric determination of urinary pH has been largely replaced for research purposes by the use of the glass electrode pH meter (see p. 38). More accurate results are obtained, and color or turbidity of the urine does not influence results.

TOTAL SOLIDS

 Drying Method. Place 5 ml. of urine in a weighed shallow dish, acidify very slightly with acetic acid (1 to 3 drops), and dry it in vacuo in the presence of sulfuric acid to constant weight. Calculate the percentage of solids in the urine sample and the total solids for the 24-hour period.

Interpretation. The average excretion of total solids by a normal adult man is about 70 g. It is largely dependent upon the protein and salts of the diet. It may be decreased in severe nephritis due to impaired excretion, and greatly increased in diabetes with high sugar elimination.

Practically all the methods whose technique includes evaporation at an increased temperature, either under atmospheric conditions or *in vacuo*, are attended with error.

Shackell's method which entails the vacuum desiccation of the frozen sample is extremely satisfactory and should be used in all biological work where the greatest accuracy is desired.

2. Calculation by Long's Coefficient. The quantity of solid material contained in the urine excreted for any 24-hour period may be approximately computed by multiplying the second and third decimal figures of the specific gravity by 2.6. This gives us the number of grams of solid matter in 1 liter of urine. From this value the total solids for the 24-hour period may easily be determined.

Calculation. If the volume of urine for the 24 hours was 1120 ml. and the specific gravity 1.018, the calculation would be as follows:

(a) $18 \times 2.6 = 46.8$ g. of solid matter in 1 liter of urine

⁽b) $\frac{46.8 \times 1120}{1000}$ = 52.4 g, of solid matter in 1120 ml. of urine

Long's coefficient was determined for urine whose specific gravity was taken at 25° C. and is probably more accurate, for conditions obtaining in America, than the older coefficient of Haeser, 2.33.

Interpretation. See the preceding method.

TOTAL NITROGEN

1. Kjeldahl Method: Principle. The principle of this method is the conversion of the various nitrogenous compounds of the urine into ammonium sulfate by boiling with concentrated sulfuric acid, the subsequent decomposition of the ammonium sulfate by means of a fixed alkali (NaOH), and the collection of the liberated ammonia in an acid of known strength. Finally, this partly neutralized acid solution is titrated with an alkali of known strength and the nitrogen content of the urine under examination computed.

Procedure: Place 5 ml. of urine in a 500 ml. long-necked pyrex glass Kjeldahl flask, add 20 ml. of concentrated sulfuric acid and about 0.2 g. of copper

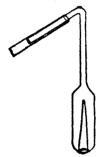

Fig. 258. Folin fume absorber.

sulfate and boil the mixture until it becomes light green or almost colorless, and then for about an hour longer. Avoid too strong a flame at this point, to prevent loss of acid. If a suitable hood or fume chamber is not available the sulfuric acid vapors may be carried away by suction. Various devices for this purpose are listed in laboratory supply dealers' catalogues; the Folin fume absorber (Fig. 258), placed in the mouth of the flask, may also be used.

When oxidation of the sample is complete, allow the flask to cool and dilute the contents with about 200 ml. of ammonia-free water. Add a little more of a concentrated solution of NaOH than is necessary to neutralize the sulfuric acid10 down the side of the flask in such a way that the alkali does not mix with the solution in the flask but forms a layer beneath it, and introduce into the flask a little coarse pumice stone, a scoop of talcum, or a few pieces of granulated zinc,11 to prevent bumping. A small piece of

paraffin may be added to lessen the tendency to froth. By means of a safety tube connect the flask with a condenser so arranged that the delivery tube passes into a receiving flask containing a few drops of methyl red indicator and a known volume (the volume used depending upon the nitrogen content of the urine) of 0.1 N sulfuric acid. The end of the delivery tube must reach beneath the surface of the fluid.12 Mix the contents of the distillation flask very thoroughly by rotatory shaking and distil the mixture until its volume has diminished about one-half. Titrate the partly neutralized 0.1 N sulfuric acid solution by means of 0.1 N sodium hydroxide, and calculate the content of nitrogen of the urine examined.

[•] There are numerous modifications of the original Kjeldahl method; the one described here, however, has given excellent satisfaction and is recommended for the determination of the nitrogen content of urine. With more resistant materials the addition of 10 g. of potassium sulfate in the acid digestion helps by raising the boiling point.

¹⁶ This concentrated sodium hydroxide solution should be prepared in quantity and "check" tests made to determine the volume of the solution necessary to neutralize the volume (20 ml.) of concentrated sulfuric acid used. A few drops of phenolphthalein may be added prior to introducing the concentrated alkali to insure the addition of an excess.

¹¹ Powdered sinc may be substituted.

¹⁵ This delivery tube should be of large caliber in order to avoid the "sucking back" of the fluid.

Calculation. Subtract the number of ml. of 0.1 N sodium hydroxide used in the titration from the number of ml. of 0.1 N sulfuric acid taken. The remainder is equivalent to the number of ml. of 0.1 N sulfuric acid, neutralized by the ammonia of the urine. One ml. of 0.1 N sulfuric acid is equivalent to 0.0014 g. of nitrogen. Therefore, if y represents the volume of urine used in the determination, and y' the number of ml. of 0.1 N sulfuric acid neutralized by the ammonia of the urine, we have the following proportion:

 $y:100::y'\times 0.0014:x$ (grams of nitrogen per 100 ml. of the urine examined)

Calculate the quantity of nitrogen in the 24-hour urine specimen.

Interpretation. An adult of medium size on a mixed diet will usually excrete 12 to 18 g. of nitrogen per day in the urine. On a low protein diet the urinary nitrogen may drop to as low as 5 g. or so per day; on a high protein diet, it may rise to 22 to 25 g. or even more. The total nitrogen determination includes the nitrogen from all the nitrogenous constituents of the urine; under ordinary circumstances the compound urea contributes about 80 per cent or more of the total nitrogen, the remainder being distributed between the various other nitrogenous constituents present (see below). In a normal adult, the total nitrogen of the urine and of the feces will often be almost exactly equal to the total nitrogen of the diet. Such a condition is called "nitrogen equilibrium." The feces usually contain very little nitrogen; it is a customary approximation in metabolic studies to assume that the fecal nitrogen will be 10 per cent of the urinary nitrogen.

Calculation of Percentage Nitrogen Distribution. In modern metabolism studies where the various forms of nitrogen are determined, in addition to the total nitrogen as yielded by the Kjeldahl method, it is customary to indicate what portion of the total nitrogen was present in the form of each of the individual nitrogenous constituents. These percentage values are secured by dividing the weight (grams) of nitrogen excreted for the day in the form of each individual nitrogenous constituent by the weight of the total nitrogen output for the same period. For example, if the total nitrogen excretion is 9.814 g. and the excretion of urea-nitrogen is 8.520 g. and the excretions of nitrogen in the forms of ammonia and creatinine are 0.271 g. and 0.639 g. respectively, the percentage distribution for these forms of nitrogen would be calculated as follows:

```
8.520 g. of urea-nitrogen \div 9.814 g. of total nitrogen = 84.3 per cent 0.271 g. of ammonia-nitrogen \div 9.814 g. of total nitrogen = 2.7 per cent 0.639 g. of creatinine-nitrogen \div 9.814 g. of total nitrogen = 6.5 per cent
```

NITROGEN PARTITION IN URINES CONTAINING ALBUMIN. If the urine to be tested contains albumin, this must be removed before an attempt at a nitrogen partition is made. This may be done by heating to boiling, acidifying with acetic acid to coagulate the protein, filtering and making up the filtrate to the original volume of the urine. If very small amounts of albumin are present, this is attended with difficulty. In these cases Tracy and Welker have suggested the use of aluminum hydroxide cream. It apparently removes none of the nitrogenous constituents of normal urine.

Procedure: One liter of urine (containing not over 1 per cent of albumin) is mixed with 1 liter of aluminum hydroxide cream¹³ and filtered.

2. Folin-Farmer Micro-Kjeldahl Method: Principle. This method belongs with the so-called microchemical methods inasmuch as it is adapted to the determination of amounts of nitrogen in the neighborhood of 1 mg. while in the ordinary Kjeldahl procedure 30 to 100 mg. of nitrogen are generally manipulated. One ml. of diluted urine is decomposed with sulfuric acid as in the Kjeldahl method, the ammonia formed is set free by the addition of alkali, and carried over into an acid solution by means of a current of air. The ammonia solution is then treated with Nessler's reagent and the color produced compared with that of a standard solution of an ammonium salt treated in the same way. The reaction is

$$NH_4OH + 2(KI)_2HgI_2 + 3KOH \rightarrow NHg_2I + 7KI + 4H_2O$$

The solution of dimercuric ammonium iodide is colloidal. The conditions of formation must be carefully controlled to obtain uniformity and prevent precipitation. Chlorides decrease the color formation.

Procedure: Introduce 5 ml. of urine into a 50-ml. volumetric flask if the specific gravity of the urine is over 1.018, or into a 25-ml. flask if the specific gravity is less than 1.018.16 Fill the flask to the mark with distilled water and invert it several times in order to guarantee thorough mixing. Transfer 1 ml, of the diluted urine to a large (20 to 25 mm, by 200 mm,) pyrex glass test tube. To this add 1 ml. of concentrated sulfuric acid, 12, of potassium sulfate, 1 drop of 5 per cent copper sulfate solution, and a small, clean, quartz pebble or glass bead. (The pebble or bead is added to prevent bumping.) Boil the mixture over a micro-burner for about six minutes, i.e., about two minutes after the mixture has become clear and light green or almost colorless. Allow to cool until the digestion mixture begins to become viscous. This ordinarily takes about three minutes, but in any event the mixture must not be permitted to solidify. Add about 6 ml. of water (a few drops at a time, at first, then more rapidly) to prevent solidification. To this acid solution add an excess of sodium hydroxide solution (3 ml. of a saturated solution are sufficient), adding the alkali down the side of the tube so that it does not mix with the acid solution but forms a layer beneath it. Connect the tube with a suitable receiver in an aeration train (see Figs. 259 and 260) placing in the receiver16 about 20 ml. of dilute (approximately 0.02 N) sulfuric acid. Start the air current (which mixes the alkali and acid in the digestion tube) and aspirate the liberated ammonia into the receiving solution. The air current should be started slowly and be only moderately rapid for the first two minutes, but at the end of this two-minute period the current should be run at its maximum speed for

¹³ See Appendix.

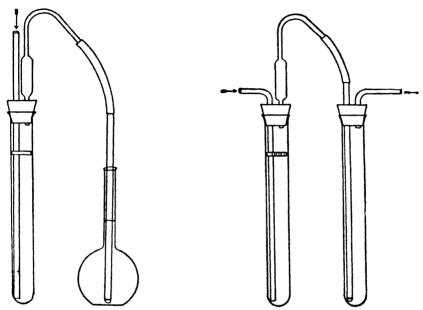

¹⁴ Folin and Farmer: J. Biol. Chem., 11, 493 (1912).

¹⁵ The purpose is to dilute the urine so that 1 ml. of the diluted fluid shall contain 0.75 to 1.5 mg. of nitrogen.

¹⁶ For a single analysis, a volumetric flask is used as receiver, and compressed air is used for aspiration. For serial analyses, a receiving tube similar to the digestion tube and fitted with a two-hole rubber stopper carrying a long inlet and short outlet tube is used. Either compressed air, or suction obtained from a water pump and applied at the end of the train, may be used. The entering air must be washed by passage through a wash-bottle containing dilute (1:10) sulfuric acid, to remove any ammonia which may be present. As many pairs of tubes as desired may be connected in series. For method of cleaning rubber tubing used for connection, see p. 502. If suction is used, in disconnecting when seration is complete, decrease the rate of air passage to a slow stream and start at the end farthest from the pump, to avoid back pressure.

an interval of eight minutes, or until all the ammonia has been driven over. The time required for complete aspiration of the ammonia will differ under different conditions and should be established by trial.¹⁷

When all the ammonia has been aerated over, disconnect the receiver, dilute the contents to about 60 ml. with ammonia-free water in a 100 ml. volumetric flask (if such a flask has not itself been used as receiver), and dilute similarly 1 mg. of nitrogen in the form of ammonium sulfate 18 in a second volumetric flask. Nesslerize both solutions as nearly as possible at

Figs. 259 (left) and 260 (right). Forms of aeration apparatus (Folin and Farmer).

the same time with 10 ml. of Nessler solution¹⁹ measured in a graduated cylinder and diluted, immediately before using, with about 20 ml. of ammonia-free water to avoid turbidity. Immediately fill the two flasks to the mark with ammonia-free water, mix well and allow to stand five minutes before reading in the colorimeter or photometer. For colorimetric comparison, match the standard against itself, and then the unknown against the standard, in the usual way (see p. 463). For photometric measurement, set the photometer to zero density (or 100 per cent transmittance) at 480 my. (see below) with a blank prepared by diluting 10 ml. of Nessler

¹⁷ Run a trial analysis and have several receivers ready. After eight minutes' aspiration, remove the first receiver and replace by a fresh one. Repeat at several later time intervals. Treat the contents of each receiver with Nessler solution, as described above for an analysis, and estimate from the color reaction the aeration time which gives complete transference of ammonia.

¹⁸ Care should be taken to secure the pure salt. Ammonium salts may contain pyridine bases which titrate like ammonia but do not react with Nessler's reagent. Pure ammonium sulfate may be prepared by decomposing a high-grade ammonium salt with sodium hydroxide and passing the liberated ammonia into pure, sulfuric acid. The salt is then precipitated by means of alcohol, brought into solution in water and then re-precipitated by alcohol. The final product should be dried in a desiccator over sulfuric acid. Pyridine-free ammonium salts are now obtainable on the market. A solution containing 0.4714 g. of ammonium sulfate in 1 liter of water, plus a few drops of concentrated sulfuric acid as preservative, contains 1 mg. of nitrogen in 10 ml. It is stable indefinitely.

¹⁹ See Appendix.

reagent to 100 ml. with water. This blank will correct for any ammonia present in the diluting water, but not in the digestion reagents, etc. For more accurate results, run a blank and a standard through the entire analytical procedure (digestion, aeration, nesslerization), set the photometer to zero density with the blank, and obtain results in terms of the density of the analyzed standard. This should correct for ammonia in the reagents as well as systematic errors in the analysis.

Calculation. For colorimetric measurement:

```
Reading of Standard Reading of Unknown X mg. of N in Standard mg. of total N in volume of urine used for analysis
```

At a 1:10 dilution of the urine, 1 ml. represents 0.1 ml. of urine; at a 1:5 dilution, 0.2 ml. of urine. Multiply the result of the above calculation by the dilution (10 or 5) to obtain the nitrogen content of the urine, in mg. per ml. or grams per liter (the two are identical). From this, the total nitrogen content of the 24-hour sample may be calculated.

For photometric measurement:

```
\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \frac{\text{mg. of N in}}{\text{Standard}} = \frac{\text{mg. of total N in volume of urine}}{\text{used for analysis}}
```

Further calculation is similar to that described for colorimetric measurement.

Interpretation. See p. 815.

Spectrophotometric Characteristics of the Nessler Color with Ammonia. The color reaction between Nessler's reagent and ammonia is the basis for many other quantitative methods of biochemical importance, in addition to its use as described here for the determination of total nitrogen. The spectrophotometric characteristics of the Nessler color therefore deserve detailed consideration, since they determine the conditions for accurate photometric measurement, such as the choice of wavelength or filter, solution depth, and range of concentration over which Beer's law is applicable. The data presented here are based on nesslerization under the conditions described above, i.e., using 10 ml. of Nessler reagent in a final volume of 100 ml., in the absence of excess strong acid or alkali, or protective substances such as gum ghatti. The values represent the conditions prevailing in the authors' laboratory at the time the analyses were made, and cannot be used for calibration purposes elsewhere, as discussed in Chapter 23, section on Colorimetry and Photometry, but may be used as a guide for such calibration.

The relation between the wavelength at which measurements are made, and the light transmittance (optical density) for various amounts of ammonia nitrogen, measured at 1 cm. solution depth, is shown in Fig. 261A. There is no wavelength of "peak" or maximum light absorption in the visible portion of the spectrum for the amounts of nitrogen ordinarily encountered and under the prescribed conditions. The choice of wavelength therefore depends largely upon the sensitivity desired and the range of concentration over which Beer's law is applicable. This information is supplied by Fig. 261B, which represents the data of Fig. 261A, plotted in terms of the relation between transmittance or density and concentration at various wavelengths.

It is shown in Fig. 261B that in a 1-cm. cuvette (or 12.5-mm. test tube, since the two are approximately equivalent) amounts of nitrogen up to 1.5 mg. in 100 ml. of nesslerized solution will read within the accurate portion of the photometer scale (see p. 476) at any wavelength between 480 and 520 m μ . Such amounts may be determined by calculation based upon the density of a 1 mg. standard in accordance with Beer's law, as evidenced by the linearity of the "calibration curves" over this range. Above 520 m μ the sensitivity decreases and slight deviation from Beer's law is noted at higher concentrations of nitrogen. Below 480 m μ , agreement with Beer's law is excellent over the usable portion of the photometer scale, but the sensitivity is so great that only small amounts of

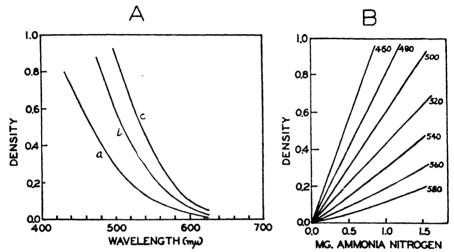

Fig. 261. Spectrophotometric characteristics of color obtained in Nessler reaction with ammonia. (A) Relation between optical density and wavelength for solutions containing 0.5 mg. (a), 1.0 mg. (b), and 1.5 mg. (c), of ammonia nitrogen per 100 ml. final volume, at a solution depth of 1 cm. (B) Relation between optical density and concentration at the wavelength indicated for each curve.

nitrogen may be accurately measured. In a 2-cm. cuvette (a 22-mm. test tube is approximately equivalent to this) the same considerations apply, but at only half the concentration range specified for a 1-cm. cuvette. Under these conditions, the standard should contain 0.5 mg. of nitrogen, and the unknown not over 1 mg. of nitrogen per 100 ml. of nesslerized solution.

The proportionality between density and concentration with the wavelength or filter chosen should be tested for a particular photometer over the concentration range expected; significant deviation from Beer's law greater than that expected from the data of Fig. 261 usually indicates that either the photometer or filter is at fault. In this event, results must be based upon the actual calibration data obtained with the instrument; the use of such a "calibration curve" and the precautions which must be associated with its use, are discussed in Chapter 23.

Alternate Aeration Procedures with Titrimetric Estimation. Instead of nesslerizing the aerated ammonia for colorimetric estimation, it may be aerated into acid and determined by titration. Two such procedures are described. They have the advantage over the colorimetric method of permitting the accurate determination of larger amounts of nitrogen (up to 3 mg. or so). A disadvantage is that too vigorous aeration may carry over a small amount of the fixed alkali used to liberate the ammonia, and thus lead to titrimetric (but not colorimetric) error. To catch any spray, the bulb portion of the aeration outlet tube may be loosely packed with glass wool; in any event, the apparatus should be tested for this possibility of error by running a blank determination or analyzing a solution containing a known amount of nitrogen.

- 1. Aeration into Boric Acid: Place 25 ml. of 2 per cent boric acid solution containing bromcresol green indicator, as described on p. 502 in connection with the determination of blood urea nitrogen, in the receiving flask or test tube. Liberate the ammonia from the digest by alkali as described for the Folin-Farmer method, and aerate the liberated ammonia into the boric acid solution. When aeration is complete, remove the receiver and titrate the contents with 0.0143 N sulfuric acid (see p. 502) until the more or less blue color is exactly restored to its original yellow-green shade, as evidenced by matching against a control 25-ml. portion of boric acid plus indicator which is diluted with water to approximately the same final volume as the titrated sample. The end-point should be sensitive to about 0.02 ml. of the standard acid.
 - Calculation. Each ml. of 0.0143 N acid is equivalent to 0.2 mg, of nitrogen. Multiply the number of milliliters of 0.0143 N acid used by 0.2 to give milligrams of nitrogen in the volume of urine used.
- Aeration into Standard Acid: Aerate the liberated ammonia into a receiver
 containing 25 ml. of 0.01 N sulfuric acid. When aeration is complete, remove the receiver, add a drop of methyl red indicator solution, and titrate
 with 0.01 N sodium hydroxide to an orange or beginning yellow shade.
 - Calculation. Subtract the number of ml. of 0.01 N alkali used from 25.0, to obtain the amount of 0.01 N acid neutralized by the ammonia. Multiply this value by 0.14 to obtain the nitrogen content in mg. of the volume of undiluted urine used in the analysis, since each ml. of 0.01 N acid represents 0.14 mg. of nitrogen.
- 3. Determination of Nitrogen by Micro-Kjeldahl and Distillation. Instead of aerating over the ammonia of a micro-Kjeldahl determination, it may be distilled over and collected in acid for subsequent determination by colorimetric or titrimetric methods. In general, more accurate and consistent results are obtained by distillation than by aeration. Bock and Benedict have described a simple distillation procedure using an ordinary small Liebig condenser; their method is described in the Eleventh Edition of this book. For research work, steam distillation has largely replaced simple distillation, and is the method of choice for all accurate micro-Kjeldahl analyses. Modern steam distillation apparatus (see Fig. 262) is compact, easy to use, almost automatic in operation, and requires but a few minutes for each sample.

Procedure: Digest the sample as described for the Folin-Farmer method, p. 816; or it may be digested with 1 ml. of concentrated sulfuric acid plus

a few small grains of metallic selenium or a "Hengar granule" (a quartz chip coated with selenium). 20 Digestion must be continued until all of the nitrogen has been converted to ammonia; the time required for complete

conversion varies with different types of material and should be

established by trial.

Transfer the digested sample with rinsings to the chamber of the steam-distillation apparatus, which has previously been cleared of any contaminating ammonia by a blank distillation. Place the receiving fluid (this varies with the procedure, see below) in a small flask arranged so that the tip of the condenser outlet dips below the surface of the receiving fluid. Add sufficient concentrated sodium hydroxide to the digest in the chamber to more than neutralize the amount of acid present (determine by trial). Start the generation of steam in the boiler. and steam distill the sample until 8 to 10 ml. or more of distillate have been collected in the receiving flask. Remove the receiver, rinsing down the sides of the condenser outlet tube with a little water in the process, and determine the ammonia in the distillate by any of the following procedures:21

a. Colorimetric or Photometric Estimation: Use 1 to 2 ml. of dilute (0.1 N) acid in the receiving flask and collect the distillate as described. Transfer the distillate to a container graduated at 25 ml., with rinsings up to about 20 ml. volume. Add 2.5 ml. of Nessler solution, dilute to 25 ml. with water, and mix. Compare in a colorimeter or photometer with a standard con-

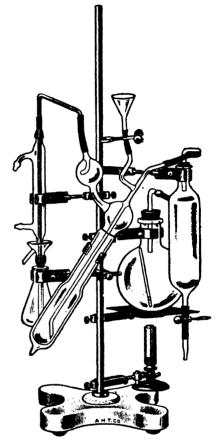

Fig. 262. Steam distillation apparatus.

taining 0.2 mg. of nitrogen, prepared in a second 25-ml. container in the same way as for the distillate. In photometric measurement, if the standard is digested and distilled as for the sample, and the photometer set to zero density with a digested and distilled blank, correction is automatically obtained for any systematic error or ammonia in the reagents.

Calculation. Similar to that given for the Folin-Farmer procedure, p. 818. The result gives the mg. of nitrogen present in the portion of sample analyzed. The conditions for photometric measurement have been presented on p. 819. For accurate measurement, not more than 0.5 mg. of nitrogen may be present if a 1-cm. cuvette is used, or half this amount with a 2-cm. cuvette. Much smaller amounts than this (down to 0.01 mg. or less) may be accurately estimated by using 1 ml. of

¹⁰ Obtainable from the Hengar Co., Philadelphia, or from dealers in laboratory supplies.
²¹ On disconnecting or diverting the steam flow from the chamber of the apparatus, the residue of the sample will usually be removed automatically by syphoning in a few moments as the chamber cools down. The apparatus is then ready for the next sample, without further rinking.

receiving acid in a test tube graduated at 10 ml., collecting the distillate up to the 10-ml. mark, adding 1 ml. of Nessler solution, and comparing photometrically with a suitable standard

b. Titrimetric Estimation: Place 10 ml. of 2 per cent boric acid, containing bromcresol green indicator as described on p. 502 for the determination of blood urea nitrogen, in the receiving flask, collect 10 to 15 ml. of distillate as described, and titrate the contents of the receiving flask with 0.0143 N (or 0.02 N) sulfuric acid until the solution has been brought back to its original yellow-green color. Match against a 10-ml. control portion of boric acid-indicator diluted with water to approximately the final volume of the titrated sample.

Calculation. Multiply the number of ml. of 0.0143 N (or 0.02 N) acid used by 0.2 (or 0.28) to obtain the mg. of nitrogen in the portion of sample used. Titration of a digested and distilled standard and blank will serve as a basis for correction for any ammonia present in the reagents. Amounts of nitrogen from 0.05 to 3 or more mg. may be accurately determined by this procedure. Alternatively, the distillate may be collected in 25 ml. of 0.01 N acid and the excess acid backtitrated with 0.01 N alkali in the presence of methyl red indicator, as described under the Folin-Farmer procedure. The boric acid method is preferred because it is a direct titration and requires only one standard solution, which is quite stable.

4. Other Methods. Many other modifications of the macro-Kjeldahl and micro-Kjeldahl determination of total nitrogen have been proposed; those described here are believed to be as satisfactory as any. For micro-Kjeldahl analyses, direct nesslerization of the diluted digest has been proposed by Folin and Denis and by Koch and McMeekin; these procedures are described in the Eleventh Edition of this book; they are similar in details to the direct nesslerization methods for the determination of blood nonprotein nitrogen, as described in Chapter 23. In general, direct nesslerization is less satisfactory for urinary nitrogen than for blood nonprotein nitrogen, because of the difficulty of avoiding turbidity, and such procedures are not recommended. Other methods of determining nitrogen include those based upon gasometric estimation; their use with urine is similar to that for blood nonprotein nitrogen, and references may be found in this connection in Chapter 23.

UREA

1. UREASE METHODS

These methods depend upon the principle that the enzyme urease is able, at ordinary temperatures, to transform urea, quickly and completely, into ammonium carbonate. Takeuchi in 1909 discovered the presence of this enzyme in the soja or soy bean. The application of this enzyme to the determination of urea in urine, blood, etc., was first proposed by Marshall, whose methods have been modified by Van Slyke and Cullen. These latter investigators prepared a permanent preparation of the enzyme, in a water-soluble form, the use of which makes more convenient the rapid and accurate determination of urea in urine, blood, and other biological fluids.

The urease method is probably the most satisfactory of all methods for the determination of urea. Other nitrogenous constituents such as allantoin are not decomposed by urease. The method involves no carefully regulated heating procedures, and is applicable to diabetic urines. Since, however, the basis for the urea determination is essentially an analysis for the ammonia produced by the action of the enzyme, every analysis will include the preformed ammonia which is also present in the urine, so that uncorrected results represent urea plus ammonia. To obtain the urea content, it is necessary to know the amount of preformed ammonia present, as established by separate analysis, and to subtract this from the results of the urea determination. Urea (and ammonia) determinations should be carried out on fresh or recently collected and preserved samples of urine, since on long standing, even in the presence of preservatives, significant amounts of urea may undergo hydrolysis to form ammonia, thus leading to misinterpretation of the significance of both the urea and the ammonia values. The conversion of urea to ammonia may take place quite rapidly in urine contaminated with bacteria.

a. Method of Van Slyke and Cullen: Principle. The urine sample is treated with urease, and the ammonia formed is aerated into 0.02 N acid, which is then back-titrated with 0.02 N alkali. A modification based on aeration into boric acid and direct titration with standard acid is also described; this is preferred over the original method because just as accurate results are obtained and only one standard solution is required, in a direct titration.

Preparation of Solid Urease.²² Digest one part of jack bean meal²³ with five parts of water at room temperature, with occasional stirring, for an hour, and clear the solution by filtration through paper pulp or centrifuging. Pour this extract slowly, with stirring, into at least 10 volumes of acetone. The acetone dehydrates the enzyme preparation. Filter, dry in vacuum, and powder. The activity of the preparation is retained indefinitely. Thus prepared it is not perfectly soluble in water, but this fact interferes in no way with its use.

Standardization of the Enzyme Preparation. Make up accurately a 3 per cent solution of pure urea. Treat this solution exactly as the urine is treated in the following method, using 0.5 ml. of the solution. The ammonia formed should neutralize 25 ml. of 0.02 N acid, or an equivalent amount of acid of other strength. If it does so the preparation is of sufficient strength to use as indicated. If not, more of the preparation must be used for a determination.

Procedure: Dilute 5 ml. of urine to 50 ml. with ammonia-free water. Measure 5 ml. of the diluted urine into a large test tube suitable for aeration (see Fig. 259, p. 817, and also Fig. 162, p. 503), add 1 drop of caprylic alcohol (to prevent frothing), and 1 ml. of enzyme solution. Close the tube with a two-hole rubber stopper fitted with a long inlet tube and a short outlet tube, as illustrated in the figures cited, and let the tube stand 15 minutes

¹³ Watermelon seeds have also been shown to be an excellent source of urease (Damodaran and Sivaramakrishnan: *Biochem. J.*, 31, 1041 (1937)).

¹⁴ The ensyme solution is prepared by dissolving 2 g. of the ensyme preparation, 0.6 g. of dipotassium phosphate, and 0.4 g. of monopotassium phosphate in 10 ml. of water. Solution is aided by stirring with a glass rod. The slightly opalescent solution should be covered with toluene and may be kept for two weeks without losing activity. Urease tablets already containing the "activating phosphates" may be obtained from E. R. Squibb, New York.

²² Van Slyke and Cullen: J. Biol. Chem., 17, 211 (1914). Dry urease prepared in this way may be obtained from E. R. Squibb in New York (Squibb's "Double Strength" urease). "Arlco Urease," obtainable from the Arlington Chemical Co., Yonkers, N. Y., is also satisfactory.

for the enzyme to act. Measure into a second similar tube 25 ml. of 0.02 N HCl or H₂SO₄. Add 1 drop of caprylic alcohol and 1 drop of a 1 per cent alizarin solution, as indicator. Connect the two tubes for aeration with washed air by either pressure or suction, as described on p. 816. At the end of 15 minutes aspirate for about one-half minute to transfer any ammonia present in the free condition to the receiving solution. After this aspiration, open the tube containing the sample and introduce 5 ml. of saturated potassium carbonate. Close the tube at once and aspirate until all the ammonia has been carried over into the acid in the receiver. The time needed for the aspiration varies for different pumps from 5 to 30 minutes, and should be determined by trial for the particular apparatus used. At the end of the time needed for the aeration, the pump is disconnected (care being taken to avoid back suction) and the excess acid in the receiver is titrated by means of 0.02 N NaOH.

Calculation. Subtract the number of ml. of 0.02 N alkali required for the titration from 25.0 to obtain the volume of 0.02 N acid equivalent to the ammonia present. Since 1 ml. of 0.02 N acid is equivalent to 0.28 mg. of nitrogen, and 0.5 ml. of urine is used in an analysis (5 ml. of a 1:10 dilution), multiply the volume of 0.02 N acid found equal to the ammonia by 0.56 (= 2 × 0.28) to obtain the urea plus ammonia nitrogen content, in grams per liter (mg. per ml.). Subtract from this value the ammonia nitrogen content, in grams per liter, as established by a separate analysis (see p. 828), to obtain the urea nitrogen content of the urine, in grams per liter. From this, and the total volume of the sample, the urea nitrogen content of the 24-hour sample is readily obtained.

Aeration into Boric Acid: Proceed exactly as described above, but aerate the ammonia into 25 ml. of the 2 per cent boric acid-indicator solution described on p. 502 in connection with the determination of blood urea nitrogen (see also the modified Folin-Farmer method, p. 820). When aeration is complete, titrate the boric acid solution with 0.0143 N (or 0.02 N) sulfuric acid until the more or less blue color has been restored to the original yellow-green color, as established by comparison with a control 25-ml. portion of boric acid-indicator solution which is diluted with water to approximately the same final volume as the titrated sample. The end-point should be sharp to about 0.02 ml. of the standard acid.

Calculation. Each ml. of 0.0143 N acid is equivalent to 0.2 mg. of nitrogen; if 0.02 N acid is used, 1 ml. equals 0.28 mg. of nitrogen. Multiply the volume in ml. of acid required for the titration by 0.2 (or 0.28), and then further by 2, to obtain the urea plus ammonia nitrogen content of the urine, in grams per liter. Subtract the ammonia nitrogen content of the urine, determined separately, to obtain the urea nitrogen content.

Interpretation. The mean average daily excretion of urea by normal adults is usually placed at about 25 to 35 g. (10-15 g. of urea nitrogen) but is very closely dependent upon the protein ingestion and metabolism and hence may vary widely. In disorders associated with increased tissue catabolism as in fevers, the excretion of urea is increased. It may be decreased in pronounced kidney and liver disorders due to decreased formation and decreased power of elimination, but these findings are not constant. The determination of urinary urea, in conjunction with the determination of blood urea, is, however, of major clinical value as an index of kidney function (see "urea clearance" test, p. 901).

The percentage of the total nitrogen of the urine occurring as urea varies on the average from 80 to 90. On a high protein diet it is nearer 90 per cent; on a very low nitrogen but high calorie diet it may not be

²⁵ Folin states that methyl red is preferable to alisarin for ammonia titrations.

over 60 per cent. In marked acidosis it may be considerably decreased relative to the total nitrogen (see Ammonia, p. 828).

b. Direct Nesslerization Method (Folin and Youngburg, 26 Modified): Principle. The diluted urine is treated with an alcoholic urease solution to convert urea into ammonia, and the ammonia present is then determined by direct nesslerization. In the original procedure, preformed ammonia is removed by treatment with Permutit (a synthetic "exchange silicate," see p. 830) and the determination carried out on the ammonia-free solution. It has been found, however, that Permutit may at times remove a significant amount of the urea as well, and its use has been dispensed with in the modification described here. The total urea plus ammonia nitrogen is determined by direct nesslerization after urease treatment; the preformed ammonia content of the urine, as determined by a separate analysis (p. 828) is subtracted from the result to give the urea nitrogen content of the urine.

Direct nesslerization is perhaps not quite so accurate as the aeration procedures because of the possibility of interference by substances other than ammonia in the color reaction, but the procedure has the advantage of simplicity and the results are quite suitable for most purposes.

Procedure: Dilute 5 ml. of urine to 100 ml. in a volumetric flask and mix well. Transfer 1 ml. of the diluted urine to a test tube, add 1 ml. of the alcoholic urease solution, 27 and 1 drop of buffer solution. 28 Digest in a beaker of warm water (40° to 55° C.) for five minutes or at room temperature for 15 minutes, at the end of which time transfer the contents of the test tube, with rinsings, to a 100-ml. volumetric flask, diluting to a volume of about 80 ml. Prepare a standard in a second flask by adding sufficient standard nitrogen solution to contain 0.5 mg. of nitrogen, 20 ml. of urease solution, and water to a volume of about 80 ml. To each flask add 1 ml. of gum ghatti solution, 30 set the flask contents to swirling and add from a graduated cylinder 10 ml. of Nessler reagent. 30 Dilute immediately to 100 ml. mix, and allow to stand five minutes. Read in a colorimeter or photometer in the usual way. For photometric measurement, set the photometer to zero density with a blank prepared similarly to the standard except that the standard nitrogen solution is omitted.

Calculation. For colorimetric measurement:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. of N in}}{\text{Standard}} \times \text{Dilution} = \frac{\text{mg. of urea plus ammonia nitrogen}}{\text{in 1 ml. of undiluted urine}}$

Subtract from this value the ammonia content of the urine, as determined separately, to obtain the urea nitrogen content of the urine. Under the conditions described, the dilution is 20, and urines containing 5 to 20 g. of urea nitrogen per liter may be accurately analyzed. For values outside this range, repeat the analysis at a more satisfactory dilution.

²⁶ Folin and Youngburg: *J. Biol. Chem.*, 38, 111 (1919); and Youngburg: *J. Biol. Chem.*, 45, 391 (1921).

³⁷ To prepare the alcoholic urease solution place 3 g. of Permutit in a flask, wash once with 2 per cent acetic acid, then twice with water; add 5 g. of fine jack bean meal and 100 ml. of 30 per cent alcohol. Shake gently but continuously for 10 to 15 minutes and filter. The filtrate contains practically all of the urease and extremely little of other materials.

²⁶ Dissolve 14.2 g. of Na₂HPO₄ and 12.0 g. of NaH₂PO₄, or equivalent amounts of the crystalline salts, in water and make up to 100 ml.

²⁹ See footnote 18, p. 817.

³⁰ See Appendix.

For photometric measurement:

Density of Unknown Density of Standard X mg. of N in Standard X Dilution = mg. of urea plus ammonia nitrogen in 1 ml. of undiluted urine

Correct for the preformed ammonia content as described above. The conditions for photometric measurement of the Nessler color have already been described (p. 818). At 480 mµ, and in a 1-cm. cuvette, the standard has a density of approximately 0.400, permitting measurement with urines containing up to about 25 g. of urea nitrogen per liter under these conditions. For higher values, or for photometric measurement at greater depth of solution, use a greater dilution of the urine.

Interpretation. See p. 824.

c. Micro-diffusion Method of Conway:31 Principle. The sample of diluted urine is incubated with urease in the outer compartment of a

Fig. 263. Conway unit.

"Conway unit" (Fig. 263).³² The ammonia formed is then liberated by addition of saturated potassium carbonate solution, and the unit is covered. The ammonia diffuses over into and is absorbed by acid in the inner compartment of the unit, where it may there be determined by titrimetric or colorimetric means. As with all urease methods for urine, separate determination of the ammonia N present is necessary in order to obtain the urea N content.

The same principle may be employed for the determination of urea N in blood, of total N in micro-Kjeldahl digests, and in general wherever a volatile absorbable substance is to be determined. Because of the simplicity of the procedure and its

application to micro-analysis, increasing use is being made of this principle in routine and research laboratorics.

Procedure: Determination of Urea N Plus Ammonia N: Dilute 1 ml. of urine to 10 ml. with water and mix. With an accurate pipet transfer 0.2 ml. of this diluted urine to the outer compartment of a Conway unit (Fig. 263). Place 1 ml. of 2 per cent boric acid solution containing added bromcresol green indicator³³ in the inner compartment. Smear a glass cover plate with a thin film of fixative³⁴ and place on the unit, greased side down. Slide the cover aside sufficient to permit the introduction of a pipet tip, and add to

²¹ Conway and Byrne: Biochem. J., 27, 419 (1933); Conway: ibid, 27, 430 (1933). The procedure as described here is a slight modification of the original Conway procedure, and includes some suggestions of Steinitz (J. Lab. Clin. Med., 25, 288 (1939-1940)). For application of the micro-diffusion principle to the determination of small amounts of nitrogen in tissue preparations, see Borsook. J. Biol. Chem., 110, 481 (1935). For application to the determination of acetone in blood and urine, see Werch: J. Lab. Clin. Med., 25, 414 (1939-1940); 26, 878 (1940-1941).

³⁵ The unit shown here is made of Coors porcelain, and may be obtained from the Arthur H. Thomas Co., Philadelphia.

³⁸ See p. 502 for preparation of this solution.

²⁴ Ordinary vaseline is satisfactory at room temperatures. If the units are to be incubated at 38°, a vaseline-paraffin wax mixture is recommended. Melt 3 parts vaseline with 1 part paraffin wax (M.P. 55°) and allow to cool.

the outer chamber 0.5 ml. of urease-phosphate solution. 15 Replace the cover, and mix the fluids in the outer chamber by slight tilting and rotation of the unit. Set aside at room temperature for 15 minutes. At the end of this time, tilt the unit slightly to displace the fluid in the outer chamber to one side, slide the cover aside slightly to permit the introduction of a pipet at a point opposite to the displaced fluid, and add 1 ml. of saturated potassium carbonate solution to the outer chamber. At once replace the cover, mix the fluids in the outer chamber by tilting and rotation as above, and set aside for 90 minutes at room temperature (or place in an incubator at 38° for 1 hour). Be sure the cover is firmly in place during this period. At the end of the period, remove the cover and titrate the contents of the inner chamber with 0.0143 N sulfuric acid,36 using a micro-buret with a fine tip which dips below the surface of the solution being titrated. Titrate until the color of the fluid in the inner chamber exactly matches that of a control unit. The control consists of a second unit treated exactly as described for an analysis except that 0.5 ml. of water replaces the urine sample.

Ammonia N Determination: Proceed as above, but use 0.2 ml. of undiluted urine and omit the treatment with urease, adding the 1 ml. of saturated potassium carbonate solution directly to the urine in the outer compartment, allowing to stand covered for diffusion and absorption of ammonia to take place, titrating, etc., as described.

Calculation. Since 1 ml. of 0.0143 N sulfuric acid is equivalent to 0.2 mg. of nitrogen, the calculation is as follows:

a. Urea N + Ammonia N:

ml. of 0.0143 N acid required \times 0.2 \times 50 = mg. of urea N + ammonia N per ml. of undiluted urine

b. Ammonia N:

ml. of 0.0143 N acid required \times 0.2 \times 5 = mg. of ammonia N per ml.

of undiluted urine

c. Urea N: subtract (b) from (a) to obtain the urea N content of the urine, in mg. per ml. (or grams per liter).

During the titration, the fluid in the inner compartment should be stirred continuously; a convenient arrangement consists of a fine glass tip delivering compressed air in a slow stream of bubbles below the surface of the solution. A magnetic stirrer acting on a "flea" (small piece of iron wire enclosed in a small sealed glass tube) placed in the inner compartment is also an excellent method of stirring during the titration. If desired, the determination may be made colorimetrically or photometrically by placing 1 ml. of dilute (0.1 N) sulfuric acid (without indicator) in the inner compartment, instead of the boric acid solution. After absorption of ammonia is complete, the contents of the inner chamber are transferred by means of a rubber-bulb pipet, with rinsings, to a test tube graduated at 25 ml. and nesslerized at this volume in the presence of 2.5 ml. of Nessler reagent. Colorimetric or photometric estimation may then be made in terms of a standard (one containing 0.2 mg. of nitrogen should be satisfactory), nesslerized similarly.

Interpretation. See previous methods.

Dissolve 400 mg. of urease powder (prepared as described on p. 823; commercial preparations may also be used) in 10 ml. of water and add 0.4 ml. of phosphate buffer (6.9 g. of NaH₂PO₄·H₂O and 17.9 g. of Na₂HPO₄·12H₂O in 100 ml. of water). Prepare the urease solution fresh daily, and discard any unused portion. The activity of the powder may be tested by a control analysis on pure urea solution. Dilute a 2.14 per cent solution of urea 1:10 with water and analyse 0.2 ml. of the diluted solution; 0.2 mg. of nitrogen should be found.

³⁶ Dilute 14.3 m), of N sulfurie acid to 1 liter in a volumetric flask and mix. This solution is quite stable.

2. OTHER METHODS

Many other methods for the determination of urinary urea content have been described, some of which combine certain features of the various procedures described here. Rose and Coleman suggested colorimetric determination of the aerated ammonia (as in the Folin-Farmer micro-Kjeldahl method, p. 816), after treatment of the urine with urease. Marshall has described a simple clinical method based upon direct titration of the ammonia liberated by urease treatment (see the Eleventh Edition of this book). Gasometric measurement in the Van Slyke-Neill apparatus (p. 642) of the carbon dioxide liberated by the action of urease on urea³⁷ is simple, rapid, and accurate; the only disadvantage is when many analyses are to be done, since each analysis must be carried to completion before the next is begun. Gasometric determination based on the liberation of nitrogen by treatment with hypobromite has been described by Stehle. 38 Methods based upon isolation of urea as the insoluble xanthydrol compound have been described by Barrett and Jones³⁹ and by Allen and Luck. 40 Direct colorimetric methods which do not involve the action of urease have been proposed by Ormsby,41 Barker,42 and Archibald.43

AMMONIA

Introduction. Many of the methods which have been proposed for the determination of urinary ammonia are based upou principles similar to those already described in connection with the micro-Kjeldahl determination, and the determination of urinary urea, since these consist essentially in the determination of ammonia produced as a result of the analytical treatment. For the accurate determination of urinary ammonia, it is necessary to separate the ammonia from interfering material, and to avoid the use of excessive heat or strong alkali in the treatment of the urine, since these may lead to the production of ammonia from other nitrogenous constituents of the urine. The successful separation of ammonia from urine by aeration was first described by Folin:44 his method was modified and improved by Van Slyke and Cullen, and their method (with modification) is described here, since it requires less urine than Folin's method, gives just as accurate results, and utilizes the same apparatus, reagents and technique as have already been described for the determination of urea in blood (p. 501) and urine (p. 823).

1. Aeration Method (Van Slyke and Cullen, Modified): Principle. The urine is treated with an equal volume of saturated potassium carbonate solution, and the liberated ammonia is transferred by aeration

²⁷ Van Slyke: J. Biol. Chem., 73, 695 (1927).

 ⁴² Barker: J. Biol. Chem., 152, 453 (1944).
 ⁴³ Archibald: J. Biol. Chem., 157, 507 (1945).

⁴⁴ Folin's method is described in the Eleventh Edition of this book.

into an acid receiving solution, where it is then determined by titration. In the original procedure, the ammonia is aerated into 0.02 N acid which is then back-titrated with 0.02 N alkali. In the modification described here, boric acid solution is used to receive the ammonia, which is then titrated directly with standard acid. Results are the same by either procedure; the boric acid method has the advantage of being a direct titration and requires only one standard solution which is quite stable.

Procedure: Measure 5 ml. of undiluted urine into one of the two large test tubes used in an aeration train (see Fig. 259, p. 817, and Fig. 162, p. 503) and connect this tube for aeration, as shown in the illustrations, with a second tube containing 25 ml. of the 2 per cent boric acid containing added bromcresol green indicator described on p. 502 in connection with the determination of blood urea nitrogen. Add a drop of caprylic alcohol to each tube to minimize foaming. When ready, remove the stopper of the tube containing the urine and add 5 ml. of saturated potassium carbonate solution. Replace the stopper tightly and start the air current (pressure or suction: the incoming air must be washed by preliminary passage through a wash-bottle containing dilute (1:10) sulfuric acid, to remove any ammonia present). The air current should be run slowly for the first two minutes, and then increased to a rate as fast as the apparatus will stand. Aeration is continued until all the ammonia has been driven over; this may take from 5 to 30 minutes depending upon the apparatus, and the time required should be established by trial.

When aeration is complete, remove the tube containing the boric acid, rinsing down the inlet tube in the process, and titrate the contents with 0.0143 N (or 0.02 N) sulfuric acid, until the more or less blue color is replaced by the original yellow-green color, as determined by matching against a control 25-ml. portion of the boric acid indicator solution which has been diluted with water to approximately the final volume of the titrated sample. The end-point should be sharp to about 0.02 ml. of standard acid.

Calculation. Each ml. of 0.0143 N acid is equivalent to 0.2 mg. of ammonia nitrogen; if 0.02 N acid is used, 1 ml. equals 0.28 mg. of ammonia nitrogen. Multiply the volume in ml. of acid required for the titration by 0.2 (or 0.28), to obtain the ammonia nitrogen content of 5 ml. of urine; divide the result by 5 to obtain the ammonia nitrogen content of the urine in mg. per ml. (or grams per liter). Results on any other basis (e.g., grams per 100 ml. or per 24-hour sample) may then be readily obtained.

If the original Van Slyke-Cullen procedure based on back-titration of 0.02 N acid with 0.02 N alkali is used, the conditions and the calculations are similar to those described on p. 824 in connection with the determination of urinary urea, except that results are divided by 10 because 10 times as much urine is used for the ammonia determination as for the urea determination.

The ammonia aerated into dilute (0.02 N) sulfuric acid may be nesslerized and determined colorimetrically or photometrically as described for the Folin-Farmer micro-Kjeldahl procedure, p. 816; this procedure was suggested by Folin and MacCallum. The amount of urine taken should not contain over 0.5 to 1.0 mg. of ammonia nitrogen, i.e., 1 to 2 ml. of normal urine, or less in acidosis, diluted to about 5 ml. with water. Comparison is made against a suitable standard, nesslerized in the same way, and the calculations are similar to those for the Folin-Farmer procedure.

Interpretation. The average daily output of ammonia nitrogen in the urine of an adult on a mixed diet is about 0.7 g., corresponding to about 50 milliequivalents, or 500 ml. of 0.1 N base, per day, and representing about 2.5 to 4.5 per cent of the total nitrogen. The amount excreted may

vary widely from this average value, however, since (along with the titratable acidity of the urine, see p. 809) the ammonia content of the urine appears to parallel the state of acid-base balance within the body. It is increased in amount by the ingestion of acids or acid-forming foods and in the acidosis of starvation or diabetes (but not of nephritis); and decreased by the ingestion of alkalies or base-forming foods and in alkalosis. As first shown by Nash and Benedict, the ammonia of the urine is synthesized by the kidneys. Possible precursors include amino acids and glutamine; the exact mechanism is not yet known. Urinary ammonia appears to function as a "synthetic" base, capable of replacing "fixed base" (sodium, potassium) in the excretion of acids as their neutralized salts, and thus conserving such fixed base to the organism.

2. Formol Titration Method (Malfatti): Principle. This method is based on the reaction that takes place when formalin solution is added to a solution containing ammonium salts (see Amino Acid Nitrogen methods). An acid reaction is produced in the mixture, which is then titrated with standard alkali using phenolphthalein as an indicator. Amino acids give the same reaction so that the result of the titration represents ammonia + amino acid nitrogen. This method may be used for the rapid clinical estimation of these forms of nitrogen as a substitute for an ammonia determination, but the results do not represent ammonia as is sometimes stated.

Procedure: To 25 ml. of urine in a 200-ml. Erlenmeyer flask add 5 g. of finely pulverized potassium oxalate, a few drops of phenolphthalein, and titrate to a faint but permanent pink color with 0.1 N NaOH. (The urine mixture just after neutralization in the urinary titratable acidity determination (see p. 810) may be used.) Then add 10 ml. of neutral formalin solution (see Amino Acid Nitrogen), mix well, and titrate with 0.1 N sodium hydroxide to a permanent pink color.

Calculation. One ml. of 0.1 N sodium hydroxide is equivalent to 1.7 mg of ammonia. Multiply the number of ml. of 0.1 N alkalı required after the addition of the formalin by 1.7 and by 4 to get the number of mg. of ammonia + amino acid nitrogen (expressed as ammonia) in 100 ml. of the urine examined.

3. Permutit Method:⁴⁵ Principle. The urine is shaken with particles of an "exchange silicate," which remove the ammonia from solution. The ammonia is set free from the silicate by treating with alkali solution. This is then nesslerized and compared with a standard ammonia solution nesslerized in the same way.

Procedure: Introduce about 2 g. of Permutit powder into a 100-ml. volumetric flask. Add about 5 ml. of water (no more), followed by 2 ml. of urine, 4 accurately measured. Rinse down the added urine by means of a

⁴⁵ Folin and Bell: J Biol. Chem., 29, 329 (1917). Permutit is a synthetic aluminum silicate which has the property of taking up ammonia quantitatively in neutral or weakly acid solution and of releasing it in strongly alkaline solution. The 60-80 mesh powder should be used. A suspension in water should settle quickly leaving the supernatant fluid clear. After use, it may be regenerated for further use if it is washed with water, 2 per cent acetic acid, and finally with water again.

⁴⁶ With urines very low in ammonia it may be necessary to use more urine (5 ml.) but in so far as it is practicable it is better not to use more than 2 ml. and to employ a weaker standard (0.5 mg. instead of 1 mg. of nitrogen) for colorimetric comparison. If in doubt about which standard to use, it is sound analytical practice to prepare both and to match the unknown against the most suitable standard as determined by inspection.

little water (1 to 5 ml.), and shake gently but continuously for five minutes. Rinse the powder to the bottom of the flask by the addition of water (25 to 40 ml.) and decant. Add water once more and decant. (In the case of urines rich in bile it is advisable to wash once or twice more.) Add a little water to the powder, introduce 2 ml. of 10 per cent sodium hydroxide, shake for a few moments and set aside, while preparing the standard ammonium sulfate solution as follows:

Transfer 10 ml. of the standard ammonium sulfate solution (see p. 817) containing 1 mg. of nitrogen (or 5 ml. containing 0.5 mg. of nitrogen if a half-strength standard is desired) to another 100-ml, volumetric flask and add 2 ml. of 10 per cent sodium hydroxide (to balance the alkali added to the Permutit mixture in the other flask). Dilute to about 75 ml. and mix. Transfer 10 ml. of Nessler's solution (see p. 816) to a measuring cylinder. Now give the volumetric flask a vigorous whirl so as to set the solution spinning within the flask and add at once the whole of the Nessler solution in the cylinder. With another whirling movement complete the mixing of the contents of the flask. If the process of nesslerization has been successful a deep red but crystal clear solution is obtained. If it is not perfectly clear discard it and prepare a fresh standard. Then dilute the contents of the flask containing the Permutit and the urinary ammonia to about 75 ml., whirl the mixture and add the Nessler reagent (10 ml.) exactly as in the case of the standard solution. Dilute the contents of both flasks to volume (100 ml.) and compare in a colorimeter with the standard set at 20 mm., or determine the densities of unknown and standard in a photometer at 480 mu. For photometric measurement, set the photometer to zero density with a blank prepared by treating about 75 ml. of water plus 2 ml. of 10 per cent sodium hydroxide in a 100-ml. volumetric flask with 10 ml. of Nessler solution as described, diluting to 100 ml., and mixing. Calculation. For colorimetric measurement:

Reading of Standard Reading of Unknown X mg. of N in Standard mg. of ammonia N in volume of urine used

Divide the result of the above calculation by the volume of urine used to obtain the ammonia nitrogen content of the urine, in mg. per ml. (or grams per liter). From this, and the volume of the 24-hour specimen, the daily output of urinary ammonia is readily obtained.

For photometric measurement:

Density of Unknown Density of Standard × mg. of N in Standard = mg. of ammonia N in volume of urine used

Further calculation is the same as for colorimetric measurement. The spectrophotometric characteristics of the Nessler color, and the conditions for accurate photometric measurement, are similar to those given on p. 818 in connection with the Folin-Farmer micro-Kjeldahl method, since similar amounts of nitrogen are dealt with here, under equivalent conditions.

Interpretation. See p. 829.

AMINO ACID NITROGEN

1. Ninhydrin Method of Van Slyke, MacFadyen, and Hamilton:⁴⁷ Principle. The urine sample, previously freed from urea by treatment with urease, is heated at 100° in a closed reaction vessel with ninhydrin (see p. 116). Amino acids present yield carbon dioxide quantitatively under these conditions. The carbon dioxide produced is transferred to the

⁴⁷ Van Slyke, MacFadyen, and Hamilton: J. Biol. Chem., 150, 251 (1943), See also Hamilton and Van Slyke: J. Biol. Chem., 150, 231 (1943); Van Slyke, Dillon, MacFadyen, and Hamilton: ibid., 141, 627 (1941); Van Slyke and Folch: ibid., 136, 509 (1940).

chamber of the Van Slyke-Neill manometric apparatus and there determined. From the amount of carbon dioxide found, the α -amino nitrogen content of the sample is readily obtained, since all of the common amino acids yield 1 mole of carbon dioxide (except aspartic acid, which yields 2 moles) per mole of α -amino nitrogen present. Proteins, peptones, peptides (other than glutathione, which has a free α -amino group) and substances other than amino acids do not react significantly. This procedure is considered to be the most specific yet devised for free amino acids.

Procedure: Removal of Urea and Preformed CO₂: Place 2 ml. of fresh urine (or urine preserved by saturation with thymol and storage in the cold) in the all-glass reaction vessel⁴⁸ (Fig. 264) and add 1 drop of 0.04 per cent bromthymol blue.⁴⁹ If a blue color is obtained, add 1 N sulfuric acid drop by drop to a yellow color, and then 1 N sodium hydroxide until just blue. If a yellow color is obtained initially, add 1 N sodium hydroxide until just blue. Then add 175 mg. of dry phosphate buffer mixture,⁵⁰ 0.2 ml. of a 1 per cent solution of urease,⁵¹ and a crystal of thymol. Stopper loosely to prevent loss of water but not of carbon dioxide and incubate overnight at 37° to 40°.

After incubation add 1 drop of 0.04 per cent bromcresol green and a drop of caprylic alcohol. Cautiously add 5 N sulfuric acid drop by drop, with gentle whirling to minimize foaming, until the solution is just yellow (pH about 3), then add 100 mg. of dry citrate buffer mixture. Add several pieces of alundum to prevent bumping and heat to boiling over a microburner. Boil exactly 1 minute (no longer). Cool to below 25° (placing in ice water for three minutes is satisfactory). Attach the short rubber connector to the side arm (Fig. 264), and wipe off any water from the inside ground glass surface of the vessel top.

48 Obtainable from E. Machlett and Son, New York, N.Y.

49 See Chapter 1 for the preparation of indicator solutions.

⁵⁰ Dry Phosphate Buffer Mixture. Grind separately in a mortar 3 parts by weight of anhydrous monopotassium phosphate and 1 part of anhydrous disodium phosphate (or 2.5 parts of disodium phosphate containing 12 molecules of water). Mix the two ground solids and grind intimately together. Dispense with a glass spoon calibrated to deliver 175 \pm 15

mg. of the powder. This mixture produces a pH of 6.2 when in solution.

Survease Solution. This is made from urease powder, prepared as described on p. 823 (Squibb's "Double Strength" Urease, obtainable from E. R. Squibb and Sons, New York may also be used.) Dissolve the powder in water in the proportion of 1 g. to 10 ml. of water. Dilute this 10 per cent solution 1:10 with water before use to make the 1 per cent solution required. This solution contains sufficient amino acid to produce a correction (as established by the blank analysis described in the procedure) equal to several per cent of the usual amino acid content of the urine. To decrease this correction to about one-third of its initial value, wash the dry urease powder with alcohol as follows: Grind 5 g. of the urease powder in a mortar with 10 successive portions of 50 ml. each of 80 per cent ethyl alcohol. Dry the solid residue (about 2.5 g.) at room temperature in vacuo, and use this purified material for the preparation of the 10 per cent solution. To free the urease completely from amino acids, the dialysis purification procedure of Archibald and Hamilton (J. Biol. Chem., 153, 155 (1943)) may be used. The activity of the urease powder should be established as described by Van Slyke; J. Biol. Chem., 73, 695 (1927). (See also Van Slyke, MacFadyen, and Hamilton: loc. cit.) If the urease splits less than 0.1 its weight of urea per minute, a proportionately stronger solution than 1 per cent should be used.

⁵² Dry Citrate Buffer Mixture. Grind separately in a mortar 2.06 g. of sodium citrate (Na₂C₄H₅O₇·2H₂O) and 19.15 g. of citric acid (C₄H₅O₇·H₂O). Mix the two ground solids and grind intimately together. Dispense with a glass spoon calibrated to deliver 100 ± 10

mg. of the powder. This mixture produces a pH of 2.5 in solution.

53 A 5-cm. length of stethoscope tubing is used (3 mm. bore, 12 mm. outside diameter). Before using for the first time, clean the tubes inside with a test tube brush, immerse in acidified water in a round bottomed flask, and boil for 30 minutes. Remove the flame, stopper the flask and cool under the tap. The vacuum caused by cooling draws excess gases from the rubber. When bubbles no longer appear, open the flask and wash the tubes with water. One treatment suffices.

Treatment with Ninhydrin: Add 100 mg. of ninhydrin⁵⁴ to the cooled reaction mixture with the aid of a small funnel having a short stem. Have the glass stopper ready with a thin film of special lubricant⁵⁵ spread over the ground

glass surface, and as soon as the ninhydrin has been added, remove the funnel and set the stopper in place, with the hole in line with the side arm, as shown in Fig. 264. Immediately attach the side arm to a good source of vacuum (preferably with attached manometer) and evacuate quickly to 39 mm, or less pressure, shaking gently if necessary to minimize effervescence. When the vessel is evacuated (10 seconds may be sufficient time), turn the stopper through 180° to close off the vessel. Press the rubber connector flat with the fingers. detach vessel and connector from the vacuum line, and insert a glass plug moistened with water or glycerol into the connector, trapping as little air as possible in the process. Tighten the stopper in place-it may be held more securely by a heavy rubber band linking stopper and side arm. Place the closed vessel upright in a wire rack and immerse completely in vigorously boiling water for eight minutes. Remove, tighten the stopper again by a slight twist if necessary, and allow to cool

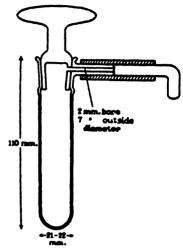

Fig. 264. Reaction vessel for ninhydrin amino acid method. (Courtesy, Hamilton and Van Slyke: J. Biol. Chem., 150, 231 (1943).)

to room temperature. The closed vessel may be kept for several days at this point if necessary, and if many analyses are to be done they may all be brought to this stage before proceeding.

Absorption and Measurement of CO₂: Warm the contents of the reaction vessel to 38° to 40° by immersion in a beaker of water at this temperature for 10 minutes. While waiting, deliver 2 ml. of the carbonate-free 0.5 N sodium hydroxide in sodium chloride solution⁵⁶ from the storage container equipped with a rubber tip (Fig. 265), into the chamber of the Van Slyke-Neill apparatus (Fig. 194), through a mercury seal in the cup (see Fig. 196 and p. 644 for method of delivery). Seal the cup capillary with a little

⁴⁴ Obtainable from the Eastman Kodak Co., Rochester, N.Y., or the Department of Chemistry, University of Illinois, Urbana, Illinois, Dispense with a glass spoon calibrated to deliver approximately the required amount (within 10 per cent).

heavy lubricant which does not leak at high temperatures must be used. "Nevastane XX heavy lubricating grease," obtainable from E. Machlett and Son, New York, is satisfactory. A suitable lubricant may be prepared in the laboratory as follows: Mix 35 g. of aluminum distearate to a paste in 100 ml. of heavy paraffin mineral oil. Heat with continuous stirring in a beaker over a low flame to effect solution of the soap. Allow to cool, then work up the friable gel to a smooth translucent paste on a glass plate with a steel spatula, preferably with warming to 45° to 50°

¹⁶ Dissolve solid sodium hydroxide in an equal weight of water and allow to stand until the carbonate settles. Standardize the supernatant solution by pipeting 7 ml. into water and titrating with standard (2 N or stronger) acid From the result, determine how much of the 1:1 NaOH is required to make 250 ml. of 0.5 N solution. Fill a 250-ml. volumetric flask to within about 10 ml. of the mark with concentrated CO₂-free NaCl solution (dissolve 250 g. of NaCl in 750 ml. of water, de-aerate and store as described on p. 648). Pipet the correct amount of 1:1 NaOH solution into the flask, delivering it below the surface of the salt solution. Add a few drops of 1 per cent alizarin solution as indicator, fill to the mark with salt solution, and mix. Transfer to a storage container (Fig. 265 in text) to protect from atmospheric carbon dioxide.

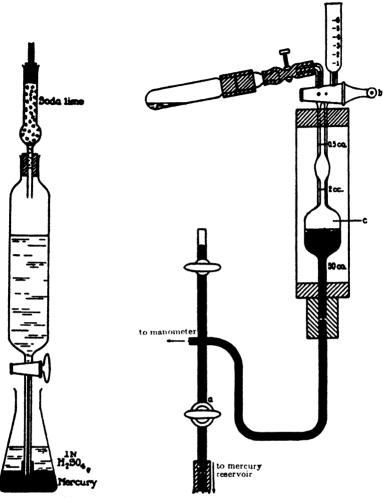

Fig. 265. Storage container for alkaline solutions, hung with tip protected from atmospheric carbon dioxide. (Courtesy, Van Slyke and Folch: J. Biol. Chem., 136, 509 (1940).)

Fig. 266. Manometric chamber with reaction vessel (earlier type) attached but not yet connected with interior of chamber. (Courtesy, Van Slyke, Dillon, MacFadyen, and Hamilton: J. Biol. Chem., 141, 627 (1941).)

mercury, lower the mercury in the chamber to about the middle of the chamber, and close the cock leading to the leveling bulb (cock a in Fig. 266). By this time the reaction vessel contents should be sufficiently warm. Remove the vessel from the water bath, remove the glass plug from the side arm, attach the rubber connector to a source of vacuum, and re-evacuate the side arm for a few seconds. Pinch the rubber connector flat with the fingers, detach from the vacuum line, and at once attach to the side arm

of the Van Slyke-Neill apparatus. Fig. 266 shows the conditions prevailing at this point. Turn the stopcock of the reaction vessel and cock b of the chamber so as to connect vessel and chamber and permit gas to pass from one to the other. Transfer the CO_2 in the reaction vessel to the chamber twhere it is absorbed by the alkali present) by repeatedly raising and lowering the mercury in the chamber by manipulation of the leveling bulb and cock a. The first lowering of the mercury must be done carefully to prevent

bumping in the reaction vessel, and at each lowering the reaction vessel is shaken by hand to distribute the fluid along the walls. Five excursions of the mercury suffice to transfer all the CO₂, each excursion taking about 10 seconds. After the last upward excursion, lower the mercury in the chamber to about the middle point, and close cocks a and b. Remove the reaction vessel and fill the side arm and the cock capillary of the manometric apparatus with mercury by suction from a small bottle containing mercury (see Fig. 267).

Open cock a, raise the leveling bulb to about even with cock b, then close a. Open b carefully to the right-hand cup at the top, allow the gases present to escape through the cup, then admit mercury to the chamber through cock a until the fluid in the chamber just reaches the top of the chamber, at cock b. Close a and then b. Place the leveling bulb at its normal position (approximately even with the 50-ml. mark at the bottom of the chamber), place a little mer-

Fig. 267. Small bottle of mercury arranged for sealing capillary of manometer stopcock. (Courtesy, Van Slyke and Folch: J. Biol. Chem., 136, 509 (1940).)

cury in the cup, and seal the cock capillary with mercury in the usual way. Through the mercury seal, add exactly 1 ml. of 2 N lactic acid in sodium chloride solution⁵⁷ from a stopcock pipet provided with a rubber ring on the tip, as illustrated in Fig. 196, p. 644, then seal the cock with a little mercury. By manipulation of the leveling bulb and cock a, lower the mercury in the chamber to the 50-ml. mark, close a, and shake the chamber for 20 to 30 seconds. The liberated CO₂ drives the mercury below the 50-ml. mark. Raise the leveling bulb, open a carefully, and adjust the mercury level to the 50-ml. mark. Close a and shake the chamber for three minutes. Place the leveling bulb high, open a, and admit mercury into the chamber until the level of the fluid (not mercury) meniscus is exactly at the 2-ml. mark on the chamber. This adjustment must be done in a consistent manner. Allow the mercury to enter through a steadily, without jerky oscillation of the chamber contents, and complete the adjustment in 30 to 40 seconds. If the adjustment is missed the first time (or for a duplicate reading) lower the mercury to the 50-ml. mark, shake for one minute, and repeat. With the fluid meniscus at the 2-ml. mark, read the manometer. This reading is p_1 .

Replace the leveling bulb to the normal position, open $\cos a$, and place 0.5 ml. of 5 N sodium hydroxide solution. In the cup above $\cos b$. Admit the alkali to the chamber slowly, over a period of about half a minute, until only enough is left to fill the capillary beneath the cup. Add a little water and mercury to the cup, and seal the cock with mercury. If the viscous alkali forms a solid column in the top of the chamber, it may be broken up by admitting a little mercury in short bursts. Mix the alkali and ensure complete absorption of CO_2 by raising and lowering the mer-

³⁷ Dilute 1 volume of concentrated lactic acid (sp. gr. 1.20) with 4 volumes of the concentrated NaCl solution described in the previous footnote.

Mix 1 volume of 1:1 NaOH solution with 3 volumes of water.

cury in the chamber three times in short excursions, then bring the fluid meniscus to just below the 2-ml. mark on the chamber. Allow one minute for drainage, then adjust exactly to the 2-ml. mark. Read the manometer; this reading is p_2 .

Calculation. The pressure P_{CO2} due to the carboxyl carbon dioxide of the amino acids present is found as follows:

$$P_{CO2} = p_1 - p_2 - c$$

where c is the correction due to the blank. To establish c, run through an entire analysis as described above (including incubation with urease, etc.) on 2 ml. of water instead of urine. The difference between the p_1 and p_2 readings for the water blank analysis equals c. This blank will serve to correct for small amounts of amino acids which may be present in the urease preparation, as well as for certain possible variables in the manometric measurement itself.

To obtain the amino acid nitrogen content of the sample, multiply P_{co2} by the proper factor, obtained from the accompanying table.

 $P_{CO2} \times \text{factor} = \text{mg. } \alpha\text{-amino nitrogen per liter of urine}$

The temperature column in the table refers to the temperature of the water in

the jacket surrounding the chamber at the time the p_1 and p_2 readings are made, and a is the volume of the gas phase when the manometer is read; a is ordinarily 2 ml., but may be reduced to 0.5 ml. if only small amounts of amino acids are present.

Interpretation. The α -amino acid nitrogen content of normal urine appears to make up about 1 per cent (or possibly even less) of the total urinary nitrogen, corresponding to a daily excretion of 100 to 150 mg. of α -amino nitrogen. Results by other methods, e.g., the nitrous acid method of Van Slyke and Kirk,⁵⁹ the formol titration procedure (see following method), and the copper titration procedure of Albanese and Irby,⁶⁰ tend to be either slightly or significantly higher than results by the ninhydrin procedure described here, presumably because of differences in specificity for α -amino nitrogen. Little is known concerning the significance of normal

^{*} Van Slyke and Kirk: J. Biol. Chem., 102, 651 (1933).

⁴⁰ Albanese and Irby: J. Biol. Chem., 153, 583 (1944).

or pathological variation in amount of urinary α -amino nitrogen. Excretion may be largely increased in disorders associated with tissue waste as typhoid, in pronounced atrophy of the liver, acidosis, etc.

2. Henriques-Sørensen Formol Titration Method:⁶¹ Principle. A solution containing amino acids is nearly neutral in reaction. If formaldehyde be added, however, a reaction takes place with the formation of derivatives which are more strongly acid in reaction due to the destruction of the basic properties of the amino groups (see p. 116 for discussion and equations). The carboxyl groups may then be titrated using phenolphthalein as an indicator. The acidity as shown by the titration is a measure of the amount of amino acid nitrogen present. Ammonia likewise reacts with formaldehyde in a similar manner as is shown in the following equation:

$$4NH_4Cl + 6CH_2O = N_4(CH_2)_6 + 6H_2O + 4HCl$$

Hence the formol titration in the presence of ammonia gives results which include both amino acid and ammonia nitrogen. Ammonia may be determined and a correction applied, or the ammonia may be removed by means of phosphotungstic acid. Phosphates also interfere by obscuring the end-point and are removed by the addition of barium salts.

It must be borne in mind that polypeptides and still more complex protein derivatives likewise react with formol to a certain degree so that the results do not strictly represent "amino acid nitrogen."

The method is, with some modifications involving the preparation of the solution to be titrated, applicable in the determination of amino acids in any medium, e.g., urine, protein digests, 62 etc. When poorly dissociated acids, e.g., some fatty acids, are present, these will in part be included in the result and lead to values which are too high. Certain of the amino acids when present in large amounts will give erroneous results, but in the ordinary urine or digest these errors are either negligible or compensate each other. In the titration of colored solutions the control solution which is necessary in this method must be colored to correspond with the color of the unknown solution.

Procedure: The determination of the amino acids is carried out as follows: The solution to be analyzed, if carbonates, phosphates, and ammonia are absent, is made neutral to litmus (paper) and the solution titrated with formaldehyde as below. 12 In case carbonates, phosphates, or ammonia are present a preliminary treatment is necessary which will vary according to the quantity of ammonia present.

a. For Small Amounts of Ammonia: Applicable to most urines. Fifty ml. of the material under examination are pipeted into a 100-ml. measuring flask and 1 ml. of phenolphthalein solution⁶⁴ and 2 g. of solid barium

⁶¹ Honriques and Sørensen: Z. physiol. Chem., 64, 120 (1909). See also Northrop: J. Gen. Physiol., 9, 767 (1926).

⁶² Northrop (J. Gen. Physiol., 9, 767 (1926)) has modified the formol titration by titrating first to pH 7 with neutral red as the indicator, then adding formaldehyde and titrating to pH 9 with phenolphthalein.

⁴² As a standard of comparison the litmus paper used for neutralisation is contrasted with a similar piece dipped in a phosphate solution having a neutral reaction $(M/15 \text{ KH}_2\text{PO}_4 \text{ and } M/15 \text{ Na}_2\text{HPO}_4$ in the proportion 40:60).

⁴⁴ A solution of 0.5 g. of phenolphthalein in 50 ml. of alcohol and 50 ml. of water.

chloride are added; the whole is shaken, to saturate the solution with barium chloride; saturated barium hydroxide solution is added until the red color of the phenolphthalein develops and then an excess of 5 ml. is added. The flask is filled to the graduation mark with water, shaken and permitted to stand for 15 minutes, after which it is filtered through a dry filter. 80 ml. of the clear red filtrate (which corresponds to 40 ml. of the liquid under examination) are placed in a 100-ml. measuring flask, neutralized to litmus and diluted to 100 ml. with freshly boiled water. Equal portions of this solution, 40 ml. (equivalent to 16 ml. of the original solution), may be taken for analysis, one for the formol titration and the other for the determination of ammonia nitrogen. 65

b. For Large Amounts of Ammonia: After the treatment with phenolphthalein, barium chloride, and barium hydroxide, and the solution has been diluted to 100 ml. as in (a) above, the ammonia is distilled off, in vacuo.⁶⁴

In case the solution is deeply colored, as in protein digests, it may be necessary to decolorize⁶⁷ before the titration is attempted.

Final Titration: For the final titration a volume of from 20 to 40 ml. which contains approximately 0.025 g. of nitrogen is the most desirable. A control solution is run composed of an equal volume of boiled distilled water and 20 ml. of the formaldehyde mixture. This control solution is colored so that its tint matches that of the solution to be titrated.

To this control is added about half the volume of 0.2 N alkali which will be used in the titration of the solution under investigation and it is then titrated with 0.2 N acid to a faint red (first stage).⁷⁰

An additional drop of 0.2 N alkali is added, which imparts a distinct red to the solution (second stage).

The solution to be analyzed is now titrated to the color produced in the second stage of the control. The formaldehyde mixture is now added; 10 ml. for each 20 ml. of the solution, and the mixture again titrated to the second stage with 0.2 N alkali.⁷¹

Two drops of the 0.2 N alkali are now added to the control solution which assumes a deep red color (third stage). 0.2 N alkali is now added to the solution under examination until it assumes a color corresponding to the third stage of the control. This completes the titration.

Calculation. The calculations are similar to those which pertain to any acidimetry procedure. Each ml. of an 0.2 N alkali or acid solution is equivalent to 0.0028 g. of nitrogen. An example will illustrate the procedure: 40 ml. of solution (16 ml. of urine) required 5.10 ml. of 0.2 N NaOH; control, 0.10 ml. of 0.2 N NaOH; total required for amino acids 5.00 ml. equivalent to 0.014 g. of nitrogen. Ammonia nitrogen in 16 ml. of urine, 0.007 g. of N. Then 0.014 - 0.007 = 0.007 g. of amino acid nitrogen in 16 ml. of urine.

⁶⁵ The determination of ammonia may be dispensed with in case a separate determination is made.

⁶⁶ For particulars with regard to the distillation, etc., see Henriques and Sørensen: Z. physiol. Chem., 64, 137 (1909).

⁴⁷ For methods see Jessen-Hansen: "Abderhalden's Arbeitsmethoden," vol. 6, p. 262, 1912.

⁶⁹ The formaldehyde solution is freshly prepared for each set of determinations as follows: to 50 ml. of commercial formaldehyde (formol) (30 to 40 per cent) add 1 ml. of the phenolphthalein solution. 0.2 N alkali is then added until the mixture acquires a faint red color. The volume of the formaldehyde used will vary with the volume of the solution to be analyzed; approximately 10 ml. of the formalin solution are added for each 20 ml. of the unknown solution.

⁵⁹ Solution of Bismark brown is very satisfactory for urines. Tropeolin O, tropeolin OO, p-nitrophenol, methyl orange, or alisarin sulfonate may be used.

⁷º This procedure is recommended in order that the final volume of the control and the unknown solutions shall be approximately the same when the process is complete.

⁷¹ This is best accomplished by adding alkali until the color is deeper than that of the control, then acid again until lighter, and finally alkali to the desired color.

Interpretation. The excretion of total amino acid nitrogen by a normal adult, as determined by this procedure, averages between 0.4 to 1.0 g. per day or from 2 to 6 per cent of the total nitrogen. Free amino acid nitrogen (see previous procedure) is considerably less than this, ordinarily 0.5 to 1.0 per cent of the total nitrogen. This discrepancy is due to the relative nonspecificity of the formol titration. For further aspects of interpretation, see preliminary discussion, and also previous procedure.

3. Other Methods. Folin proposed the colorimetric determination of amino acids in urine by reaction with naphthoquinone sulfonic acid, ⁷² after preliminary treatment of the urine with Permutit to remove ammonia, which interferes. Although this color reaction is sufficiently reliable for its use in the determination of blood amino acids (see Chapter 23), where interference by ammonia does not arise, the procedure is not recommended for urine analysis since the Permutit treatment removes some of the amino acids as well as ammonia. A more satisfactory procedure for removal of ammonia might render the method applicable to urine. Albanese and Irby⁷³ have proposed a simple titrimetric method for the determination of urinary amino acid nitrogen; their procedure appears to have approximately the specificity of the formol titration. For details of the nitrous acid reaction for urinary amino acids, see Van Slyke and Kirk.⁷⁴

CREATININE

1. Folin's Method: Principle. This method is based upon the characteristic property possessed by creatinine, of yielding a certain definite color reaction in the presence of picric acid in alkaline solution. This reaction (Jaffe reaction) is due to the formation of a red tautomer of creatinine picrate. The production of this tautomer is "dependent upon the formation of a salt, a keto-enol change within the creatinine molecule, and a change in the picric acid molecule involving the hydrogens in the meta positions and, probably all three nitro groups."

In the original Folin "macro" method (for description see the Eleventh Edition of this book), 10 ml. of urine are used for a determination, the color is developed at a final volume of 500 ml., and comparison is made visually against an artificial standard (0.5 N potassium bichromate solution) under rigorously defined conditions. The Folin "micro" modification described here is preferred because it requires less urine, is based upon comparison against standard creatinine solutions, and is therefore more flexible and accurate, and is adaptable to either colorimetric or photometric measurement.⁷⁷

⁷² This procedure is described in the Eleventh Edition of this book.

¹⁷ For studies on the photometric determination of creatinine by the Jaffe reaction, see Bonsnes and Taussky: J. Biol. Chem., 153, 581 (1945); Peters: J. Biol. Chem., 146, 179 (1942). The use of 3,5-dinitrobensoic acid for the colorimetric determination of creatinine has been proposed by Benedict and Behre: J. Biol. Chem., 114, 515 (1936), and Langley and Evans: ibid., 115, 333 (1936).

Procedure:

- a. For Colorimetric Comparison: Measure 1 ml. of urine into a 100-ml. volumetric flask, and in a second similar flask place 1 ml. of the standard creatinine solution, 78 containing 1 mg. of creatinine per ml. To each flask add 20 ml. of 1 per cent picric acid solution 79 (measured with sufficient accuracy from a graduated cylinder), followed by 1.5 ml. of 10 per cent sodium hydroxide solution. Mix gently and allow to stand 15 minutes. Dilute to the mark with water and mix by inversion. Compare standard against unknown in the usual way, setting the standard at 20 mm.
- b. For Photometric Measurement. Measure 0.5 ml. of urine into a 100-ml. volumetric flask and add 0.5 ml. of water. In a second flask, which serves as a blank, place 1 ml. of water. To each flask add 20 ml. of 1 per cent picric acid solution, followed by 1.5 ml. of 10 per cent sodium hydroxide solution. Mix gently and allow to stand 15 minutes. Dilute to the mark with water and mix by inversion. Transfer portions of blank and unknown to photometer cuvettes. Set the photometer to zero density with the blank, at 520 mg, and determine the density of the unknown. Alternately, the photometer may be set to zero density with water, and the densities of both blank and unknown determined. The density of the blank is then subtracted from the measured density of the unknown, to obtain the true density of the unknown.

Calculation. For colorimetric measurement:

Reading of Standard Reading of Unknown X mg. of creatinine in Standard = mg. of creatinine in volume of urine analyzed

With a urine volume of 1 ml., and a 1-mg. standard, the result of the calculation gives the creatinine content of the urine directly, in mg. per ml., or grams per liter. Urines containing 0.75 to 1.25 g. of creatinine per liter (i.e., the standard and unknown read within a few mm. of each other) may be accurately determined with the 1-mg. standard described. For values outside this range, the calculation is not accurate because of the deviation from Beer's law shown by the Jaffe reaction for creatinine. In such cases the determination must be repeated using less or more urine as the case may be, to provide a portion of sample containing approximately 1 mg. of creatinine. When this is done, differences in volume between standard and unknown before adding the picric acid must be equalized by the proper addition of water to one or the other as required. The further procedure and the calculations are as described. For very dilute urines (creatinine content less than 0.2 g. per liter), the Shaffer modification of the Folin procedure may be used (see the Eleventh Edition of this book for details).

For photometric measurement: the creatinine content of the unknown is established from its photometric density by reference to a calibration curve showing the densities for known amounts of creatinine determined by the procedure described. Direct calculation of results in terms of Beer's law is not valid in this procedure because of the lack of adherence to Beer's law over the concentration range in question.

To prepare a calibration curve, measure 0.0, 0.25, 0.50, 0.75, and 1.00 ml. portions of standard creatinine solution, containing 1 mg. per ml., into separate 100-ml. volumetric flasks (preferably in duplicate). Add water to each where necessary to bring all to 1 ml. volume, and treat with picric acid and alkali exactly as described under "Procedure" for the photometric analysis of an

75 Prepared from pural picric scid (see Appendix). Keep in a dark bottle.

¹⁸ Standard Creatinine Solution: Dissolve 1 g. of pure dry creatinine in sufficient 0.1 N hydrochloric acid to make 1 liter, and mix well. This solution contains 1 mg. of creatinine per ml., and is stable indefinitely. Pure creatinine may be purchased from laboratory supply houses, or may be made from urine by Benedict's method (see p. 733). Creatinine-sine chloride may be used in place of creatinine, in which case 1.61 g. of the creatinine-sine chloride salt is used per liter of 0.1 N acid to give the standard solution containing 1 mg. of creatinine per ml.

unknown. Determine the densities for each of the standards, using the first or blank solution to set the photometer to zero density, or set the photometer to zero density with water and subtract the determined density of the blank from

that for each standard to obtain the true densities of the standards. On a sheet of ordinary cross-section paper, plot the density of each standard on the y-axis against the amount of creatinine present, in mg., on the x-axis. Draw a smooth curve to include all the points. A curve similar to that shown in Fig. 268 will be obtained.

The amount of creatinine present in an unknown is obtained by reference to the curve. It 0.5 ml. of urine is used in an analysis, the result from the curve gives the creatinine content in this volume of sample. Multiply by 2 to obtain the creatinine content in mg. per ml. or grams per liter.

The spectrophotometric characteristics of the creatmine color are shown in Fig. 269. At 520 m μ , and in a 1-cm, cuvette, the densities for various amounts of creatinine have approximately the values indicated in Fig. 268. Any creatinine content up to

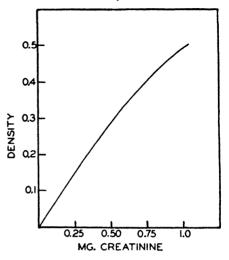

Fig. 268. Typical calibration curve for photometric determination of creatinine in urine.

about 2 g. per liter may be accurately determined under these conditions. For higher values, or for photometric measurement at greater depth of solution, the urine should be diluted, a portion of the diluted sample used for analysis, and the creatinine content as read from the curve multiplied by the dilution to obtain the true creatinine content of the original undiluted urine.

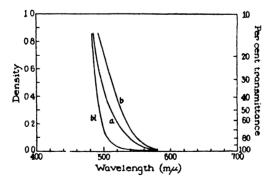

Fig. 269. Absorption spectra of colored solutions obtained in urinary creatinine method, for the alkaline picrate blank (bl), blank plus 0.25 mg. (a), and 0.50 mg. (b) of creatinine. Solution depth, 1 cm.

The sources of error in the use of a previously prepared calibration curve have been discussed in Chapter 23. For accurate results the curve should be checked at intervals and reconstructed if necessary. In an analysis, every effort should be made to have the analytical conditions as nearly identical as possible with those

prevailing at the time the curve was established; the time of standing after adding the alkali and after diluting, and the room temperature, are particularly important in this connection. The curve should be checked or reestablished with each new lot of picric acid.

Interpretation. The daily excretion of creatinine by normal adults ranges from about 1.0 to 1.8 g.; under certain conditions it may be considerably higher. 80 The value is nearly constant from day to day for a given normal individual, being influenced by the diet only to the extent that the diet itself contains significant amounts of creatinine, as in the case of a heavy meat diet. Creatinine excretion is not influenced by exercise or by the level of nitrogen metabolism in the body. Creatinine appears to be entirely a waste product, unutilizable by the body, and is excreted almost if not entirely quantitatively when ingested or injected. The relative constancy of creatinine excretion on a creatinine-free diet appears to reflect some constant metabolic process involving the body creatine (from which creatinine is almost certainly derived), but the nature of this process is still obscure (see p. 730 for further discussion) and therefore the significance of a constant creatinine excretion cannot be too precisely evaluated. Since the bulk of the creatine of the body is in the muscles, there is a rough correlation between the creatinine excretion and the amount of muscular tissue in the body; for example, obese individuals excrete less creatinine relative to their body weight than do thin persons. The number of mg. of creatinine excreted daily per kg. of body weight is known as the "creatinine coefficient," which has a normal range of 19 to 30. Some investigators designate the creatinine coefficient in terms of the number of mg. of creatinine-nitrogen excreted daily per kg. of body weight; the normal range in this case is 7 to 11.

Creatinine excretion is decreased in disorders associated with muscular atrophy and muscular weakness. It increases with increased tissue catabolism as in fever.

CREATINE

1. Folin Method:⁸¹ Principle. Creatine on boiling with acid is transformed into creatinine. By determining the creatinine content before and after treatment with acid (picric acid is used here), the amount of creatine present may be obtained by difference. The method is not applicable to diabetic urines, since acetone and glucose interfere.

Procedure: Measure the urine (1 ml. for colorimetric measurement, 0.5 ml. for photometric measurement) into a 300-ml. flask. Add 20 ml. of 1 per cent picric acid solution and a few small pebblas or pieces of alundum. Weigh the flask and contents on a rough balance to the nearest gram. Add about 150 ml. of water and heat to boiling. Boil gently for 45 minutes, then more rapidly until the volume has been reduced to somewhat under the original volume of urine plus picric acid solution, as established by weighing. Add sufficient water to the flask to restore the original weight, within

⁸⁰ See Hobson: Biochem. J., 23, 1425 (1939).

⁸¹ Folin: J. Biol. Chem., 17, 469 (1914).

²⁵ The reagents required are those used for the determination of urinary creatinine (p. 839).

about a gram. Cool to room temperature (this is important). Add 1.5 ml. of 10 per cent sodium hydroxide solution, and mix. Let stand 15 minutes. Rinse into a 100-ml. volumetric flask, dilute with water to the mark, and mix. For colorimetric measurement, compare against a standard creatinine solution, containing 1 mg. of creatinine, prepared in a second 100-ml. volumetric flask as described on p. 840 for the determination of urinary creatinine. For photometric measurement, determine the density (corrected for the picrate blank) as described on p. 840, and obtain results from a calibration curve, as described below.

Calculation. For colorimetric measurement:

```
Reading of Standard Reading of Unknown X mg. of creatinine mg. of "total" creatinine in vol. of urine used
```

From this, the "total" creatinine content per liter or in the 24-hour sample may be obtained. Subtract from the "total" creatinine value the preformed creatinine content, determined separately as described on p. 839, to obtain the creatine content (expressed as creatinine).

```
(Total creatinine - Preformed creatinine) = Creatine (as creatinine)
```

To convert creatine expressed as creatinine into the amount of creatine itself, multiply by 1.16:

```
(Total creatinine - Preformed creatinine) × 1.16 = Creatine
```

The same precautions concerning close agreement between standard and unknown that are emphasized in the determination of urinary creatinine are applicable here. The total creatinine content of the sample should not be greater than about 1.25 g. per liter, when a 1-mg. standard is used. If it is higher than this, repeat the analysis using less urine, or an aliquot of diluted urine.

For photometric measurement: from the determined density of the unknown (corrected for the picrate blank), obtain the "total" creatinine content of the volume of urine used by reference to a calibration curve, as described on p. 841 for the photometric determination of urinary creatinine (the same curve may be used) Determine the creatine content as described above, by subtracting from the "total" creatinine content the amount of preformed creatinine present, determined separately. If the photometric density of the unknown is beyond the limits of the calibration curve, repeat the analysis using less urine.

Interpretation. Creatine occurs only in small amount (approximate range 0 to 200 mg. per day) in the urine of normal adults, but is found in larger amounts in the urine of children. More creatine is found in the urine during activity than when at rest. Hobson⁸³ found significant creatinuria (in one instance 1.4 g. per day) in the case of adult male athletes in training, on a high carbohydrate diet; decrease in carbohydrate intake resulted in a markedly decreased excretion of creatine. Albanese and Wangerin⁸⁴ found significant amounts of creatine in the urine of 30 normal adults, with no sex differences being apparent. According to these latter investigators, earlier views that creatinuria is not found in normal adults are possibly due to technical difficulties in the analysis.

Increased creatine excretion is noted in pregnancy, in fasting, and after high water ingestion. A significant creatinuria is noted in many pathological conditions associated with malnutrition and disintegration of

^{**} Hobson: Biochem. J., 33, 1425 (1939).

⁶⁴ Albanese and Wangerin: Science, 100, 58 (1944). See, however. Lambert: J. Biol. Chem., 161, 679 (1945)

muscular tissue, in fever, etc. Very large amounts have been found in the urine from cases of carcinoma of the liver. Ingestion of creatine by normal adults does not increase the creatine content of the urine, i.e., the ingested creatine is completely retained. In certain pathological conditions, however, notably progressive muscular dystrophy, this ability to retain ingested creatine is impaired and extra creatine appears in the urine after a test dose. This is the basis for the *creatine tolerance test*, ⁸⁶ which is sometimes used clinically for diagnostic purposes.

2. Other Methods. Various modifications of the acid treatment for the conversion of creatine to creatinine have been described. In the original Folin method, the urine is heated with an equal volume of 1 N hydrochloric acid for three hours on a boiling water bath: Folin felt that the picric acid method described here is superior to this first procedure. Autoclaving with pieric acid solution at 115° to 120° for 20 minutes has also been proposed; according to Albanese and Wangerin, 84 this does not give complete conversion, and Bonsnes and Taussky⁸⁶ have confirmed this. In the Benedict⁸⁷ procedure, the urine is taken to dryness in the presence of 1 to 2 volumes of normal hydrochloric acid, with a few granules of lead to minimize pigment formation. This procedure appears to give complete conversion, but it has not as yet been shown to be applicable to the small amounts of creatine concerned in modern micromethods. Bonsnes and Taussky⁸⁶ and Peters⁸⁸ have described procedures for the determination of urinary creatine under conditions whereby the diluted sample is treated by procedures similar to those used for blood filtrates. 89 thus permitting the determination of both blood and urine creatine and creatinine in essentially the same manner.

URIC ACID

1. Direct Colorimetric Method of Benedict and Franke: 90 Principle. The diluted urine is treated directly with arsenophosphotungstic acid reagent and sodium cyanide. The blue color obtained is compared with that of a standard uric acid solution treated in the same way. This method is known to be somewhat nonspecific for uric acid, as are all "direct" methods (see discussion under the other methods described in this section) but is believed to be quite satisfactory for many purposes.

Procedure: 1 The urine 2 is so diluted that 10 ml. will contain between 0.15 and 0.30 mg. of uric acid. (Usually a dilution of 1 to 20 is satisfactory.)

 - ** Peters: J. Biol. Chem., 146, 179 (1942).
 - ** See Chapter 23.
- ⁹⁰ Benedict and Franke: J. Biol. Chem., 52, 387 (1922). For a modification of this method, claimed to be superior, see Christman and Ravwitch: J. Biol. Chem., 95, 115 (1932). A photometric version of the Christman-Ravwitch procedure is used in the "uricase" procedure of Buchanan, Block, and Christman described in the text (p. 846).
- ployed is the one used in the Benedict procedure for the direct determination of uric acid in blood (Benedict: J. Biol. Chem., 51, 187 (1922)) and is prepared as follows: 100 g. of pure sodium tungstate (preferably Merck's, or J. T. Baker's C. P. product) are placed in a liter pyrex flask and dissolved in about 600 ml. of water. 50 g. of pure arsenic acid (AssO₄)

Ten ml. of the diluted urine are measured into a 50 ml. volumetric flask, 5 ml. of the 5 per cent sodium cyanide solution (poisonous!) are added from a buret, followed by 1 ml. of the arsenophosphotungstic acid reagent. The contents of the flask are mixed by gentle shaking, and at the end of five minutes diluted to the 50-ml. mark with distilled water and mixed. For colorimetric measurement, this blue solution is then compared with a simultaneously prepared solution obtained by treating 10 ml. of the standard uric acid solution (0.2 mg. of uric acid) in a 50-ml. flask with 5 ml. of the sodium cyanide solution, 1 ml. of the reagent, and diluting to the mark at the end of five minutes. For photometric measurement, determine the densities of unknown and standar at 520 mg, setting the photometer to zero density with a blank solution obtained by treating 10 ml. of water in a 50-ml. flask with cyanide and reagent exactly as described for unknown and standard.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{D}{10} = \frac{\text{uric acid content of the urine,}}{\text{in grams per liter}}$$

D is the dilution (usually 20) of the urine. For most accurate results, the standard and unknown should read within a few mm. of each other. If they differ significantly, repeat the analysis using a greater or lesser dilution of the urine as required.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.2 \times \frac{\text{D}}{10} = \frac{\text{uric acid content of the urine,}}{\text{in grams per liter}}$$

As above, D is the dilution of the urine. The spectrophotometric characteristics of the uric acid color are shown in Fig. 270. At 520 m μ , and in a 1-cm, cuvette, the standard has a density of approximately 0.300. Agreement with Beer's law is satisfactory only at a uric acid content about equal to that of the standard. For higher values, or for photometric measurement at greater depths of solution, carry out the analysis on a greater dilution of the urine. For more accurate results, prepare a calibration curve as described for the following method (p. 848).

Interpretation. For adults on a mixed diet the average excretion of uric acid is about 0.7 g. It arises from the purines of ingested food (exogenous uric acid) and from purines derived from the body tissues by disintegration of nuclear material (endogenous uric acid). This distinction

are now added, followed by 25 ml. of 85 per cent phosphoric acid and 20 ml. of concentrated hydrochloric acid. The mixture is boiled for about 20 minutes, cooled, and diluted to 1 liter. The reagent appears to keep indefinitely.

^{2.} Sodium Cyanide. A 5 per cent solution of sodium cyanide, containing 2 ml. of concentrated NH₄OH per liter, which should be prepared fresh once in about six to seven weeks.

^{3.} Uric Acid. A standard solution of uric acid, acidified with hydrochleric acid, containing 0.2 mg. of uric acid in 10 ml. is employed. This solution may be readily prepared by dilution of Benedict's phosphate standard uric acid solution described in connection with the Newton uric acid method for blood (see p. 515). 50 ml. of the phosphate standard solution (containing 10 mg. of uric acid) are measured into a 500-ml. volumetric flask and diluted to about 400 ml. with distilled water. 25 ml. of dilute hydrochloric acid (made by diluting 1 volume of the concentrated acid with 9 volumes of water) are added, and the solution is diluted to 500 ml. and mixed. This dilute standard solution should be prepared fresh from the phosphate standard every 10 days to 2 weeks.

⁹² Uric acid tends to precipitate out of urine on short standing, particularly if the urine is concentrated or acid. Analyses should therefore be carried out as soon as possible after obtaining the urine, and on the well-mixed sample, otherwise results will be misleading.

between two metabolic sources of urinary uric acid, first postulated by Folin many years ago, appears to be confirmed by more recent work based on the use of isotopes. Sexogenous uric acid depending entirely upon the diet is greatly increased by the ingestion of purine-rich foods (meat, liver, sweetbreads, etc.) and reduced to a very low level on purine-free foods, e.g., milk, eggs, etc. (see table, Chapter 33). Endogenous uric acid is influenced by exercise and by the diet (protein foods particularly giving rise to increases). It appears to be partly the result of gastro-intestinal secretory activity. On a purine-free diet the average excretion is 0.1 to 0.5 g. On a high purine diet the uric acid output may be 2 g. per day.

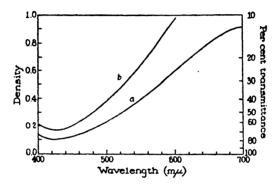

Fig. 270. Absorption spectra of colored solutions obtained in Benedict-Franke method for uric acid in urine, for standards containing 0.2 mg. (a) and 0.4 mg. (b) of uric acid. Solution depth, 1 cm.

In gout the uric acid content of the urine is low preceding an attack and increases during the attack, this fall and rise being more or less characteristic. The excretion rises after cincophen administration apparently due to increased kidney activity. In leukemia the excretion is extremely high due to nuclear destruction. The uric acid content of the urine is of importance in relation to the formation of uric acid calculi. The administration of alkali carbonates and citrates by decreasing the acidity of the urine increases its solvent power for uric acid, and decreases the possibility of the formation of this type of calculus.

2. Uricase Method of Buchanan, Block and Christman: 94 Principle. The color intensity resulting from the application of a uric acid color reaction directly to a portion of the diluted urine is determined photometrically. A second portion of urine is incubated with a preparation of the enzyme uricase, which specifically destroys uric acid, and the uric acid color reaction applied to this incubated sample. The difference

⁹² Plentl and Schoenheimer: J. Biol. Chem., 153, 203 (1944).

²⁴ Buchanan, Block, and Christman: J. Biol. Chem., 157, 181 (1945). For a similar procedure see Schaffer: J. Biol. Chem., 153, 163 (1944).

in color value before and after treatment with uricase is considered to be a measure of the true uric acid content of the urine.

Procedure:95

- a. Total Color: Transfer 5 ml. of urine to a 250-ml. volumetric flask, dilute with water to the mark, and mix. Transfer 10 ml. of this diluted urine to a 50-ml. volumetric flask and add 15 ml. of water. In a second similar flask place 25 ml. of water; this serves as a photometric blank. To each flask add 2.5 ml. of urea-cyanide solution, followed by 1 ml. of arsenophosphotungstic acid. Both of these reagents are extremely poisonous; they should be handled with care, and always dispensed from burets. Immediately after the addition of the arsenophosphotungstic acid, dilute the contents of the flask to the 50-ml. mark with water and mix thoroughly. Allow to stand for exactly 30 minutes after so diluting (in serial analyses a suitable time schedule should be established), then determine the density of the unknown in a photometer at 690 my, setting the photometer to zero density with the blank.
- b. Residual Color. Place 5 ml. of the original undiluted urine in a small flask, add 10 ml. of water and a few drops of 0.04 per cent thymol blue solution as indicator. Titrate with 0.1 N sodium hydroxide solution to a definite blue tint. Record the amount of alkali required, and discard the mixture. Transfer a fresh 5-ml. portion of the urine to a 50-ml. volumetric flask, and add the predetermined amount of alkali (without indicator). Add 250 mg. of uricase powder, 5 ml. of borate buffer (pH 9.2), and wash down the sides of the flask with 10 ml. of water. Place in a water bath at 45° for

³³ Reagents Required: *Urea-Cyanide Solution*. Dissolve 25 g. of pure sodium cyanide and 50 g. of anhydrous sodium carbonate in 400 ml. of water. Cool, add 75 g. of pure urea and dilute with water to 500 ml. This solution is usable for several months, even though a slight precipitate will settle out on standing. *It is extremely poisonous and must be handled carefully*.

Arsenophosphotungstic Acid. This is the same reagent that is used in the Benedict-Franke method (see p. 844).

Uricase Powder. Remove the superficial fat from 5 pounds of fresh beef kidneys and grind in a meat-chopper. Transfer to a large wide-mouthed bottle and wash by running in cold tap water slowly through a tube reaching to the bottle until the supernatant fluid is quite clear and colorless. Homogenize small portions of the resulting material in a Waring blendor with an approximately equal weight of benzene. To the combined total homogenate add 2 volumes of cold acctone. Allow the precipitate to settle, filter through cheesecloth or a towel, and squeeze dry. Suspend the solid material in about three times its weight of acctone, allow it to settle, and again filter off. Repeat until the resulting powder is thoroughly dehydrated and defatted. Spread the material on towels and allow to dry in air overnight. Screen the powder through a 40-mesh sieve and store in a vacuum desiccator.

This powder should give no blank color when carried through the incubation procedure and subsequent color reaction described in the text. To test for activity, prepare a special lithium carbonate solution of uric acid containing 1 g. of uric acid and 0.6 g. of lithium carbonate per liter by following the procedure described on p. 512 for the preparation of the Folin stock uric acid solution up to but not including the addition of formaldehyde and sulfuric acid, which if present will interfere with uricase activity. Each ml. of this solution contains 1 mg. of uric acid. Incubate 3 to 4 ml. of this solution with 250 mg. of the uricase powder, borate buffer, etc., and continue with the color reaction as for the analysis of an unknown. If the uricase is active, no residual color will be obtained. The special lithium carbonate standard is unstable and must be made up fresh on the day of use.

Standard Uric Acid Solution. The Folin stock standard solution is used, containing 1 mg. of uric acid per ml., prepared as described on p. 512 in connection with the determination of uric acid in blood. Suitable dilutions of this stock standard are used in the preparation of the calibration curve, as described in the text. Dilute standards are unstable and must be prepared fresh on the day of use.

Borate Buffer (pH 9.2). Dissolve 12.4 g. of boric acid in 1 liter of 0.1 N sodium hydroxide solution.

10 Per Cent Sodium Tungstate, 0.66 N Sulfuric Acid. The same reagents used in the preparation of Folin-Wu blood filtrates (see p. 493).

two hours. Add 1 ml. of 10 per cent sodium tungstate and 1.5 ml. of two-thirds normal sulfuric acid. Dilute to 50 ml. with water, mix well, and pour onto a dry filter. Transfer 10 ml. of the filtrate to a 50-ml. volumetric flask, add 15 ml. of water, and continue with the addition of the color reagents and measurement exactly as described above for the "total color" procedure. The same reagent blank may be used for setting the photometer to zero density, or a 5-ml. portion of water may be treated with uricase, buffer, etc., as described for the analysis of the urine, and the final solution after treatment with the color reagents used as a photometric blank.

Calculation.

- A. "Total Color" Value. Determine the amount of uric acid in mg. equivalent to the photometer reading of the "total color" sample by reference to a calibration curve (see below). Multiply this by 5 (since the 10 ml. of urine diluted 1:50 represents 0.2 ml. of original urine) to obtain the uric acid content for the undiluted urine equivalent to the "total color," in mg. per ml. (or grams per liter).
- B. "Residual Color" Value. In a similar way, determine the uric acid content equivalent to the "residual color": the value in mg. obtained from the calibration curve gives directly the residual color equivalent of the original urine, in mg. per ml., or grams per liter, since 10 ml. of urine diluted 1:10 are used.
- c. TRUE URIC ACID CONTENT. Subtract the "residual color" value from the "total color" value, to obtain the true uric acid content of the urine:

```
Total Color — Residual Color = True uric acid content (as uric acid) — (as uric acid) — (in grams per liter)
```

Multiply the result by the urine volume (expressed in liters) to obtain the uric acid content of the entire sample.

Other dilutions and aliquots than those specified may be used if the final colored solutions are either too light or too dark for accurate photometric measurement; in such case the calculations must be corrected accordingly.

The use of a calibration curve prepared from standard uric acid solutions is recommended because of the deviation from Beer's law shown by lower concentrations of uric acid. To prepare such a curve, proceed as follows: Dilute 1 ml, of the stock Folin uric acid standard (containing 1 mg, per ml.) to 100 ml, with water and mix, thus obtaining a solution containing 0.01 mg. of uric acid per ml. Measure aliquots of this dilute standard into 50-ml, volumetric flasks (preferably in duplicate) to give a series of solutions of known uric acid content covering the range of satisfactory photometric measurement (0.01 to 0.12 mg, for measurement at 2 cm. solution depth or its approximate equivalent, as with the Evelyn photometer; 0.02 to 0.24 mg. if 1-cm. cuvettes or their equivalent are to be used). Include a blank flask containing water alone in the series. Adjust the volume in each flask to 25 ml. by adding water where necessary, then add 2.5 ml. of urea-cyanide solution to each flask. At timed (e.g., one-minute) intervals add 1 ml. of arsenophosphotungstic acid to a flask, dilute immediately to 50 ml. with water, and mix thoroughly. At the end of 30 minutes, set the photometer to zero density with the blank, and determine the density for each standard exactly 30 minutes after diluting and mixing. Plot the determined densities against the amount of uric acid present (in mg.) on cross-section paper, and draw a smooth curve to include the points.

In an analysis, the determined density of an unknown is translated into its equivalent uric acid value by reference to the curve. For accurate results the curve should be checked at intervals, particularly if new reagents are made up, and re-constructed if necessary. In an analysis, environmental and other conditions should reproduce as consistently as possible those prevailing at the time the curve was established. For further discussion concerning the validity and use of calibration curves in photometric analysis, see the section on "Photometry" in Chapter 23.

Interpretation. Results by the uricase method described here indicate that only 80 to 90 per cent of the color obtained by direct treatment of urine with uric acid color reagents may actually be due to uric acid; this discrepancy may be much greater if the diet contains significant amounts of the methyl xanthines (caffeine, theophylline, and theobromine, found in coffee, tea, and cocoa). In such instances, the uricase method appears to be even more specific for uric acid than the "isolation" procedures (see following method). For further aspects of interpretation, see under previous method.

- 3. Colorimetric Methods of Folin: Principle. Phosphotungstic acid is reduced by uric acid with the production of a blue color which is compared with that produced with a standard solution of uric acid. Polyphenols also react, thus giving too high results, and amino acids decrease the color. The direct application of the reaction to urine is not therefore an accurate method but may be useful for many clinical purposes. The indirect method in which the uric acid is first separated by precipitation with silver nitrate is claimed to be an accurate method if conditions are strictly followed.
- a. Indirect Method: Procedure. Half fill a 100-ml. volumetric flask with water. With a Folin-Ostwald pipet introduce 1 ml. of the urine. Add 10 ml. of the chloride-acetate solution⁹⁷ and then without shaking so as to avoid foaming, dilute to the mark with water and mix.

Transfer 5 ml. of the diluted urine to one 15-ml. centrifuge tube and 3 ml. plus 2 ml. of water to another. To each add 3 ml. of the silver nitrate solution and centrifuge at once fairly rapidly for four to five minutes so as to get perfectly clear supernatant solutions. A few tiny flakes may float on the surface but these contain no uric acid. Decant and drain over a sink. It is permissible to let cold tap water rinse the mouths of the tubes during the draining. With a 25-ml. cylinder or a buret, to each tube add 10 ml. of the urea-cyanide solution (poisonous!). Stir immediately and simultaneously with glass rods until the two sediments have completely dissolved. Transfer the silver cyanide solutions to test tubes graduated at 25 ml. and rinse with exactly 5 ml. of water. Mix by whirling at an angle of about 60° until the solutions are visibly uniform. In another graduated test tube place 5 ml. of the standard uric acid solution containing 0.02 mg. of uric acid together with 10 ml. of the urea-cyanide solutions and mix.

With a 10-ml. blood pipet add to each of the three tubes 4 ml. of the uric acid reagent and let stand for 20 minutes. Dilute to volume and mix. For colorimetric measurement, make the comparison between the standard and the unknown which is nearest to it in depth of color. When the standard is set at 20 mm., colorimetric readings between 35 mm. and 10 mm. are acceptable. For photometric measurement, only one unknown is necessary. Determine its density, and that of the standard, in a photometer at 660 my, setting the photometer to zero density with a blank

⁹⁶ Folin: J. Biol. Chem., 101, 111 (1933); 106, 311 (1934).

⁹⁷ Chloride-acetate Solution. A solution containing 1 per cent NaCl, 2 per cent cryst. sodium acetate, and 1 volume per cent of 99 per cent acetic acid.

⁵ Per Cent Solution of Silver Nitrate. This solution, even if perfectly clear when first prepared, may develop a slight color on standing. This color is most quickly produced by heating to 100° C. for 2 hours in a flask covered with a beaker. After cooling, add a few ml. of a solution containing 50 mg. of NaCl, shake thoroughly and filter through a double layer of quantitative filter paper until crystal clear. Thereafter the solution will remain perfectly colorless and need not be kept in brown bottles.

Other solutions are the same as those used in blood methods (see p. 512),

prepared by treating 5 ml. of water with urea-cyanide and color reagent, etc., exactly as described for the preparation of the standard.

b. Direct Method: Procedure. Half fill a 100-ml. volumetric flask with water. With a Folin-Ostwald pipet introduce 1 ml. of urine, dilute to volume and mix. Introduce into test tubes graduated at 25 ml., 5 ml. of the diluted urine and 3 ml. of the diluted urine plus 2 ml. of water. To another graduated test tube add 5 ml. of the standard uric acid solution. Add 10 ml. of the urea-cyanide solution (poisonous!) to each, mix, and add 4 ml. of the uric acid reagent. Let stand for 20 minutes. Dilute to volume and mix. Continue with colorimetric or photometric measurement as described above for the indirect method.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{v} = \frac{\text{Uric acid content of undiluted}}{\text{urine, in grams per liter}}$$

v is the volume of *diluted* urine (5 ml. or 3 ml.) used in an analysis. The same calculations are used for both indirect and direct methods.

For photometric measurement:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.02 \times \frac{100}{v} = \frac{\text{Uric acid content of undiluted}}{\text{urine, in grams per liter}}$$

The significance of v is the same as for colorimetric measurement. The conditions for satisfactory photometric measurement are the same as those given on p. 513 in connection with the determination of uric acid in blood, since the same standards and color reaction are used.

Interpretation. See previous methods.

- 4. Folin-Shaffer Method: Principle. Phosphates and some organic matter are removed by means of uranium acetate. The uric acid is precipitated as ammonium urate which is titrated with potassium permanganate. For details, see the Eleventh Edition of this book.
- 5. Krüger-Schmid Method. Krüger and Schmid have devised a method for the combined determination of uric acid and the other purine derivatives present in urine. This procedure is described under Purine Bases, below, as is also a modification by Hunter and Givens.

PURINE BASES

1. Krüger and Schmid's Method: Principle. This method serves for the determination of both uric acid and the purine bases. The principle involved is the precipitation of both the uric acid and the purine bases in combination with copper oxide and the subsequent decomposition of this precipitate by means of sodium sulfide. The uric acid is then precipitated by means of hydrochloric acid and the purine bases are separated from the filtrate in the form of their copper or silver compounds. The nitrogen content of the precipitates of uric acid and purine bases is then determined by means of the Kjeldahl method (see p. 814) and the corresponding values for uric acid and purine bases calculated. For a study of this method as applied to the determination of purines in protein-free tissue extracts, on a micro-scale, see Hitchings and Fiske. 98

⁵⁶ Hitchings and Fiske: J. Biol. Chem., 146, 491 (1941).

Procedure: To 400 ml. of albumin-free urine in a liter flask, 100 add 24 g. of sodium acetate, 40 ml. of a solution of sodium bisulfite. 101 and heat the mixture to boiling. Add 40 to 80 ml. 102 of a 10 per cent solution of copper sulfate and maintain the temperature of the mixture at the boiling point for at least three minutes. Filter off the flocculent precipitate, wash it with hot water until the wash water is colorless, and return the washed precipitate to the flask by puncturing the tip of the filter paper and washing the precipitate through by means of hot water. Add water until the volume in the flask is approximately 200 ml., heat the mixture to boiling, and decompose the precipitate of copper oxide by the addition of 30 ml. of sodium sulfide solution. 103 After decomposition is complete, the mixture should be acidified with acetic acid and heated to boiling until the separating sulfur collects in a mass. Filter the hot fluid with the aid of a filter pump, wash with hot water, add 10 ml, of 10 per cent hydrochloric acid. and evaporate the filtrate in a porcelain dish until the total volume has been reduced to about 10 ml. Permit this residue to stand about two hours to allow for the separation of the uric acid, leaving the purine bases in solution. Filter off the precipitate of uric acid, using a small filter paper, and wash the uric acid, with water made acid with sulfuric acid, until the total volume of the original filtrate and the wash water aggregates 75 ml. Determine the nitrogen content of the precipitate by means of the Kieldahl method (see p. 814), and calculate the uric acid equivalent. 104

Render the filtrate from the uric acid crystals alkaline with sodium hydroxide, add acetic acid until faintly acid, and heat to 70° C. Now add 1 ml. of a 10 per cent solution of acetic acid and 10 ml. of a suspension of manganese dioxide¹⁰⁵ to oxidize the traces of uric acid which remain in the solution. Agitate the mixture for one minute, add 10 ml. of the sodium bisulfite solution¹⁰⁸ and 5 ml. of a 10 per cent solution of copper sulfate, and heat the mixture to boiling for three minutes. Filter off the precipitate, wash it with hot water, and determine its nitrogen content by means of the Kjeldahl method (see p. 814). Inasmuch as the composition and proportion of the purine bases present in urine is variable, no factor can be applied. The result as regards these bases must therefore be expressed in terms of nitrogen.

Benedict and Saiki report cases in which the total purine nitrogen by this method was less than the uric acid nitrogen as determined by the Folin-Shaffer method. The inaccuracy was found to lie in the Krüger and Schmid method. To obviate this they advise the addition of 20 ml. of glacial acetic acid for each 300 ml. of urine employed, the acid being added before the first precipitation.

Interpretation. The amount of purine bases excreted by a normal man is small and variable. Values from 16 to 60 mg. have been found.

^{**} If albumin is present, the urine should be heated to boiling, acidified with acetic acid, and filtered.

¹⁰⁰ The total volume of urine for the 24 hours should be sufficiently diluted with water to make the total volume of the solution 1600 to 2000 ml.

¹⁰¹ A solution containing 50 g. of sodium bisulfite in 100 ml. of water.

¹⁰² The exact amount depending upon the content of the purine bases.

¹⁰³ This is made by saturating a 1 per cent solution of sodium hydroxide with hydrogen sulfide gas and adding an equal volume of 1 per cent sodium hydroxide. Ordinarily the addition of 30 ml. of this solution is sufficient, but the presence of an excess of sulfide should be *proved* by adding a drop of lead acetate to a drop of the solution. Under these conditions a dark brown color will show the presence of an excess of sodium sulfide.

¹⁰⁴ This may be done by multiplying the nitrogen value by three and adding 3.5 mg. to the product as a correction for the uric acid remaining in solution in the 75 ml.

¹⁰⁵ Made by heating a 0.5 per cent solution of potassium permanganate with a little alcohol until it is decolorised.

¹⁰⁴ To dissolve the excess of manganese dioxide.

The purine base nitrogen is of course only a fraction of this. The amount excreted is influenced by the diet somewhat in the same way as is the excretion of uric acid, being also increased in disorders associated with increased uric acid excretion such as leukemia. The purine bases form a higher percentage of the total purine excretion in the case of the monkey, sheep, and goat than in the case of man.

2. Hunter and Givens' Modification of the Krüger-Schmid Method: 107 Principle. The Krüger-Schmid process is combined with the micro-chemical colorimetric method for uric acid (see p. 849).

Procedure: The first copper-purine precipitate as obtained in the Krüger-Schmid procedure is suspended in about 200 ml. of water, to which there is added about 1 ml. of concentrated hydrochloric acid. The mixture is vigorously boiled, whereupon the whole or greater part of the precipitate goes into solution. Removal of the copper is effected by treatment, while hot, with hydrogen sulfide and excess of the sulfide is completely expelled by renewed boiling. Filtration under suction, and thorough washing of flask and filter result in a filtrate which is perfectly clear and nearly colorless. This is concentrated if necessary, and made up to a convenient volume which must of course be sufficiently large to retain, when cool, the uric acid in solution. Of this an aliquot part is utilized directly for the colorimetric determination of uric acid. In the remainder the residual uric acid is destroyed and bases determined according to the regular Krüger-Schmid procedure. This modification is recommended particularly where the amount of uric acid present is minute.

3. Welker's Modification of the Methods of Arnstein and of Salkowski: Principle. The phosphates are removed by treatment with magnesia mixture. The purine bases and uric acid are then thrown down as their silver salts and the nitrogen content of this precipitate determined. For details, see the Eleventh Edition of this book.

ALLANTOIN

1. Method of Larson: 108 Principle. The urine is treated with phosphotungstic acid to remove interfering substances. Basic lead acetate is then added to remove excess phosphotungstic acid and residual interfering substances. Excess lead is removed by sulfuric acid and excess acid neutralized by sodium hydroxide. The solution is then boiled with Folin ammoniacal reagent and acid molybdate reagent added to the cooled solution. After proper dilution a colorimetric comparison is made against a 1-mg. allantoin standard.

Procedure: Transfer 1.5 g. of phosphotungstic acid¹⁰⁹ to a 50-ml. centrifuge tube and add 5 ml. of water. Rotate gently to insure solution; then add

¹⁰⁷ Hunter and Givens: J. Biol. Chem., 17, 37 (1914).

¹⁰⁸ Larson: J. Biol. Chem., 94, 727 (1932). According to Young and Conway (J. Biol. Chem., 142, 839 (1942)), the Larson procedure, although giving reasonably good recovery of added allantoin, gives results on urine which are somewhat high compared to the procedure they describe, which is claimed to be more specific and satisfactory. For details, see the original article. For a photometric version of the Young-Conway procedure, and method for the determination of allantoin in blood, see Young. MacPherson, Wentworth, and Hawkins: J Biol. Chem., 152, 245 (1944).

¹⁰⁰ Phospho-24-lungstic Acid. Dissolve 100 g. of Na₂WO₄·2H₂O in about 100 ml. of water with the aid of heat. Add 10 ml. of 85 per cent H₂PO₄ and then 80 ml. of concentrated

5 ml. of animal urine. Centrifuge immediately, place the tube in a refrigerator for one-half hour, then centrifuge again until perfectly clear. The addition of a crystal of phosphotungstic acid should not cause further precipitation. Add 5 ml. of basic lead acetate solution which precipitates the excess phosphotungstic acid as well as the remaining interfering substances. Centrifuge the mixture, then treat with 5 ml. of 5 per cent sulfuric acid to remove the excess lead, and centrifuge until perfectly clear. Pipet 2 ml. of the resulting water-clear liquid into a Folin-Wu sugar tube, neutralize with 5 per cent sodium hydroxide, and then add 2 ml. of Folin ammoniacal copper reagent. Place the tubes in a rapidly boiling water bath for 10 minutes, cool, then add 2 ml. of acid molybdate reagent. Dilute the tubes to volume and read in a colorimeter against a 1-mg. allantoin standard. Photometric data on this procedure are not available.

Calculation:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 1 \times \frac{100}{5} = \text{mg. of allantoin per 100 ml.}$

Interpretation. Allantoin has been found in only small amounts in human urine (35 to 45 mg. per day), and appears to be mainly, though not entirely, exogenous in origin. It forms, however, the principal end-product of the purine metabolism of practically all mammals other than man and the anthropoid apes, with the notable exception of the pure-bred Dalmatian coach hound which excretes a considerable fraction of its purine nitrogen as uric acid. Thus over 90 per cent of the purine-allantoin

HCl. Cool. After four hours or more, filter on a Buchner funnel and suck as dry as possible. Redissolve the precipitate in 120 ml. of $\rm H_2O$, pour the solution into a liter separatory funnel, add about 90 ml. of ether, and then add 40 ml. of concentrated HCl. Shake. After standing a few minutes, there should be three layers of liquid. The lowest layer contains nearly all the complex acid. If there are only two layers, more ether must be added and the mixture shaken again. Transfer the lowest layer to another separatory funnel, add about 120 ml. of water, and shake vigorously; then add 50 ml. of ether and finally 50 ml. of concentrated HCl. After standing, the lowest layer, which should be perfectly clear, is transferred to a crystallizing dish. Add 30 ml. of $\rm H_2O$ and 1 drop of liquid bromine and evaporate on a steam bath. The solution should be greenish in color. If the slightest trace of dust or organic matter is present, a pinkish color develops; and one or two drops more of liquid bromine must be added to oxidize this foreign material.

Evaporate on the steam bath until crystals begin to form on the surface. Let stand overnight. The crystals obtained are sucked as dry as possible on a large Buchner funnel. After air-drying for one week, powder the crystals and keep in an amber glass container. This phosphotungstic acid should dissolve instantly to give a perfectly clear, practically colorless solution.

110 Folin Ammoniacal Copper Solution. Dissolve 100 g. of ammonium sulfate in about 400 ml. of water and filter into a volumetric liter flask, 100 ml. of 10 per cent sodium hydroxide are then added, 12 g. of sodium tartrate, and finally a solution of 5 g. of copper sulfate. Dilute to volume and mix. This reagent will not give a blank for months, if kept in the dark in well-filled, tightly stoppered, amber glass bottles. The bottles should be of small volume.

¹¹¹ Folin Acid Molybdate Reagent. Prepare a stock solution of 30 per cent brominated sodium molybdate as follows: Dissolve 300 g. of sodium molybdate in water and make up to 1 liter. The solution is slightly turbid. Add two or three drops of liquid bromine and let stand overnight. Transfer 500 ml. of the clear supernatant liquid to a liter flask and add, with stirring, 225 ml. of 85 per cent phosphoric acid. Then add 150 ml. of cool sulfuric acid (25 volumes per cent). The bromine which is liberated is removed by aeration. Add 75 ml. of 99 per cent acetic acid, mix, and dilute to 1 liter.

111 Allantoin Standard. Dissolve 100 mg. of allantoin in about 50 ml. of water with the aid of heat, but do not allow to boil. Cool, transfer to a 100-ml. volumetric flask, and dilute to volume. Cover with toluene. Such a standard will keep for about two weeks at room temperature without deterioration. Without toluene, a loss of 1 per cent of the allantoin is noted after standing one week. Givens reports a loss of 1.7 per cent after 90 days.

nitrogen excretion of the dog, the cow, and the pig occurs as allantoin. In these animals its origin is from exogenous and endogenous purines, and its excretion is influenced by much the same factors as is that of

D A

Fig. 271. Continuous extraction apparatus (Griffith). (A) 500-ml. Kjeldahl flask; (B) glass tube (420 × 15 mm.) with side opening; (C) glass tube (400 × 6 mm.) with widened top and small openings at bottom; (D) condenser.

uric acid in man. It appears to be entirely a waste product, since if injected into the blood of man or dogs it is excreted almost quantitatively in the urine. 113

HIPPURIC ACID

1. Method of Griffith: 114 Principle. Hippuric acid is extracted from urine with ether in a continuous extraction apparatus. The residue obtained by distilling off the ether is treated with bromine and sodium hypobromite to destroy traces of urea. Hippuric acid nitrogen is then determined in the residue by the Kjeldahl procedure.

In Quick's method¹¹⁵ the hippuric acid is extracted in a similar manner, and the amino nitrogen determined by the formol titration (see p. 837). The older methods involved hydrolysis of the hippuric acid and titration of the liberated benzoic acid. These may give misleading results, however, because benzoic acid may be present also in the form of glucuronic acid monobenzoate (benzoyl glucuronic acid).

Procedure: Place 10 ml. of protein-free urine (containing not more than 150 mg. of hippuric acid) and 0.1 ml. of concentrated HCl in the extraction tube and 100 ml. of ether in the 500-ml. Kjeldahl flask. (The arrangement of the extraction apparatus is shown in Fig. 271.) Immerse the lower portion of the flask in a water bath heated to 60° to 70° C. and continue the extraction for one hour. Distil off the ether. To the dry residue in the flask add 5 ml. of sodium hypobromite¹¹⁶ solution and shake one minute. Add 2 ml. of sulfuric acid (diluted 1:5). Mix thoroughly. Add 2 ml. of 25 per cent NaOH and 2 ml. of the hypobromite solution and shake one minute. Proceed with the determination of nitrogen in the flask by the Kjeldahl method.

Calculation. If y represents the number of ml. of 0.1 N acid neutralized by ammonia in the Kieldahl titration, then

$$y \times 1.4 \times \frac{179}{14}$$
 = mg. of hippuric acid in 10 ml. of urine

Interpretation. The average excretion of hippuric acid by a normal adult man is about 0.7 g. per day. The amount is increased by the inges-

¹¹² Young, Wentworth, and Hawkins: J. Pharmacol., 81, 1 (1944).

¹¹⁴ Griffith: J. Biol. Chem., 69, 197 (1926). Also private communication.

¹¹⁶ Quick: J. Biol. Chem., 67, 477 (1926).

¹¹⁶ Prepared by mixing equal volumes of 25 per cent NaOH and a solution containing 12.5 g. of bromine and 12.5 g. of sodium bromide dissolved in 100 ml. of water.

tion of benzoic acid or fruits such as plums, prunes, cranberries which contain, in addition to benzoic acid, certain other precursors of hippuric acid (quinic acid, etc.). It arises in part apparently from putrefaction products formed in the intestine. In herbivora it is often the most abundant nitrogenous constituent of the urine.

2. Hippuric Acid Test for Liver Function (Quick¹¹⁷): Principle. If benzoic acid is ingested or injected, a major portion of it combines with glycine to form hippuric acid which is then excreted in the urine (for reactions, see p. 119). In man (but not necessarily in other animals) this synthesis appears to take place primarily in the liver. If the liver is damaged, the amount of hippuric acid excreted is diminished relative to that found normally. It is claimed that clinically the decrease in hippuric acid excretion under test conditions is fairly proportional to the extent of hepatic impairment.

Procedure: Just before the test, which is preferably given in the morning about one hour after a light breakfast (cereals or toast, and coffee, tea, or milk), the patient is instructed to empty his bladder as completely as possible, and the urine obtained is discarded. A dose of 6 g. of sodium benzoate dissolved in 30 ml. of water (flavored with oil of peppermint if desired) is then ingested, 118 followed by half a glass of water. More water may be taken during the test if necessary but excessive water intake should be discouraged in order to keep the urine volume down. A complete specimen of urine is collected each hour after the test dose, for four hours.

Measure the volume of each hourly specimen in a graduate. If a specimen volume exceeds 150 ml., it is advisable to acidify slightly with acetic acid and to concentrate the sample on a water bath to about 50 ml. Combine the four specimens in a graduated cylinder, measure the volume, and transfer to a beaker. Add solid ammonium sulfate in the proportion of 5 g. for each 10 ml. of urine, and stir to dissolve. Filter or centrifuge. To the clear filtrate or centrifugate in a beaker add sufficient concentrated hydrochloric acid (usually about 1 ml. is required) to render distinctly acid to Congo red or thymol blue (pH about 2).¹¹⁹ Stir vigorously with a glass rod, scratching the sides of the beaker to promote crystallization, then place in the refrigerator or in ice water for 30 minutes. Filter off the crystalline hippuric acid by suction on a small Buchner funnel, and wash the precipitate with several small portions of ice-cold distilled water, using the wash water to complete the transfer of the crystals from the beaker to the Buchner funnel.

Quantitatively transfer the precipitate and filter paper to a beaker (a little water may be used to aid in the transfer), add sufficient water to cover, and heat to dissolve. Add a few drops of phenolphthalein solution and titrate with 0.5 N sodium hydroxide solution to a permanent pink. Record the buret reading.

Calculation. Each ml. of 0.5 N sodium hydroxide is equivalent to 0.0895 g. of hippuric acid. Therefore:

ml. of 0.5 N alkali used × 0.0895 = grams of hippuric acid titrated

To determine the amount of hippuric acid excreted, a correction for the solubility of the compound must be added. In the presence of ammonium sulfate

¹¹⁷ Quick: Am. J. Clin. Path., 10, 222 (1940). See also Weichselbaum and Probstein: J. Lab. Clin. Med., 24, 636 (1938-1939): Hepler and Gurley: ibid., 27, 1593 (1941-1942). ¹¹⁵ For details of the intravenous test, see Quick (loc. cit.).

^{118 &}quot;Alk-Acid" test paper (obtainable from Fisher Scientific Co., Pittsburgh, Pa.) may also be used.

as described, the solubility has been established as 0.001 g. per ml. of urine. If V is the total volume of urine in milliliters before adding the ammonium sulfate, the solubility correction is $V \times 0.001$ g. Therefore:

Hippuric acid excreted = (ml. of 0.5 N alkali used \times 0.0895) + ($V \times$ 0.001) (in grams)

To convert the amount of hippuric acid into the amount of benzoic acid it represents, multiply by 0.68:

Grams of hippuric acid \times 0.68 = grams of benzoic acid

Interpretation. Under the conditions of this test, the average healthy adult will excrete 3.0 to 3.5 g. (or even more) of benzoic acid in the form of hippuric acid. There is some indication that increased excretion above 3 g. (arbitrarily taken as 100 per cent) is roughly proportional to body weight (or surface area) in normal individuals. ¹²⁰ Any excretion of 90 per cent (i.e., 2.7 g.) or more is considered nonpathological. Marked diminution in output is found in various liver disorders. For further aspects of clinical interpretation, see texts on clinical diagnosis.

LACTIC ACID

1. Method of Friedemann and Graeser: 121 Principle. By treatment with phosphoric acid and potassium permanganate, the lactic acid is converted to acetaldehyde.

$$CH_3 \cdot CHOH \cdot COOH \rightarrow CH_3CHO + CO + H_2O$$

The aldehyde is bound with sodium bisulfite.

The bound sulfite is titrated iodimetrically.

Procedure: A 10- to 25-ml. sample of urine is introduced into a 250-ml. volumetric flask, 10 ml. of 20 per cent CuSO₄·5H₂O and 10 ml. of a suspension of Ca(OH)₂ are added.¹²² The suspension is diluted to the mark and filtered,

120 Hepler and Gurley: loc. cit.

¹²¹ Friedemann and Graeser: J. Biol. Chem., 100, 291 (1933). The authors describe adaptations of this method for blood (see p. 572), milk, culture media, and tissues.

122 Special Reagents: Calcium Hydroxide Suspension. 1 kg. of fresh unslaked lime is slaked with water and immediately afterward sufficient water is added to bring the volume to approximately 5 liters. The suspension is thoroughly shaken, allowed to stand for a few seconds, and decanted from the coarser particles.

Phosphoric Acid-Manganese Sulfate Reagent. 100 g. of MnSO₄4H₂O are dissolved in about 500 ml. of warm water. To this are added 25 ml. of syrupy phosphoric acid (85 per cent, 15 M). The solution is cooled and diluted to a volume of approximately 1 liter.

Oxidizing Agent. To 10 ml. of 0.1 N KMnO₄, diluted to approximately 800 ml., are added 2 ml. of the H₂PO₄-MnSO₄ reagent, stirring while adding. The volume is brought to about 1000 ml. and the solution is again well mixed. The reduction is complete in 5 to 10 minutes.

Sodium Bisulfite. 25 g. are dissolved in 2 liters of water. The solution should be kept in a stoppered bottle.

Starch Indicator. 5 g. of arrowroot starch are suspended in 10 to 20 ml. of cold water and poured into 500 ml. of boiling water; 500 ml. of hot water are added and boiling is continued for 15 minutes. The flask is covered with a beaker, cooled, and kept in the refrigerator. The supernatant clear solution only is used. The solution will keep several weeks if care is taken to avoid bacterial growth.

Strong Iodine Solution. 40 g. of iodine and 75 g. of KI are dissolved in a small quantity

an aliquot representing not more than 5 ml. of urine being used for analysis.

Ten ml. of H₂PO₄-MnSO₄ reagent and a pinch of finely powdered talc are placed in a 300-ml. Kjeldahl flask, followed by the sample of urine. About 85 ml. of water is added and the flask attached to the apparatus (see Fig.

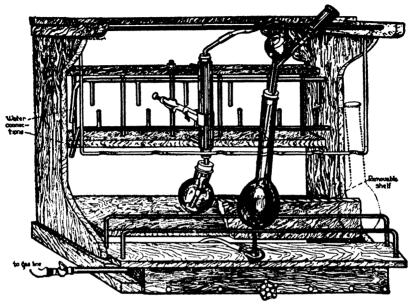

Fig. 272. Apparatus for the determination of lactic acid (Friedemann and Graeser).

272). Ten ml. of NaHSO₃ solution is placed in the 150-ml. extraction flask (receiver). The micro-burner is adjusted to bring the solution to boiling in about three minutes. Addition of oxidizing agent is begun as soon as vapors appear in the condenser. The rate of addition is unimportant, but

of water and the volume is brought up to about 2 liters.

Standard Iodine Solution. The weak iodine solutions (0.01 to 0.002 N) may be prepared either by dilution of a standard iodine solution or by liberation of iodine from 0.1 N iodate + KI. The latter method is preferred because of the permanence of iodate solutions. 0.1 N KH(IO₃)₂ solution contains 3.2496 g. per liter. 0.1 N KIO₄ contains 3.567 g. per liter. Five to 10 g. of c.p. KI, about 200 ml. of cool, distilled water, and 2 to 5 ml. of 5 N H₂SO₄ are placed in a volumetric flask. Standard iodate is added and the volume is brought almost to the mark with cooled water. It is then warmed to 20° and the volume adjusted to the mark. Since iodine is volatile even from dilute solutions, they should be kept cool. Lactic Acid Standard. Lithium lactate is preferred because this salt is anhydrous and not

Lactic Acid Standard. Lithium lactate is preferred because this salt is anhydrous and not hygroscopic. It is prepared as follows:

U.S.P. lactic acid (85 per cent) is diluted with an equal volume of water and a few drops of phenol red indicator are added. Saturated (approximately 20 per cent) lithium hydroxide or LiCO₂ (the former is preferred) solution is added to slight excess, as is indicated by the phenol red. The solution is heated to boiling and the alkali is again added to slight alkalinity. It is now cooled. Four volumes of 95 per cent alcohol are added and after cooling for some time, the mass of crystals is filtered off on a Buchner funnel and washed thoroughly with 95 per cent alcohol. This preparation is recrystallized from water and dried at 100°.

9.60 g. of lithium lactate are transferred to a 1-liter volumetric flask. Enough H₂SO₄ is added to bring the final concentration to 0.2 N when diluted to the mark. This 0.1 M lactic acid standard will keep for at least one year, provided it is kept away from strong light or stored in a refrigerator.

it is essential to have an excess of oxidizing agent throughout the distillation, as indicated by a brownish (not gray) color. It is best to add from 25 to 40 ml. over a 15-minute oxidation period. Shortly before the end of the oxidation the receiving flask is detached from the stopper and lowered. The glass tip is rinsed and the flask containing a total volume of 50 to 75 ml. is cooled prior to titration.

For the removal of excess bisulfite 1 ml. of starch solution is added, followed by a slight excess of the strong iodine solution which is immediately removed by the cautious addition of 0.1 N thiosulfate. The walls of the flask are now washed down by a thin stream of water after which the end-point is adjusted to a faint blue with dilute iodine solution.

The flask is cooled and approximately 15 ml. of saturated NaHCO₁ are added. The solution is titrated with dilute standard iodine solution which is run in rapidly so as to keep pace with the decomposition into aldehyde and bisulfite. When this slows up, 1 ml. of 10 per cent Na₂CO₄ is added until the end-point persists for at least ½ minute.

A blank determination should be run with pure water.

Calculation. Each ml. of 0.1 N iodine solution used in the titration of bound sulfite is equivalent to 0.45 mg. of lactic acid.

Interpretation. Normally the urine contains 5 to 13 mg. of lactic acid per 100 ml. These values are increased after severe exercise and probably in such pathological conditions as are accompanied by deficient oxidative metabolism. For a discussion of lactic acid in the urine, see p. 744.

CONJUGATED GLUCURONIC ACIDS

A satisfactory quantitative method which is applicable to the analysis of all conjugated glucuronic acids is not available. Quick¹²³ has described a method for menthol glucuronic acid in urine which has been extended, with slight modifications, to the determination of other conjugated glucuronic acids. It consists in extraction of the compound with ether, hydrolysis with dilute acid, and finally determination of the liberated glucuronic acid by a copper reduction method. A method for benzoyl glucuronic acid, similar to the above, was reported by Csonka.¹²⁴ Maughan, Evelyn, and Browne¹²⁴ have described a quantitative photometric version of the naphthoresorcinol test (see p. 776) which appears to give good results.

GLUCOSE125

1. Benedict's Method: 126 Principle. Benedict's reagent for the estimation of reducing sugars contains potassium thiocyanate as well as copper sulfate, and in the presence of the former a white precipitate of cuprous thiocyanate is formed in reduction instead of the usual red precipitate of cuprous oxide. The small amount of potassium ferrocyanide also aids in keeping cuprous oxide in solution. As the precipitate formed is white the loss of all blue tint in the solution, indicating complete reduction of the copper, is readily observed. The alkali used is sodium carbon-

¹⁸²⁶ Maughan, Evelyn, and Browne: J. Biol. Chem., 126, 567 (1938). See also Deichmann: J. Lab. Clin. Med., 28, 770 (1943).

¹⁸⁵ The method for sugar adopted by the Committee on Urinary Impairments of the Association of Life Insurance Medical Directors of America may be found on p. 864.

¹⁸⁶ Benedict: J. Am. Med. Assoc., 57, 1193 (1911).

ate, which has the advantage over hydroxides of being less likely to cause destruction of small amounts of sugar. The solution also has the great advantage of being stable for an indefinite length of time. The method is recommended for its simplicity and accuracy.

Procedure: The urine, 10 ml, of which should be diluted with water to 100 ml. (unless the sugar content is believed to be low, when it may be used undiluted), is placed in a 50-ml. buret and the volume adjusted to the zero mark. Twenty-five ml. of the reagent¹²⁷ are measured with a pipet into a porcelain evaporation dish or casserole (100 to 125 mm. in diameter), 20 g. of crystallized sodium carbonate (or one-half the weight of the anhydrous salt) are added, together with a small quantity of powdered pumice stone or talcum, and the mixture heated to boiling over a free flame, stirring with a glass rod to aid in dissolving the bulk of the carbonate. The diluted urine is now run in from the buret, rather rapidly, until a chalk-white precipitate forms in noticeable amount and the blue color of the mixture begins to lessen perceptibly, after which the solution from the buret must be run in a few drops at a time, until the disappearance of the last trace of blue color, which marks the end-point. The final color at the end-point may be yellow or brown, due to urinary pigments, but there should be no trace of blue (or green) color. The solution must be kept vigorously boiling and be stirred continuously throughout the entire titration. If the mixture becomes too concentrated during the process, water may be added from time to time to replace the volume lost by evaporation. Any material which dries out on the sides of the dish during the titration must be pushed back into the solution with the stirring rod before the end-point is reached.

Calculation. The 25 ml. of copper solution are reduced by exactly 50 mg. of glucose. Therefore the volume run out of the buret to effect the reduction contained 50 mg. of the sugar. The formula for calculating the percentage of the sugar is the following: $\frac{0.050}{x} \times D \times 100 = \text{per cent in original sample, wherein } x \text{ is the number of ml. of the diluted urine required to reduce 25 ml. of the copper solution, and D is the dilution of the urine (D equals 1 for undiluted urine, 10 for urine diluted 1:10, etc.).$

In the use of this method chloroform must not be present during the titration. If used as a preservative in the urine it may be removed by boiling a sample for a few minutes, and then diluting to its original volume.

Interpretation. Glucose in the urine in amounts sufficient to be detected by the commonly employed qualitative tests (i.e., 0.1 to 0.2 per cent or more) ordinarily indicates a pathological condition, although it must be remembered that benign glucosuria is not uncommon (see p. 755

127 Copper sulfate (crystallized)	18.0 g.
Sodium carbonate (crystallized, one-half the weight of the anhy-	
drous salt may be used)	200.0 g.
Sodium or potassium citrate	200.0 g.
Potassium thiocyanate	125.0 g.
Potassium ferrocyanide (5 per cent solution)	5.0 ml,
Distilled water to make a total volume of	1000.0 ml.

With the aid of heat dissolve the carbonate, citrate, and thiocyanate in enough water to make about 800 ml. of the mixture and filter if necessary. Dissolve the copper sulfate separately in about 100 ml. of water and pour the solution slowly into the other liquid, with constant stirring. Add the ferrocyanide solution, cool and dilute to exactly 1 liter. Of the various constituents, the copper salt only need be weighed with exactness. Twenty-five ml. of the reagent are reduced by 50 mg, of glucose.

for further discussion), and that other reducing sugars (lactose, pentose) cannot be distinguished from glucose by the ordinary reduction tests, either qualitative or quantitative. Persistent glucosuria may indicate diabetes mellitus, a disorder in which the amount of sugar may rise as high as 10 per cent and averages 3 to 5 per cent. The volume of urine excreted per day is usually also large and the absolute sugar excretion may thus be very great (100 g. of glucose per day are not uncommon). The quantitative methods for the estimation of sugar in urine enable us to determine the severity of this disorder as well as to follow its course under treatment, etc.

2. Sumner's Method: 128 Principle. Urine is heated with a dinitrosalicylic acid reagent which is reduced by the sugar, and the resultant color is compared with standards. This method is applicable to normal as well as glycosuric urine.

Procedure: Pipet into a Folin-Wu blood sugar tube 1 ml. of urine (diluted if necessary) and 3 ml. of the dinitrosalicylic acid reagent. 129 Mix and heat five minutes in boiling water. Cool three minutes in running water, dilute to 25 ml., mix and compare in a colorimeter with a standard glucose solution treated simultaneously in the same way. 0.1 per cent glucose is a satisfactory concentration for the standard solution. If the color obtained with the urine is too dark, repeat the test using more dilute urine.

Calculation:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{Dilution}}{10} = \text{per cent glucose}$$

- 3. Folin-McEllroy-Peck Method: Principle. The method is a titration procedure depending upon the use of an alkaline copper solution in which the cupric hydroxide is held in solution by means of phosphate instead of the customary tartrates, citrates, or glycerol. The method is applicable to the determination of lactose in milk. For details, see the Eleventh Edition of this book.
- 4. Method of Shaffer and Hartmann: 130 Principle. The sugar solution is boiled with Fehling's alkaline copper solution (as modified by Soxblet) under the conditions prescribed in the standard method of Munson and Walker whose tables may therefore be used in the calculation of results. The residual cupric salt may then be converted into cuprous iodide with the liberation of an equivalent amount of iodine. 2Cu⁺⁺ + $4I^- \rightarrow 2CuI + I_2$. Or the cuprous salt may be oxidized in the presence of a known amount of iodine. $2Cu^+ + I_2 \rightarrow 2Cu^{++} + 2I^-$. Iodine liber-

<sup>Sumner: J. Biol. Chem., 383 (1925).
To 10 g. of crystallized phenol add 22 ml. of 10 per cent NaOH. Dissolve in a little</sup> water and dilute to 100 ml. Weigh 6.9 g. of sodium bisulfite and to this add 69 ml. of the alkaline phenol solution. To this add a solution containing 300 ml. of 4.5 per cent NaOH, 255 g. of Rochelle salt (NaKC4H4O4'4H2O), and 880 ml. of 1 per cent dinitrosalicylic acid. Mix and keep tightly stoppered in well-filled bottles. The reagent should keep for at least one year. Dinitrocalicylic acid may be obtained from the Eastman Kodak Co., Rochester, N. Y., or may be prepared from the directions given by Sumner: J. Biol. Chem., 47, 5 (1921).

¹³⁴ Shaffer and Hartmann: J. Biol. Chem., 45, 365 (1921).

ated, or excess iodine found in the second case may be titrated with sodium thiosulfate. In the titration of cuprous copper, oxalate is added to depress the ionization of the cupric salt. Shaffer and Hartmann prefer the cuprous titration.

Procedure: Pipet 25 ml. of each of the two Fehling's solutions¹³¹ into a 300-or 400-ml. flask. Add 50 ml. or less of the (approximately neutral) sugar solution containing from 20 to 200 mg. of sugar, and water (if necessary) to make a total volume of 100 ml. Cover with a small inverted beaker, and heat on an asbestos mat over a flame so adjusted as to bring the solution to boiling in four minutes. Boil two minutes. Stand the flask in the sink under running water till cool (three to four minutes). Then use one of the two following procedures.

Cuprous Titration: Add 50 ml. (accurate pipet) or 25 ml. if but little cuprous oxide is present, of iodate-iodide solution, ¹³² followed by 15 to 17 ml. of 5 N H₂SO₄. The acid should be added from a cylinder or fast-flowing pipet in order that acidification of the whole solution be accomplished promptly. Shake the solution gently for a few moments until the cuprous oxide has dissolved. The solution should become clear but some cuprous iodide may separate. Add 20 ml. of saturated solution of potassium oxalate and rotate the flask until the cuprous iodide is completely dissolved.

Titrate with 0.1 N sodium thiosulfate (see Appendix) adding a few ml. of starch solution toward the end before the disappearance of the green color. Run a blank by boiling the Fehling's solution with 50 ml. of water instead of sugar solution.

or sugar solution.

Calculation: From the blank titration subtract the titration of the sugar determination, the remainder representing I₂ required for the oxidation of the cuprous salt. Multiply by the copper factor of the thiosulfate (1 ml. of 0.1 N = 6.36 mg. of Cu), and find the amount of sugar equivalent to the copper by reference to Munson-Walker tables¹³³ or divide the amount of copper reduced by the corresponding ratio obtained from the glucose curve in Fig. 273.

Cupric Titration: To the cooled alkaline copper solution add 6 g. of KI and 25 ml. of 5 N H₂SO₄. Titrate with standard thiosulfate, adding starch solution toward the end. The titration is subtracted from a similar blank determination on the Fehling's solution, the difference representing copper reduced by the sugar. For the cupric titration the copper solution must be measured accurately. Consult tables or chart (Fig. 273) for sugar values.

5. Hanes' Modification of the Hagedorn-Jensen Method: Principle. The Hagedorn-Jensen method (see Chapter 23, Blood and Tissue Analysis) is modified so that it may be used for larger amounts of glucose (1 to 3 mg.). Maltose may also be determined in the presence of starch. Power and Wilder adapt the method to the determination of 1 to 50 mg. of glucose in urine. For accurate results the urine must be cleared with mercury. For an accuracy within 1 to 5 per cent on diabetic urines the uncleared urine may be used, a correction of 0.25 per cent glucose being subtracted.

¹³¹ Fehling's Solutions (Soxhiet Modification). (I) Dissolve 34.64 g. of CuSO₄·5H₂O in water to make 500 ml. (II) Dissolve 173 g. of Rochelle salt and 50 g. of NaOH in water to make 500 ml.

¹²² Iodate-Iodide Solution. Dissolve 5.4 g. of KIO₃ and 60 g. of KI in water to which a small amount of alkali has been added and dilute to a liter.

¹³⁸ "Methods of Analysis of the Association of Official Agricultural Chemists," Washington, D. C., 1935; Mathews: "Physiological Chemistry," New York, Wm. Wood and Co., 5th ed., p. 959, 1930.

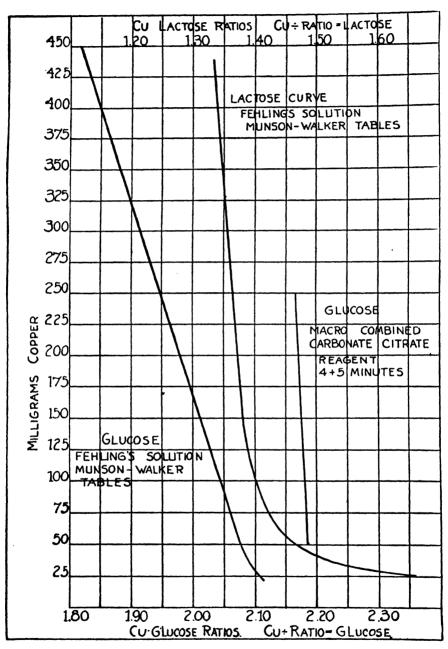

Fig. 273. Copper: glucose ratios for Fehling's solution and for the macrocombined reagent, and copper: lactose ratios for Fehling's solution. Divide the amount of reduced copper by its corresponding ratio as shown by the respective curves.

Procedure: Into a test tube $(1 \times 7 \text{ in.})$ pipet 5 ml. of Solution A (alkaline ferricyanide). ¹³²⁶ Add 5 ml. of unknown solution (if necessary add water to make the 5 ml. volume). In another tube put 5 ml. of water and 5 ml. of Solution A. Incline the tube to mix in any drops of liquid adhering to the sides. Cover with glass bulbs (with about an inch of tubing left attached). Place for 15 minutes in a boiling water bath two to three in. deep. Cool for three minutes in cold running water.

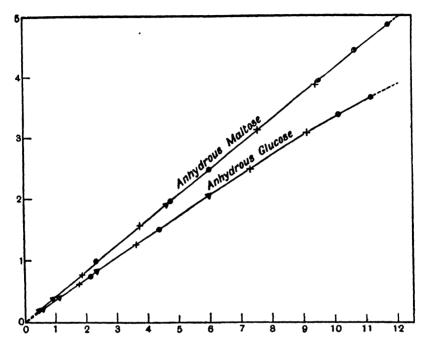

Fig. 274. Chart for sugar values by Hanes' method. Ordinates: Mg. of glucose or maltose. Abscissas: Ml. of 0.01 N ferricyanide reduced.

Add 5 ml. of Solution B and then 3 ml. of Solution C, using rapid pipets which need not be precise. Run in thiosulfate to a pale yellow color, add a few drops of starch, and titrate to disappearance of the blue color. Subtract titration of unknown from titration of the blank. Convert result into ml. of 0.01 N thiosulfate. Consult Fig. 274 for amounts of glucose or maltose. In the presence of starch stir more vigorously and titrate more slowly. The maltose values are also easily calculated by multiplying the number of ml. of 0.01 N thiosulfate used by 0.414 mg. Invert sugar and thus indirectly

1326 Solution A. Dissolve 8.25 g. of potassium ferricyanide and 10.6 g. of anhydrous sodium carbonate in water to make 1000 ml. Store in an opaque bottle and keep two to three days before use. Solution B. Dissolve 12.5 g. of KI, 25.0 g. of zinc sulfate, and 125 g. of NaCl in water to make 500 ml. Traces of iodine appear in the solution on storing. Remove by filtering through two thicknesses of filter paper. Solution C. Dilute 5 ml. of glacial acetic acid to 100 ml. Starch. Stir up 1 g. of Merck soluble starch with 20 ml. of water, add to 60 ml. of boiling water, boil 2 min., cool, and make up to 100 ml. Will keep for several months. Sodium Thiosulfate. An approximately N/75 solution used in a 10-ml. buret graduated in 0.02-ml. divisions. Dissolve 3.33 g. of the salt in 10 liters of boiled-out water. Keep in bottle protected by soda-lime tube and run into buret by siphon. Standardize each day at first, then every three to four days. Pipet 5 ml. of 0.02 N KIO₃ solution (0.715 g. in 1000 ml.) into a tube. Add 5 ml. of 2 per cent KI and 3 ml. of 5 per cent acetic acid. Titrate using starch as indicator.

sucrose may also be determined. The factor for invert sugar using a final volume of 15 instead of the usual 10 ml. is 0.347 and for sucrose 0.329. For a standard invert sugar solution dissolve 0.95 g. of sucrose in 150 ml. of water, add 30 ml. of 0.5 N HCl, heat to boiling, and boil one minute. Cool rapidly, add 30 ml. of 0.5 N NaOH, and dilute to 500 ml. 100 ml. will contain 0.2 g. of invert sugar. Other sugars may also be determined. The factor for fructose is 0.32, for ribose or an equimolecular mixture of glucose and galactose 0.38, arabinose 0.35, mannose and rhamnose 0.34, xylose 0.33, lactose and galactose 0.43.

6. Benedict's Picrate Method (Adopted by the Committee on Urinary Impairments of the Association of Life Insurance Medical Directors of America): Principle. The color produced by the reduction of picric acid (p. 59) is compared with permanent inorganic standards representing definite concentrations of sugar.

Procedure: Measure 1 ml. of urine into a test tube graduated at 25 ml. Add 3 ml. of picric acid solution (2 g. of pure dry picric acid per liter) and 0.5 ml. of 5 per cent NaOH. Add next five drops of 50 per cent acetone solution (prepared fresh each day by diluting acetone with an equal volume of water) and place the tube promptly in a boiling water bath. In 12 minutes remove the tube, cool, and dilute the contents to 25 ml. Compare this colored solution with the permanent standards in tubes of the same dimensions, and estimate the amount of sugar. The permanent sugar standards are made as described below.

PERMANENT SUGAR STANDARDS¹³⁴

Put each standard in test tubes of the same diameter as used in sugar determination.

Sugar	Ferric Chloride Solution	Cobalt Chloride Solution	Dilute Hydrochloric Acid	Water	
0.1%	18 ml.	7 ml.	8 ml.		
0.2%	28 ml.	13 ml.	8 ml.		
0.3%	22 ml.	22 ml.	8 ml.	To mak 100 ml.	
0.4%	16 ml.	30 ml.	8 ml.		
0.5%	14 ml.	40 ml.	8 ml.		

¹³⁴ Solutions needed.

Ferric Chloride (Merck's Analyzed).

Dissolve 200 g. of ferric chloride (FeCl₂·6H₂O) in about 300 ml. of distilled water, transfer to a 500-ml. volumetric flask, make up to volume with distilled water, and mix well. Filter through a dry filter paper.

Cobalt Chloride (analyzed grade).

Dissolve 150 g. of cobalt chloride (CoCl₂·H₂O) in about 300 ml. of distilled water, transfer to a 500-ml. volumetric flask, make up to volume with distilled water and mix well. Filter through a dry filter paper.

Dilute Hydrochloric Acid.

Dilute 5 ml. of concentrated hydrochloric acid to 50 ml. with distilled water.

7. Hawkins and Van Slyke Method: 135 Principle. The time required for the urine to decolorize potassium ferricyanide solution is an index of the amount of reducing sugar present. Since normal constituents in concentrated urine may give reduction equivalent to as high as 0.4 per cent glucose, the method is regulated to determine reducing substances in concentrated urines in concentrations of 0.5 per cent and above, and in dilute urine in concentrations of 0.25 per cent and above.

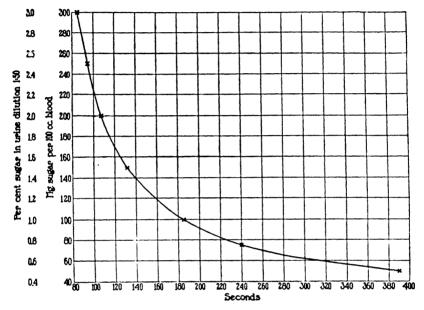

Fig. 275. Chart of urine sugar values for Hawkins-Van Slyke method. (J. Biol. Chem., 81, 459 (1929).)

Procedure: Dilute 1 ml. of urine to 50 ml. If urine is known to be high in sugar (over 3 per cent) dilute 1:100; if low in sugar, dilute 1:25. Albumin need not be removed. Pipet 2 ml. of diluted urine into a pyrex test tube (14 × 125 mm. outside diameter). Add 2 ml. of ferricyanide solution. 136 Mix. Immerse in a beaker of boiling water. A similar test tube containing water is immersed for comparison. Make a white background by pasting paper on the side of the beaker away from the observer. A casserole may be used instead of a beaker. Determine the time in seconds required for the last trace of yellow to disappear, preferablyusing a stop watch. From the chart, Fig. 275, obtain the percentage of sugar in the urine. The chart is for a dilution of

¹³⁶ Hawkins and Van Slyke: J. Biol. Chem., 81, 459 (1929). For a similar procedure using smaller volumes of solution (and therefore with a slightly different calibration curve), which is also directly applicable to tungstic acid filtrates of blood, see Hawkins: J. Biol. Chem., 84, 69 (1929). A photometric adaptation of this procedure is described by Hoffman: J. Biol. Chem., 120, 51 (1937).

¹³⁶ Potassium Ferricyanide Reagent. Dissolve 75 g. of anhydrous potassium carbonate and 75 g. of potassium bicarbonate in about 750 ml. of water. Dissolve 1 g. of potassium ferricyanide in about 100 ml. of water. Add the ferricyanide solution quantitatively (rinsing with water) to the carbonate-bicarbonate solution in a 1-liter volumetric flask. Dilute to the mark with water and mix. Filter and store in a brown glass-stoppered bottle in the dark. This reagent appears to keep indefinitely. Of the various ingredients, only the ferricyanide need be weighed accurately.

1:50. If a 1:25 dilution is used, divide the result obtained from the chart by 2; for a 1:100 dilution, multiply the result by 2.

8. Fermentation Method: Principle. This method consists in the measurement of the volume of carbon dioxide evolved when the dextrose of the urine undergoes fermentation with yeast. None of the various methods whose manipulation is based upon this principle is absolutely accurate. The method in which Einhorn's saccharometer (Fig. 17, p. 60) is employed is perhaps as satisfactory as any for clinical purposes.

Procedure: Place about 15 ml. of urine in a mortar, add about 1 g. of yeast (1/16 of the ordinary cake of compressed yeast) and carefully crush the latter by means of a pestle. Transfer the mixture to the saccharometer, being careful to note that the graduated tube is completely filled and that no air bubbles gather at the top. Allow the apparatus to stand in a warm place (30° C.) for 12 hours, and observe the percentage of dextrose as indicated by the graduated scale of the instrument. Both the percentage of dextrose and the number of cubic centimeters of carbon dioxide are indicated by the graduations on the side of the saccharometer tube. Controls should be run using normal urine and such urine to which sugar has been added.

9. Polariscopic Examination. Before subjecting urine to a polariscopic examination, the slightly acid fluid should be decolorized as thoroughly as possible by the addition of a little basic lead acetate. The urine should be well stirred and then filtered through a filter paper which has not been previously moistened. In this way a perfectly clear and almost colorless liquid is obtained.

In determining dextrose by means of the polariscope it should be borne in mind that this carbohydrate is often accompanied by other optically active substances, such as proteins, fructose, β -hydroxybutyric acid, and conjugate glucuronates which may introduce an error into the polariscopic reading; the method is, however, sufficiently accurate for practical purposes.

For directions as to the manipulation of the polariscope, see p. 60.

Below are given the specific rotations of some physiologically important sugars as well as of certain other optically active substances the possible presence of which must be borne in mind in determining glucose polarimetrically in urine.

	Specific Rotation		Specific Rotation
Glucose	+52.49	Fructose	-92.25
Maltose	+136.5	β-Hydroxybutyric acid	-24.12
Isomaltose	+68.0		
Lactose	+52.53	Conjugated glucuronic acids	Levorotatory in varying degrees

DETERMINATION OF SUGAR IN NORMAL URINE

Principle. Since the nature of normal urine "sugar" (i.e., reducing substances) is not definitely established, it is not possible to state which of the methods of determination is to be preferred. The methods involve removal of interfering substances and colorimetric determination of reducing power.

Procedure:

- a. Removal of Interfering Substances: Method of Folin and Svedberg:137 To 5 ml. of urine in a 50-ml. Erlenmeyer flask add 5 ml. of 0.05 N oxalic acid, 10 ml. of water, and (last) 1.5 g. of Lloyd's alkaloidal reagent. 138 Shake gently for four minutes. Filter through a quantitative paper into another small flask containing 2 g. of Permutit. Shake three minutes. Decant.
- b. Determination of Sugar: Sugar may be determined in filtrates from treatment with Lloyd's reagent by one of the methods used for blood sugar 139 (see Chapter 23). The method of Sumner (see p. 860) is said to be applicable to urine without previous treatment. The urine may also be fermented and fermentable sugar determined by measurement of CO₂ given off or by difference. To 10 ml. of the filtrate from treatment with Lloyd's reagent add 3 ml. of a suspension of 1 cake of compressed yeast in 20 ml. of water. Keep at 37° for 40 minutes. Filter and determine sugar. Fermentable sugar is usually about 0.01 per cent (see Chapter 28). The urine may also be hydrolyzed and total sugar determined. To 8 ml. of urine filtrate add 1 ml. of 2.6 N H₂SO₄ and heat in a boiling water bath for 75 minutes. Add 1 ml. of silica-free NaOH exactly equivalent to the acid added. Determine sugar by any of above methods.

PROTEIN140

1. Colorimetric Determination of Proteins: Method of Hiller. McIntosh, and Van Slyke:141 Principle. The protein is precipitated with trichloroacetic acid, 142 dissolved in NaOH solution, and copper ions added to give a biuret color which is compared with a standard.

Procedure: Measure 2 ml. of the urine (previously adjusted to a pH of about 7.4) into a centrifuge tube, add an equal volume of 10 per cent trichloroacetic acid solution, mix and centrifuge for five minutes. If the volume of the precipitate is less than 0.2 or more than 0.6 ml., repeat using more or less urine. Pour off the supernatant fluid. Dissolve the precipitate in about 3 ml. of 3 per cent NaOH and wash into a tube graduated at 10 ml, with portions of the 3 per cent NaOH until the volume is about 9 ml. Add 0.25 ml. of 20 per cent copper sulfate solution and dilute to 10 ml. with the NaOH. Mix by shaking. Let stand 10 minutes. Centrifuge and compare with a standard. For a standard measure 5 ml. of a biuret solution containing 13.33 mg. of biuret, equivalent to 12.3 mg. of protein, into a tube graduated at 10 ml. Add distilled water to 8 ml., 1 ml. of 30 per cent NaOH, 0.25 ml. of copper sulfate, and water to make 10 ml. Mix, let stand for 10 minutes, centrifuge, and compare in a colorimeter with the unknown, setting this standard at 15 mm.

For determining albumin add to 10 ml. of the urine, at pH 7.4, 10 ml. of 44 per cent sodium sulfate solution, mix well, and put in an incubator at 37° C. for three hours. Filter. Proceed as for total protein, using four times the volume. The globulin is estimated by difference.

141 Hiller, McIntosh, and Van Slyke: J. Clin. Invest., 4, 235 (1927).

¹¹⁷ Folin and Svedberg: J. Biol. Chem., 70, 405 (1926). Hamilton (J. Biol. Chem., 78, 63 (1928)) omits Permutit but uses Lloyd's reagent extracted with concentrated HCl for 1 day, washed with water, and then extracted with concentrated HNO2 for one day.

¹³⁸ Obtainable from Eli Lilly and Co., Indianapolis, Ind.
139 See Folin: J. Biol. Chem., 76, 405 (1926); Benedict: J. Biol. Chem., 68, 766 (1926).
140 The method for albumin adopted by the Committee on Urinary Impairments of the

Association of Life Insurance Medical Directors of America may be found on p. 869.

¹⁴³ According to Beckman, Hiller, Shedlovsky, and Archibald (J. Biol. Chem., 143, 247 (1943)), from 4 to 20 per cent of the protein in proteinuria may not be precipitable by trichloroacetic acid. This may account for discrepancies in protein determination between methods involving trichloroacetic acid precipitation and those not involving such precipitation.

Calculation. For total protein:

$$\frac{15}{R} \times \frac{12.3}{\text{ml. of urine used}} = g.$$
 of protein per liter

For albumin:

$$\frac{15}{R} \times \frac{12.3 \times 2}{\text{ml. of filtrate used}} = g.$$
 of albumin per liter

2. Folin's Gravimetric Method for the Determination of Protein in Urine: Principle. The protein precipitated by heat and acetic acid is centrifuged, washed, dried, and weighed.

Procedure: Pipet 10 ml. of urine into an ordinary conical centrifuge tube, which has been previously weighed; add 1 ml. of 5 per cent acetic acid, and let stand for 15 minutes in a beaker of boiling water. At the end of this time remove the tube from the water bath, and centrifuge for a few minutes. Pour off the supernatant liquid, stir up the precipitate in the tube with about 10 ml. of boiling 0.5 per cent acetic acid, and again centrifuge. Remove the supernatant liquid from the precipitate in the tube, and wash once more, this time with 50 per cent alcohol. After centrifuging, pour off the supernatant alcohol and place the tube for two hours in an air bath at 100 to 110°, then cool in a desiccator, and weigh.

The precipitate may also be filtered off and washed on a small tared filter paper, then dried and weighed. In this case it is better to use a larger volume of urine. Instead of weighing,

the nitrogen in the precipitate may be determined by the Kjeldahl method. 143

Interpretation. The amount of albumin occurring in the urine is not necessarily an index of the severity or type of the disorder giving rise to it. Hence no significant figures can be given. Normal human urine probably contains a trace of albumin which is too slight to be detected or determined by the usual procedures. The determination of albumin may be of assistance in following the course of kidney disturbances, but the results can be interpreted only in the light of other clinical findings. (See discussion under Albumin, p. 760.)

Fig. 276. Esbach's albuminometer.

3. Esbach's Method: Principle. This method depends upon the precipitation of protein by Esbach's reagent¹⁴⁴ and the apparatus used in the estimation is Esbach's albuminometer (Fig. 276).

Procedure: In making a determination fill the albuminometer to the point U with urine, then introduce the reagent until the point R is reached. Now stopper the tube, invert it slowly several times in order to insure the thorough mixing of the fluids, and stand the tube aside for 24 hours. Creatinine, resin, acids, etc., are precipitated in this method, and for this

¹⁴⁸ In order to arrive at correct figures for the protein content, it is then only necessary to multiply the total nitrogen content by 6.25 (see p. 213). Correction should be made for the nitrogen content of the filter paper used unless this factor is negligible.

144 See Appendix.

and other reasons it is not so accurate as the coagulation method. It is, however, extensively used clinically. According to Sahli, the method is "accurate approximately to one part per 1000," whereas Pfeiffer claims it is not accurate for less than one-half or for more than five parts per 1000. According to Quick a 10 per cent solution of trichloroacetic acid is a better precipitant than Esbach's reagent.

Calculation. The graduations indicate grams of protein per liter of urine. To express the amount of protein in per cent, simply move the decimal point one place to the left. Thus a reading of 3 indicates 3 g. per liter, or 0.3 per cent protein.

Interpretation. See above.

4. The Determination of Albumin (Method Adopted by the Committee on Urinary Impairments of the Association of Life Insurance Medical Directors of America): Principle. (larified urine is treated with sulfosalicylic acid and the degree of turbidity produced is measured by comparison with artificial standards. Procedure: Pipet 2.5 ml. of centrifuged urine into a test tube graduated at 10 ml. and add 3 per cent sulfosalicylic acid (30 g. in 1000 ml. of distilled water) to the 10-ml. mark. Invert the tube to mix, allow to stand 10 minutes, and compare the turbidity with the permanent turbidity standards. Record the value of the standard most closely matched, as the albumin content of the urine.

Preparation of Permanent Albumin Standards:145 Dissolve 20 g. of gelatin (Super X brand in sheet form, Coignet Chemical Products Co., New York) in 120 to 140 ml. of distilled water at 45° to 55° C. and make up to 200 ml. Add about half the white of an egg and stir in. Heat in a water bath for at least 30 minutes after a temperature of 90° C. has been attained. Filter hot through a Whatman's No. 4 paper yielding a perfectly clear, slightly vellow solution. Immediately before using, add 0.3 ml. of formalin (40 per cent formaldehyde solution) to each 100 ml. of gelatin solution. Formazin, the material to be suspended in the gelatin, is made as follows: Dissolve 2.5 g. of urotropin in 25 ml. of distilled water at room temperature. Add to 25 ml. of 1 per cent hydrazine sulfate solution also at room temperature. Mix, stopper, and allow to stand at least 15 hours. Suspend the white amorphous precipitate uniformly by gently inverting the flask a few times. Add 14.5 ml, of the formazin suspension to 100 ml, of 10 per cent gelatin solution at 45° to 55° C. (to which the correct amount of formalin has been added) and mix thoroughly. This produces a turbidity equivalent to that made by an albumin solution of 0.1 per cent, or one containing 100 mg. of albumin in 100 ml. when precipitated by 3 volumes of 3 per cent sulfosalicylic acid. Dilute this stock suspension as follows to make the remaining standards:

Stock Formazin Suspension Equivalen\$\fo\$ to 100 mg. of Albumin per 100 ml.	10% Clarified Gelatin	Value of Standard Made
ml.	ml.	
25.0	26	0.05 % or 50 mg.
20.0	30	0.04 % or 40 mg.
15.0	35	0.03 % or 30 mg.
10.0	40	0.02 % or 20 mg.
5.0	45	0.01 ° or 10 mg.
2.5	55	0.005% or 5 mg.
		1

¹⁴ These permanent standards were developed in the laboratories of the Metropolitan Life Insurance Company and the Mutual Benefit Life Insurance Company. For a detailed description of the preparation of these standards, see Kingsbury, Clark, Williams, and Post: J. Lab. Clin. Med., 11, 981 (1926).

Pour each standard into a test tube of the same dimensions as those used in making the test with urine. Seal the tube with a waxed stopper and allow to cool to room temperature. In a short time the gelatin should solidify and after a few days cannot be melted at any room temperature. In extremely hot weather put the tubes in a cool place for a few days before any attempt is made to use them. Keep the standards in a well-lighted room. If in time they become greenish, they may be bleached by exposure to sunlight without changing their turbidimetric value. The standards may be checked against sheep serum standards of known protein content precipitated in the same manner as in the urine test. Standards older than 8 months should be replaced unless actual tests show that they have their original degree of turbidity. In the course of a year there may be only a very slight diminution in the turbidimetric value of the standards. There is no detectable change in 6 to 8 months.

ACETONE BODIES

1. Van Slyke's Methods:¹⁴⁶ Principle. The method is based on a combination of Shaffer's oxidation of β -hydroxybutyric acid to acctone (p. 873), and Denigè's precipitation of acctone as a basic mercuric sulfate compound. Glucose and certain other interfering substances are removed by precipitation with copper sulfate and calcium hydroxide. Preservatives other than toluene or copper sulfate should not be used.

Procedure: Removal of Glucose and Other Interfering Substances from Urine: Place 25 ml. of urine in a 250-ml. measuring flask. Add 100 ml. of water, 50 ml. of copper sulfate solution, 147 and mix. Then add 50 ml. of 10 per cent calcium hydroxide suspension, shake, and test with litmus. If not alkaline, add more calcium hydroxide. Dilute to the mark and let stand at least one-half hour for glucose to precipitate. Filter through a dry folded filter. This procedure will remove up to 8 per cent of glucose. Urine containing more should be diluted enough to bring the glucose down to 8 per cent. The copper treatment is depended upon to remove interfering substances other than glucose, and should therefore never be omitted, even when glucose is absent. The filtrate may be tested for glucose by boiling a little in a test tube. A precipitate of yellow cuprous oxide will be obtained if the removal has not been complete. A slight precipitate of white calcium salts always forms, but does not interfere with the detection of the yellow cuprous oxide.

Determination of Total Acetone Bodies (Acetone, Acetoacetic Acid, and 3-Hydroxybutyric Acid): Place in a 500-ml. Erlenmeyer flask 25 ml. of urine filtrate. Add 100 ml. of water, 10 ml. of 50 per cent sulfuric acid, and 35 ml. of the 10 per cent mercuric sulfate. Or, in place of adding the water and reagents separately, add 145 ml. of the "combined reagents." Connect the flask with a reflux condenser having a straight condensing tube of 8 or 10 mm. diameter, and heat to boiling. After boiling has begun, add 5 ml.

¹⁴⁶ Van Slyke: J. Biol. Chem., 32, 455 (1917); 83, 415 (1929).

¹⁴⁷ Solutions Required. 20 Per Cent Copper Sulfate. 200 g. of CuSO₄·5H₂O dissolved in water and made up to 1 liter.

¹⁰ Per Cent Mercuric Sulfate. 73 g. of pure red mercuric oxide dissolved in 1 liter of H_2SO_4 of 4 N concentration.

⁵⁰ Volume Per Cent Sulfuric Acid. 500 ml. of sulfuric acid of specific gravity 1.835, diluted to 1 liter with water. Concentration of H₂SO₄ must be readjusted if necessary to make it 17.0 N by titration.

¹⁰ Per Cent Calcium Hydroxide Suspension. Mix 100 g. of Merck's fine light "reagent" Ca(OH); with 1 liter of water.

⁶ Per Cent Potassium Bichromate, 50 g. of K2Cr2O7 dissolved in water and made up to 1 liter.

Combined Reagents for Total Acetone Body Determination. 1 liter of the above 50 per cent sulfuric said, 3.5 liters of the mercuric sulfate, 10 liters of water.

of the 5 per cent bichromate through the condenser tube. Continue boiling gently 1½ hours. The yellow precipitate which forms consists of the mercury sulfate-chromate compound of acetone (total). It is collected in a Gooch or "medium density" alundum or fritted glass crucible, washed with 200 ml. of cold water, and dried for an hour at 110°. The crucible is allowed to cool in room air (a desiccator is unnecessary and undesirable) and weighed. Several precipitates may be collected, one above the other, without cleaning the crucible. As an alternative to weighing, the precipitate may be dissolved and titrated as described below.

Determination of Acetone and Acetoacetic Acid: The acetone plus the aceto-acetic acid, which completely decomposes into acetone and CO₂ on heating, is determined without the \(\mathcal{G}\)-hydroxybutyric acid exactly as the total acetone bodies, except that (1) no bichromate is added to oxidize the \(\mathcal{G}\)-hydroxybutyric acid and (2) the boiling must continue for not less than 30 nor more than 45 minutes. Boiling for more than 45 minutes splits off a little acetone from \(\mathcal{G}\)-hydroxybutyric acid even in the absence of chromic acid. 149

Determination of §-Hydroxybutyric Acid: The §-hydroxybutyric acid alone is determined exactly as total acetone bodies except that the preformed acetone and that from the acetoacetic acid are first boiled off. To do this the 25 ml. of urine filtrate plus 100 ml. of water are treated with 2 ml. of the 50 per cent sulfuric acid and boiled in the open flask for 10 minutes. The volume of solution left in the flask is measured in a cylinder. The solution is returned to the flask, and the cylinder washed with enough water to replace that boiled off and restore the volume of the solution to 127 ml. Then 8 ml. of the 50 per cent sulfuric acid and 35 ml. of mercuric sulfate are added. The flask is connected under the condenser and the determination is continued as described for total acetone bodies.

Titration of the Precipitate in the Above Methods: Instead of weighing the precipitate, one may wash the contents of the Gooch, including the asbestos, into a small beaker with as little water as possible, and add 15 ml. of normal HCl. The mixture is then heated, and the precipitate quickly dissolves. In case an alundum or glass crucible is used, it is set into the beaker of acid until the precipitate dissolves, and then washed with suction, the washings being added to the beaker. In place of using either a Gooch or alundum crucible one may, when titration is employed, wash the precipitate without suction on a small quantitative filter paper, which is transferred with the precipitate to the beaker and broken up with a rod in 15 ml. of normal HCl.

In order to obtain a good end-point in the subsequent titration it is necessary to reduce the acidity of the solution. For this purpose it has been found that the addition of excess sodium acetate is the most satisfactory means. Six to 7 ml. of 3 M acetate are added to the cooled solution of redissolved precipitate. Then the 0.2 M KI is run in rapidly from a buret with constant stirring. If more than a small amount of mercury is present, a red precipitate of HgI₂ at once forms, and redissolves as youn as 2 or 3 ml.

¹⁴⁸ This contains about 77 per cent mercury and in the absence of chromate has approximately one of the following formulas: 3HgSO₄·5HgO·2(CH₂)₂CO or 2HgSO₄·3HgO·(CH₂)₂-CO.

149 Blank Determination of Precipitate from Substances in Urine Other than the Acetone Bodies. The 25 ml. aliquot of urine filtrate is treated with sulfuric acid and water and boiled 10 minutes to drive off acetone. The residue is made up to 175 ml. with the same amounts of mercuric sulfate and sulfuric acid used in the above determinations, but without chromate, and is boiled under the reflux for 45 minutes. Longer boiling splits of some acetone from β -hydroxybutyric acid, and must therefore be avoided. The weight of precipitate obtained may be subtracted from that obtained in the above determination.

The blank is so small that it appears to be relatively significant only when compared with the small amounts of acetone bodies found in normal or nearly normal urines. In

routine analyses of diabetic urines it is not determined.

Tests of Reagents. When the complete total acetone bodies determination, including the preliminary copper sulfate treatment, is performed on a sample of distilled water instead of urine, no precipitate whatever should be obtained. This test must not be omitted.

of KI in excess of the amount required to form the soluble K_2HgI_4 have been added. If only a few mg. of mercury are present, the excess of KI may be added before the HgI_2 has had time to precipitate so that the titrated solution remains clear. In this case not less than 5 ml. of the 0.2 M KI are added, as it has been found that the final titration is not satisfactory if less is present. The excess of KI is titrated back by adding 0.05 M $HgCI_2$ from another buret until a permanent red precipitate forms. Since the reaction involved is $HgCI_2 + 4KI = K_2HgI_4 + 2KCl$, 1 ml. of 0.05 M $HgCI_2$ is equivalent in the titration to 1 ml. of the 0.2 M KI.

In preparing the two standard solutions the 0.05 M HgCl, is standardized by the sulfide method, and the lodine is standardized by titration against it. A slight error appears to be introduced if the iodide solution is gravimetrically standardized and used for checking the mercury solution,

instead of vice versa.

In standardizing the mercuric chloride the following procedure has been found convenient: 25 ml. of 0.05 M HgCl₂ are measured with a calibrated pipet, diluted to about 100 ml., and H₂S is run in until the black precipitate flocculates and leaves a clear solution. The HgS, collected in a Gooch crucible and dried at 110°, should weigh 0.2908 g. if the solution is accurate.

Both by gravimetric analyses of the basic mercuric sulfate-acetone precipitate and by titration, the mercury content of the precipitate has been found to average 76.9 per cent. On this basis, each ml. of 0.2 M KI solution, being equivalent to 10.0 mg. of Hg, is equivalent to 13.0 mg. of the mercury acetone precipitate.

Titration is not quite so accurate as weighing, but, except when the amounts determined are very small, the titration is satisfactory.

Calculation. 1 mg. of β-hydroxybutyric acid yields 8.45 mg. of precipitate. 1 mg. of acetone yields 20.0 mg. of precipitate. 1 ml. of 0.2 M KI solution is equivalent to 13 mg. of precipitate in titration of the latter.

In order to calculate the acetone bodies as β -hydroxybutyric acid rather than acetone, use the above factors multiplied by the ratio of the molecular weights $\frac{\beta\text{-acid}}{\text{acetone}} = \frac{104}{58} = 1.793$. In order to calculate the acetone bodies in terms of molecular concentration, divide the factors in the table by 58. To calculate ml. of 0.1 M acetone bodies per liter of urine, use the above factors multiplied by $\frac{10,000}{58} = 172.4$.

Special Factors for Calculation of Results When 25 ML of Urine Filtrate, Equivalent to 2.5 ML of Urine, Are Used for the Determination

Determination Performed	Acetone Bodies, Calculated as g. of Acetone per Liter of Urine, Indicated by:			
	1 g. of precipitate	1 ml. of 0.2 M KI sol.		
Total acetone bodies*	24.8 26.4 20.0	0.322 0.344 0.260		

^{*} The "total acetone bodies" factor is calculated on the assumption that the molecular proportion of them in the form β -hydroxybutyric acid is 75 per cent of the total, which proportion is usually approximated in acetonuria. Because β -hydroxybutyric acid yields only 0.75 molecule of acetone, the factors are strictly accurate only when this proportion is present, but the error introduced by the use of the approximate factors is for ordinary purposes not serious. The actual errors in percentage of the amounts determined are as follows: molecular proportion of acetone bodies as β -acid 0.50, error 6.5 per cent; β -acid 0.90, error 3.8 per cent; β -acid 0.80, error 1.3 per cent.

Interpretation. Normal adults on a mixed diet excrete on the average 3 to 15 mg. of combined acetone and acetoacetic acid per day, and anything over 20 mg. is usually pathological. Usually about one-fourth of this total is acetone, although the proportion varies considerably. The amount is considerably increased in fasting and on a carbohydrate-free diet due to the development of ketosis. In severe diabetic ketosis values up to 6 g. per day or even higher may be noted. It is sometimes found in large amounts in intoxications associated with pregnancy. It may be found in increased amour ts in the urine in a great variety of pathological conditions. Quantitative estimation enables us to follow the course of the ketosis. Ammonia excretion is also largely increased in these conditions, being used in the neutralization of the excess acids formed in the body. (See also Chapter 29.)

 β -Hydroxybutyric acid may occur in normal human urine to the extent of 20 to 30 mg. per day. In fasting or on a carbohydrate-free diet very large amounts may be excreted (up to 20 g. per day). In severe diabetes mellitus the largest amounts are found, and excretions of 50 or even 100 g. or over per day have been noted. In this condition it is usually the most abundant of the acetone bodies making up from 60 to 80 per cent of the total. The ratio is, however, by no means constant, and it should be borne in mind that in rare cases large amounts of β -hydroxybutyric acid may be eliminated although the acetone excretion is very low. It is always present in the urine when large amounts of acetone are present.

A discussion of disturbance of acid-base equilibrium due to abnormal fat metabolism may be found on pp. 622 and 623.

2. Method of Shaffer and Marriott:¹⁵⁰ Principle. By this procedure the combined acetone and acetoacetic acid is determined in the same sample of urine used in the determination of β -hydroxybutyric acid. The preformed acetone and the acetoacetic acid are distilled off together as acetone and determined by the iodine titration method. The β -hydroxybutyric acid remains in the residue from distillation and is oxidized by means of potassium bichromate. The product of the oxidation is acetone which is distilled off and determined as such.

Procedure: Determination of Acetone and Acetoacetic Acid: Measure from 25 to 100 ml. 161 or more of urine (usually 50 ml.) with a pipet into a 500-ml. volumetric flask containing 200 to 300 ml. of water. Add basic lead acetate solution (U.S.P.) in volume equal to that of the urine used 152 and mix well. Add concentrated ammonium hydroxide in amount equal to about one-half that of the lead acetate solution. Dilute the contents of the flask to the mark with water, shake, and let stand for a few minutes. Then filter the liquid, preferably through a folded filter. Measure 200 ml. of the filtrate

¹⁵⁰ Shaffer and Marriott: J. Biol. Chem., 16, 265 (1915).

¹⁵¹ The amount used depends upon the expected yield of β -hydroxybutyric acid. In urines which give a strong ferric chloride reaction for acetoacetic acid, or when 5 to 10 g. or more of β -hydroxybutyric acid are expected, it is unnecessary to use more than 25 to 50 ml. of urine. However, in case only a trace of β -hydroxybutyric acid is expected, the volume should be much larger as indicated. Under all conditions, the amount specified is sufficient for duplicate determinations. It is desirable to use such a volume of urine as contains the proper amount of β -hydroxybutyric acid to yield 25 to 50 mg. of acetone.

¹⁵² If the urine contains but little or no sugar, only half the amount or less of lead acetate should be used.

into a round-bottom flask (800-ml. or liter Kjeldahl flasks are convenient), dilute with water to about 600 ml., and add 15 ml. of concentrated sulfuric acid and a little talc or a boiling stone. Distil until about 200 ml. of distillate have been collected. The tube of the condenser should dip beneath the surface of the water in the receiving flask so that no loss of acetone will occur. The distilling flask must also be fitted with a dropping tube or dropping funnel so water may be run in from time to time and the volume of liquid in the flask kept from becoming less than 400 to 500 ml. A good condenser should be used, but it is not necessary to cool the distillate in ice.

The distillate thus obtained is transferred to a second Kjeldahl flask and 10 ml. of 10 per cent NaOH added. It is then redistilled for about 20 minutes. ¹⁵³ The second distillate is then titrated with standard iodine and thiosulfate solutions.

This is done by adding 10 to 25 ml. of 0.1 N iodine solution (0.02 N if the amount of acetone bodies as indicated by a qualitative test is small) and 10 ml. of strong NaOH (about 40 per cent). Let stand for 10 minutes. Add 18 ml. of concentrated HCl. Titrate with 0.1 N sodium thiosulfate solution to a pale yellow color, add a few ml. of soluble starch solution (see Appendix) and continue titration to disappearance of the blue color.

Calculation. Subtract the number of ml. of 0.1 N thiosulfate solution used from the volume of 0.1 N iodine solution employed. Since 1 ml. of the iodine solution is equivalent to 0.967 mg. of acetone, and since 1 ml. of the thiosulfate solution is equivalent to 1 ml. of the iodine solution, if we multiply the remainder from the above subtraction by 0.967 we will obtain the number of mg. of acetone and acetoacetic acid, expressed as acetone, in the volume of urine taken for analysis.

Determination of the \(\beta\)-Hydroxybutyric Acid: The flask containing the residue from the first distillation above is used in the determination of the B-hydroxybutyric acid. A new receiver is arranged as before with the tip from the condenser dipping beneath the surface of the water. The distillation is then continued and water added whenever necessary to keep the volume between 400 and 600 ml. A dilute solution (1 per cent) of potassium bichromate is added during the distillation. At first 20 ml. of this 1 per cent solution are added slowly through the dropping tube and then 10-ml. portions every 15 to 20 minutes until the whole has been added.154 Should the liquid become markedly green the bichromate must be added at correspondingly shorter intervals and in amount sufficient to maintain a slight red-yellow color of the chromic acid which may be detected even in the presence of the green. Continue the distillation with moderate boiling for from two to three hours. The distillate which should be collected in a liter flask to avoid transference is again distilled for about 20 minutes after adding 10 ml. of 10 per cent sodium hydroxide and 25 ml. of 3 per cent hydrogen peroxide. The flask must be heated cautiously until the peroxide has been decomposed. This final distillate is titrated with standard iodine and thiosulfate solutions in the usual manner and the result expressed as hydroxybutyric acid. One ml. of 0.1 N iodine solution is equivalent to 1.736 mg. of hydroxybutyric acid. About 10 per cent should be added to the results for \(\beta\)-hydroxybutyric acid as obtained by this method as the yield of acetone is only about 90 per cent of the theoretical. This error appears to be practically constant, so that satisfactory results may be obtained by correction.

¹⁶⁸ In many instances when a high degree of accuracy is not required, this redistillation may be omitted and the first distillate titrated directly. The results so obtained are slightly higher than those after redistillation from alkali. The object of the redistillation is to get rid of fatty acids, of which formic acid is one of the most troublesome.

should be added unless the liquid turns green, indicating a great reduction to chromium sulfate. Very rarely 2 or 3 g. of bichromate may be necessary, especially if the sugar has not been completely removed.

3. Method of Behre and Benedict, Modified by Behre: Principle. The acetone, preformed, from acetoacetic acid, and (after removal of interfering substances) from β -hydroxybutyric acid, is distilled from acid solution, and determined colorimetrically or photometrically by its reaction with salicylic aldehyde in alkaline solution. The colored product is dihydroxydibenzene acetone.

Procedure:156

1. Determination of Acetone and Acetoacetic Acid, but Not \(\begin{aligned} \text{-Hydroxybutyric} \end{aligned} \) Acid: To a 200- to 300-ml, distilling flask transfer a measured volume of urine (usually 15 to 30 ml.), and add three to four drops of 1:1 sulfuric acid. Add a few glass beads and connect immediately to a 200-mm. water-cooled condenser fitted with a delivery tube drawn out to a fine tip. An all-glass apparatus is preferred, the joints being lubricated with water; if this is not available, connections may be made with well-fitting cork (not rubber) stoppers. As receiver for the distillate, use a 15-ml. graduated centrifuge tube, so arranged that the enlarged portion of the delivery tube rests on the rim of the centrifuge tube, acting as a cover for it, and the fine tip of the delivery tube reaches just to the bottom of the receiver. Place a minimal amount of water in the receiver, to cover the tip outlet. Apply heat with a micro-burner to the contents of the distilling flask, slowly at first to prevent excessive bubbling in the receiver, and distill over a volume of distillate equal to one-third, or more, of the original volume. Remove the receiver, rinsing off the tip of the delivery tube with a little water in the process, measure the total volume in the receiver, or dilute with water to a definite volume, and mix by inversion.

For color development, transfer 0.1 ml. of salicylic aldehyde to a test tube graduated at 5 and 10 ml. Add 2 ml. of distillate, followed by 1.5 ml. of saturated potassium hydroxide solution from a buret with a fine glass tip. Mix the contents of the tube by several churning motions with a footed glass rod, leave the rod in the tube, and allow to stand

186 Behre and Benedict: J. Biol. Chem., 70, 487 (1926); Behre: ibid., 136, 25 (1940).

186 Reagents Required: Sulfuric Acid, 1:1. Carefully pour 500 ml. of concentrated sulfuric acid into 500 ml. of water, with stirring. Cool, dilute to 1 liter, and mix.

Salicylic Aldehyde. Eastman's technical grade, or Eimer and Amend's "Acid Salicylous, Synthetic" are satisfactory.

Saturated Potassium Hydroxide Solution. Add an excess of solid reagent-grade potassium hydroxide to some water in a beaker. Stir to dissolve as completely as possible, allow to settle, and use the clear supernatant solution. The specific gravity should be 1.540.

Aqueous Alcohol. A 70 to 75 per cent solution of ethyl alcohol in water. Dilute 75 ml. of 95 per cent ethyl alcohol to 100 ml. with water, and mix.

Standard Acctone Solutions. Dilute 5 ml. of freshly opened or well-kept c.p. acetone to 500 ml. with water, and mix. For approximate purposes, this may be assumed to produce a 0.78 to 0.79 per cent solution. For accurate work it should be standardized by iodimetric titration. Place 5 ml. of acetone solution in a 250-ml. glass-stoppered flask, and add 25 ml. of normal sodium hydroxide solution, followed by 50 ml. (accurately measured) of 0.1 normal iodine solution. Add the iodine solution a little at a time, with mixing. Stopper and allow to stand 10 to 15 minutes. Add 25 to 30 ml. of normal sulfuric acid (there must be an excess over the alkali present, to liberate all the iodine) and titrate the excess iodine with 0.1 normal sodium thiosulfate solution, using starch as indicator. Subtract the buret reading from 50, to obtain the ml. of iodine used up. 1 ml. of 0.1 normal iodine is equivalent to 0.9675 mg. of acetone.

From the standardized acctone solution, prepare by dilution a solution containing 1 mg. of acctone per ml. This stock standard will keep for about 1 month. Freshly prepared dilute standards containing 0.1, 1.0, and 5.0 mg. per cent are made from the stock standard by diluting 0.1 ml., 1.0 ml., and 5.0 ml. respectively to 100 ml. with water and mixing. Other concentrations (for preparing a photometric calibration curve) may be made similarly.

Potassium Bichromate, 0.2 Per Cent. Dissolve 2 g. of reagent-grade potassium bichromate in water and dilute to 1 liter.

20 minutes at room temperature. Finally add either (A) water to the 10-ml. mark, or (B) aqueous alcohol to the 5-ml. mark, rinsing and removing the rod in the process. Mix by tapping or inversion. Choice between procedures A and B will depend largely upon the amount of acetone present; A gives less color than B, and is for larger amounts of acetone. This choice can usually be estimated roughly by inspection during the period of color development. For many purposes one procedure can be used consistently; both are described to permit the accurate covering of a wide range of acetone concentration.

For colorimetric measurement, compare the unknown in the colorimeter against a suitable standard acetone solution treated in the same way and at the same time as for the unknown. For the preparation and choice of standards, see under "Calculation." For photometric measurement, determine the density in a photometer at 520 my, within 15 minutes after dilution by procedure A or 30 minutes after dilution by procedure B. Set the photometer to zero density with a blank prepared by treating 2 ml. of water by the same procedure as was used for the unknown.

2. Determination of B-Hydroxybutyric Acid: Glucose and other interfering substances are removed by the treatment with calcium hydroxide and copper sulfate as in the Van Slyke procedure, p. 870. All volumes may be reduced proportionately if advisable. If the urine is dilute, its volume may be increased in relation to the volume of the final mixture, twice the amount of copper sulfate (in 40 per cent solution) and calcium hydroxide being used. After standing for 30 to 45 minutes, the mixture is filtered, or centrifuged and filtered. Transfer an aliquot of the filtrate (the amount depending upon the β-hydroxybutyric acid content of the urine) to a distilling flask similar to that used for the acetone determination, but in addition fitted with a dropping funnel. Make up the volume in the flask to not less than 30 ml. by adding water if necessary, and acidify with three to four drops of 1:1 sulfuric acid. Distill off onethird or more of the original volume as described for the acetone determination, to get rid of preformed acetone and acetoacetic acid. Discard the distillate; it cannot be used for simultaneous acetone determination since some acetone is lost by the treatment with calcium hydroxide and copper sulfate. Place a 200-ml, round-bottomed flask in position as receiver for the distillate, closed and containing sufficient water to cover the tip of the delivery tube as described for the acetone determination in section 1. Bring the residual solution in the flask (volume of approximately 20 to 60 ml.) to a boil, and add through the dropping funnel 15 ml. of 1:1 sulfuric acid and 10 ml. of 0.2 per cent potassium bichromate solution, by drops, during the first five minutes of distillation, followed by 25 ml. of bichromate during each of the next two five-minute periods. Regulate the rate of distillation so that 50 to 85 ml. of distillate are obtained in 15 minutes.

Measure the volume of distillate, or dilute to a known volume with water and mix, and determine the acetone content of a 2-ml. portion as described in section 1.

Calculation. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times S \times \frac{\text{Distillate Vol.}}{2} \times \frac{100}{\text{Urine Vol.}} = \frac{\text{mg. of acetone per}}{100 \text{ ml. of urine}}$$

where S is the acetone content of the standard, in mg., and the volumes of distillate, and urine whose acetone is contained in the distillate, are measured in ml. The standard should have an acetone content approximating that of the

¹⁵⁷ Behre (loc. cit.) describes the preparation of "artificial standards" suitable for approximate clinical purposes.

distillate. If this is not known, or will vary widely from one unknown to another, a series of five standards may be prepared which will permit the accurate estimation of any concentration of acctone in the distillate from 0.05 to 200 mg. per cent (0.001 to 4.0 mg. per 2 ml.). First prepare dilute standard acetone solutions containing 0.1, 1.0, and 5.0 mg. per cent acetone, by dilution of the stock standard. Set up five test tubes, each containing 0.1 ml. of salicylic aldehyde. Add to each the amount of a particular standard as indicated in the table, followed by 1.5 ml. of potassium hydroxide solution and subsequent treatment for color development exactly as described for the analysis of an unknown. Dilute each standard after color development to the volume and with the solvent indicated in the table. The S value for each standard, to be used in the calculation, is given in the last column of the table.

Standard	Final Volume After Color Development, and Solvent	S
1—1 ml. of 0.1 mg. per cent acctone, + 1 ml. of water	5 ml., alcohol 10 ml., alcohol 10 ml., water	0.002

Read the unknown against the nearest standard in the same solvent. If the unknown is known to come within the range of any one standard, naturally only that standard need be prepared. If the color of the unknown in the alcohol solvent is more than twice that of Standard 3, or in the water solvent more than twice that of Standard 5, it may be diluted with the same solvent until approximate color match with a standard is obtained, and then read. Results in this event must be multiplied by the dilution. Dilution up to 200-ml. final volume is permissible.

For photometric measurement, the acctone content in the 2 ml, of distillate taken for analysis is established by reference to a calibration curve prepared previously from standard acctone solutions. The calculation is then:

$$\frac{\text{Mg. of acetone in}}{2 \text{ ml. of distillate}} \times \frac{\text{Distillate Vol.}}{2} \times \frac{100}{\text{Urine Vol.}} = \frac{\text{mg. of acetone per}}{100 \text{ ml. of urine}}$$

To prepare a calibration curve for procedure A (water solvent, 10 ml. volume), 2-ml. portions of standard acetone solutions containing from 0.0 to 0.16 mg. of acetone give a satisfactory curve relating density and concentration, at 520 m μ and 1 cm. solution depth (or its equivalent). For procedure B (alcohol solvent, 5 ml. volume) the corresponding range is 0.0 to 0.03 mg. of acetone. If the unknown is beyond the range of the curve, repeat the analysis using a smaller aliquot of distillate (or diluted distillate) made up to 2 ml. with water, and correct the calculations accordingly. In using a calibration curve for photometric measurement, the experimental conditions during an analysis (time of standing before and after dilution, temperature, etc.) should be uniform and should reproduce as far as possible those used when the curve was constructed. For accurate results the curve should be checked at intervals, particularly if new reagents are prepared, and reëstablished if necessary.

Results obtained by the procedure in which β -hydroxybutyric acid is not determined (section 1) represent the preformed acctone present, as well as

acetone equivalent to the acetoacetic acid present, which is decomposed into acetone during the analysis. In the β -hydroxybutyric acid analysis (section 2), results represent the acetone equivalent of the β -hydroxybutyric acid present. For factors used to obtain the content of β -hydroxybutyric acid itself, see previous methods.

INDICAN

1. Methods. Indican (indoxylsulfuric acid) is usually determined by oxidation and condensation to form indigo or similar substances, followed by extraction with chloroform or other suitable solvents, and colorimetric or photometric estimation in terms of a standard. In Parker's modification of Askenstedt's method (for details see the Eleventh Edition of this book) a standard solution of indigo is used. This type of standard has been criticized by Meiklejohn and Cohen, 158 who state that the final color intensity obtained from urine may be deeper than that corresponding to a saturated solution of pure indigo, in the same solvent. These authors describe a photometric modification of the method of Sharlit, 159 which appears to give satisfactory results, and which is based upon calibration of the photometer with standard indican solutions. In Sharlit's procedure, developed for visual colorimetry, standard indican solutions may also be used, but the author likewise describes an artificial standard containing cobalt sulfate, whose indican equivalence is defined. Kumon 160 has described a procedure claimed to be quite specific, based upon the color reaction between indican and ninhydrin. It is not felt practical to describe any of these procedures here, because of the difficulty of obtaining pure indican for standardization purposes. 161 The reader is referred to the original papers for details.

Interpretation. According to Sharlit (loc. cit.), the daily excretion of indican is considerably higher than heretofore supposed, ranging from 40 to 150 mg. per day in normal individuals.

Indican is apparently formed within the body from indole produced in the intestinal lumen by bacterial action; there is no good evidence that either indole or indican are intermediates in tryptophane metabolism by animal tissues. In normal individuals, variations in indican excretion appear to be dependent mainly upon the diet, a meat diet increasing excretion while a milk or carbohydrate diet decreases excretion. Pathologically the greatest increases are found in disorders involving increased putrefaction and stagnation of intestinal contents. Bacterial decomposition of body protein, as in gangrene, putrid pus formation, etc., gives rise to increases.

PHENOLS

1. Method of Volterra:162 Principle. The urine is distilled from slightly alkaline solution to obtain the free volatile phenols in the distilled

¹⁶⁸ Meiklejohn and Cohen: J. Lab. Clin. Med., 27, 949 (1941-1942). See also Townsend: ibid, 23, 809 (1937-1938).

¹⁵⁰ Sharlit: J. Biol. Chem., 99, 537 (1932).

¹⁶⁰ Kumon: Z. physiol. Chem., 231, 205 (1935).

¹⁶¹ For method of preparing indican from the urine of dogs fed indole, see Ellinger:
Z. physiol. Chem., 38, 178 (1903).
168 Volterra: Am. J. Clin. Path., 12, 525, 580 (1942).

late. After acidification, a second distillate is obtained; this represents the conjugated volatile phenols present. Ether extraction of the remaining fluid separates the aromatic hydroxy acids from "residual phenols." The significance of these various fractions is discussed under "Interpretation." Each fraction, after proper preparation, is treated with the phosphotungstic-phosphomolybdic acid color reagent of Folin and Ciocalteu and the resulting color compared with that obtained from a standard phenol solution.

Procedure:163

- A. Free Volatile Phenols: Transfer 10 ml. of the well-mixed 24-hour sample of urine to a 250-ml. distilling flask fitted with a condenser. Add 150 to 175 ml. of water, followed by sufficient sodium bicarbonate solution to render the solution alkaline to litmus. Distill, collecting the distillate until 30 to 40 ml. have been obtained. Stop the distillation and measure the volume of distillate. Use a 10-ml. portion for the color reaction, as described below.
- B. Conjugated Volatile Phenols: When the contents of the distilling flask have cooled somewhat, add sufficient dilute sulfuric acid to render distinctly acid to Congo red, and start the distillation again. Collect 100 to 120 ml. of distillate, then test for completeness of distillation by collecting a separate 5-ml. portion of distillate and treat this by the phenol color reaction described below, using proportionately reduced amounts of reagents. If an evident color reaction is obtained in this test sample, add 50 to 100 ml. of water to the distilling flask and continue distillation until volatile phenols no longer distill over. Only in exceptional cases must more than about 150 ml. of distillate be obtained. Measure the volume of distillate, mix, and use a 10-ml. portion for the color reaction.
- C. Total Aromatic Hydroxy Acids: Transfer the acid solution in the distilling flask to a 250-ml. separatory funnel, using water for rinsing and dilution to about 100 ml., and shake for three minutes with 30 to 40 ml. of petroleum ether. Draw off the aqueous layer into a second separatory funnel (discard the petroleum ether layer) and shake twice with 30-ml.

162 Reagents Required: Silver Lactate Solution. 3 per cent silver lactate in 3 per cent lactic acid.

Colloidal Iron. Eimer and Amend's "Dialysed Iron, 5 Per Cent" is satisfactory.

Acid Sodium Chloride Solution. To 1 liter of a saturated solution of sodium chloride, add 10 ml. of concentrated hydrochloric acid.

Phenol Reagent (Folin and Ciocalteu: J. Biol. Chem., 73, 627 (1929)). Into a 1500-ml. Florence flask introduce 100 g. of sodium tungstate, Na₂WO₄·2H₂O, 25 g. of sodium molybdate, Na₂MoO₄·2H₂O, 700 ml. of water, 50 ml. of 85 per cent phosphoric acid, and 100 ml. of concentrated hydrochloric acid, and reflux gently for 10 hours. Add 150 g. of lithium sulfate, 50 ml. of water, and a few drops of bromine. Boil the mixture for 15 minutes without condenser, to remove excess bromine. Cool, dilute to 1 liter, and filter. The reagent should have no greenish tint. Protect from dust. Dilute a portion with an equal volume of water before use.

Standard Phenol Solution. Prepare and standardise a stock solution of phenol, containing 1 mg. of phenol per ml., as follows: Dissolve a little over 1 g. of crystallised phenol in a liter of 0.1 N hydrochloric acid. Transfer 25 ml. of this solution to a 250-ml. flask, add 50 ml. of 0.1 N sodium hydroxide, heat to 65° C., add 25 ml. of 0.1 N iodine solution, stopper the flask, and let stand at room temperature for 30 or 40 minutes. Add 5 ml. of concentrated hydrochloric acid and titrate the excess of iodine with 0.1 N thiosulfate solution. Each ml. of 0.1 N iodine solution used up corresponds to 1.567 mg. of phenol. On the basis of the result, dilute the remainder of the phenol solution with 0.1 N acid to give a solution containing 1 mg. of phenol per ml. This stock solution is quite stable. For a working standard, dilute 0.3 ml. of the stock standard to 100 ml. with water and mix. This solution contains 0.03 mg. of phenol in 10 ml., and is made up fresh at the time of using.

portions of ordinary ether, removing and combining the ether extracts, and saving the residual aqueous fluid. Wash the combined ether extracts by shaking with water, draw off the water, transfer the ether extract to an evaporating dish, and evaporate off the ether on a steam bath. Just before evaporation is complete, add about 5 ml. of water, and then complete the removal of the ether. Transfer the aqueous fluid remaining to a graduated cylinder and make up with rinsings to 10 ml. Mix, dilute 1 ml. to 10 ml. with water, and use this diluted portion for color development.

D. "Residual Phenols": Dilute the residue from the ether extraction to 200 ml. with water. To a 10-ml. portion, add 1.0 to 1.5 ml. of silver lactate solution, and one to two drops of colloidal iron. Shake, dilute to 20 ml. with water, allow to stand 15 minutes, and filter. To 10 ml. of filtrate add 1.0 to 1.5 ml. of acid sodium chloride solution, dilute to 20 ml. with water, mix, and filter. Use 10 ml. of filtrate for the color reaction.

Color Reaction: To 10 ml. of unknown in a test tube, add 0.5 ml. of diluted phenol reagent, followed by 2 ml. of 20 per cent sodium carbonate solution. Mix by shaking, and after 20 to 30 seconds place the tube in a boiling water bath for exactly one minute. Remove and cool in running cold water. Compare the color with that obtained by treating 10 ml. of standard phenol solution (containing 0.03 mg. of phenol) by the same procedure, at the same time.

Calculation.

a. Volatile Phenols (Free or Conjugated):

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. of phenol}}{\text{in Standard}} \times \frac{\text{ml. of distillate}}{10} = \frac{\text{mg. of phenol in vol. of urine used (10 ml.)}}{\text{urine used (10 ml.)}}$$

Results on the distillate from A give the free volatile phenol content and from B the conjugated volatile phenols (both expressed as phenol). From the volume of the urine, the total output per 24 hours can be calculated.

b Aromatic Hydroxy Acids:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. of phenol}}{\text{in Standard}} \times 10 = \frac{\text{mg. of aromatic hydroxy acids}}{\text{(as phenol) in vol. of urine used}}$$

Multiply results by 1.5 to express in terms of p-hydroxyphenylacetic acid instead of phenol. It may be necessary to dilute the 10-ml. aqueous solution of ether-soluble material, of which 1 ml. is used for analysis, to a greater volume to get color match with the standard, in which case the value 10 in the formula is replaced by the volume after dilution.

c. "Residual Phenols":

Interpretation. Results on normal and pathological urine by this method indicate that free volatile phenols (phenol, p-cresol, etc.) are ordinarily present only in traces, if at all, and these findings are in agreement with the results of others (Deichmann and Shafer, 164 Schmidt 165) using different methods. Conjugated phenols range in amount from 20 to 70 mg. per day normally, and do not appear to be significantly altered in amount by diet or fasting, at least in short experiments. Pathologically, increases in conjugated phenols have been noted in conditions associated

165 Schmidt: J. Biol. Chem., 145, 533 (1942).

¹⁴⁴ Deichmann and Shafer: Am. J. Clin. Path., 12, 129 (1942).

with extensive tissue destruction and in intestinal obstruction. Ingestion of phenol or benzene likewise leads to increases. Aromatic hydroxy acids (p-hydroxyphenylacetic acid, p-hydroxyphenylpropionic acid, p-hydroxybenzoic acid, p-hydroxyphenyllactic acid, and possibly p-hydroxphenylpyruvic acid) are excreted normally in amounts ranging from 50 to 90 mg. (as p-hydroxyphenylacetic acid) per day. Pathological variations have not been extensively studied. According to Schmidt (loc. cit), about two-thirds of the total aromatic hydroxy acid excretion is normally in the free form and one-third in the conjugated form. The significance of the "residual phenol" analysis is obscure. Values ranging from 150 to 500 mg. per day are found normally, but it is generally recognized that many nonphenolic substances, such as imidazoles, etc., are included in this fraction, rendering interpretation difficult. Values for "residual phenols" as obtained by the method described here correspond roughly to the "total phenol" values of the admittedly nonspecific method of Folin and Denis. 166

SULFONAMIDES ("SULFA" DRUGS)

1. Method of Bratton and Marshall:¹⁶⁷ Principle. The principle is the same as that applied to the determination of sulfonamides in blood (p. 601). The protein-free urine is treated with nitrous acid to diazotize any free sulfonamide present, excess nitrous acid is destroyed, and the diazotized sulfonamide is coupled with N-(1-naphthyl)ethylene-diamine to form a stable red color which is then compared with a standard treated in the same way. Total sulfonamide is determined after hydrolysis with acid. The difference between free and total sulfonamide represents acetylated sulfonamide.

Procedure: 188 Transfer 1 ml. of urine to a 25-ml. volumetric flask and dilute to the mark with water. Mix, and place 2 ml. of the diluted urine in a small flask. From a buret add 30 ml. of water, followed by 8 ml. of 15 per cent trichloroacetic acid. Mix and filter.

Free Sulfonamide: Transfer a 10-ml. portion of the trichloroacetic acid filtrate to a small flask or wide test tube, and treat with nitrite, sulfamate, etc., exactly as described for a blood filtrate (p. 603).

Total Sulfonamide: Transfer a 10-ml. portion of filtrate to a test tube or other container graduated at 10 ml., and add 0.5 ml. of 4 N hydrochloric acid. Place in a boiling water bath for one hour, cool, and make up to 10 ml. with water. Continue with treatment with nitrite, sulfamate, etc., as for free sulfonamide.

Compare the final color obtained against a suitable standard as described for blood analysis, the same standards being satisfactory. If the urine is unusually low or high in sulfonamide content, the determination is repeated on a more satisfactory dilution of the sample. In every case, however, the final 10-ml. portion analyzed should contain 3 per cent trichloroacetic acid. The calculation is the same as for blood analysis, except that the dilution of the urine (i.e., in the present instance the dilution is 500) replaces the value 20 in the blood calculations. Either a colorimeter or a photometer may be used, as with blood.

¹⁶⁶ See the Eleventh Edition of this book for the details of this procedure.

¹⁶⁷ Bratton and Marshall: J. Biol. Chem., 128, 537 (1939).

¹⁶⁸ The reagents required are the same as those described on p. 603 for the determination of sulfonamides in blood.

The procedure as described provides for urine containing protein as well as protein-free urine. If the urine is known to be free from protein, the treatment with trichloroacetic acid may be omitted. The urine is diluted so as to contain from 1 to 2 mg. per cent of sulfonamide, and then 50 ml. of this diluted urine, plus 5 ml. of 4 N hydrochloric acid are diluted to 100 ml. with water. Free sulfonamide is determined on a 10-ml. portion of this final dilution as with a blood filtrate. Total sulfonamide is determined on a 10-ml. portion, heated without further addition of acid, made up to volume, and the analysis continued as above.

Interpretation. As with blood, the sulfonamide content of urine may vary between wide limits. The procedure as described is satisfactory for urines containing from 50 to 500 mg. per cent. If smaller or larger amounts than this are present, other suitable dilutions must be made.

Sulfonamides found in the urine may be either in the form of the free drug, its acetylated derivative, 169 or oxidized forms possibly combined with glucuronic acid. 170 Only the acetylated derivative does not respond to the colorimetric procedure: the difference between free and total sulfonamide therefore represents acetylated sulfonamide. The proportion of free drug to its various derivatives depends upon a number of factors, of which the nature of the sulfonamide itself is perhaps most important; sulfanilamide is relatively little acetylated as compared to sulfadiazine, for example. Clinically, the sulfonamide content of the urine is of importance in at least two respects; these include the possible formation of urinary calculi by the insoluble and precipitated drug, and the possibility of renal damage and hematuria associated with the deposition of crystalline sulfonamide or acetylsulfonamide in the renal tubules. Studies on these two possible manifestations of sulfonamide excretion have shown that the various sulfonamides and their derivatives differ significantly in their solubility in urine and in their propensity to precipitate out, either in the renal tubules or in the urine itself; in general, the therapy consists of maintaining an alkaline urine, since the compounds responsible are more soluble at alkaline reaction. Thus far, only the free drug and its acetylated product appear to be involved here; other excretory forms of the sulfonamides, where they have been recognized, are quite soluble.

UROBILINOGEN

Method of Wallace and Diamond:¹⁷¹ Principle. A series of dilutions of urine is carried to the point where the red color resulting from the reaction between urobilinogen and Ehrlich's aldehyde reagent is just discernible. This method is regarded as more accurate than the spectroscopic method of Wilbur and Addis.¹⁷² A more extended, and probably more accurate, method for the determination of urobilin and urobilinogen in urine and feces is described by Watson.¹⁷³ According to White, Meikle-

¹⁶⁹ Marshall, Bratton, and Litchfield: Science, 88, 597 (1938).

¹⁷⁰ Scudi: Science, 91, 486 (1940); also Scudi and Jelinek: J. Pharmacol., 81, 218 (1944).

Wallace and Diamond: Arch. Internal Med., 35, 698 (1925).
 Wilbur and Addis: Arch. Internal Med., 13, 235 (1914).

¹⁷⁸ Watson: Am. J. Clin. Path., 6, 458 (1936). See also Watson and Bilden: Arch. Internal Med., 68, 740 (1941).

john, Deutsch, and Kark,¹⁷⁴ the method of Watson is superior for research purposes to the Wallace and Diamond method described here, but not necessarily so for routine clinical purposes under the proper conditions.

Procedure: One ml. of Ehrlich's aldehyde reagent¹⁷⁵ is added to 10 ml. of undiluted urine and allowed to stand one to three minutes. An idea as to the quantity of urobilinogen is gained by noting the rapidity and intensity of color development. Dilutions are not carried out if the color remains a light red (normal values). For higher concentrations, prepare a series of dilutions of the urine from 1:10 to 1:200 or higher, as indicated by the preliminary test. Tap water may be used, but should not be too cold. Add 1 ml. of the reagent to each dilution and after three to five minutes note the highest dilution that shows a faint pink discoloration. Express the result in terms of this dilution. The test is best performed in daylight but in the absence of bright sunlight.

Interpretation. The appearance of the color in dilutions up to 1:20 may be regarded as normal. Constipation may produce a temporary rise in urobilinogen. This substance is believed to originate by reduction of the bile pigment. The latter may be extrahepatic as well as hepatic in origin (see p. 544). Excessive amounts of urobilinogen are, therefore, excreted in diseases of the liver and biliary tract, including toxemias of pregnancy, infectious diseases, and alcoholic intoxication, and in hemolytic diseases, including poisoning by lead, sulfonal, mushrooms, and hemolytic poisons in general.¹⁷⁶ It is claimed that urinary urobilinogen affords no accurate index to blood decomposition; according to Miller, Singer, and Dameshek,¹⁷⁷ however, the fecal output of urobilinogen is of value in this connection.

OXALIC ACID

Dakin Modification of Salkowski-Autenrieth and Barth Method: Principle. The oxalic acid is precipitated by means of CaCl₂. From the solution of this precipitate in hydrochloric acid the oxalic acid is extracted with ether and reprecipitated as calcium oxalate. 178

Procedure: To a 24-hour specimen of urine (or as large a quantity as is available) add HCl to make about a 5 per cent solution and heat on the water bath for 20 minutes to break up oxaluric acid. Add an excess of calcium chloride and make fairly strongly alkaline with ammonia. Let stand in a warm place overnight. Filter off on a folded filter and wash the precipitate well with boiling water. Observe the filtrate for a short time. If calcium oxalate sediments, filter again. Transfer the precipitates to a beaker and warm with a small quantity of dilute HCl. Filter through a small folded filter. Wash the residue by digesting with successive portions of hot water. Concentrate the filtrate to 5 to 7 ml. Transfer to an extraction tube for continuous extraction with ether (see Fig. 277), and extract for five to six

¹⁷⁴ White, Meiklejohn, Deutsch, and Kark: Am. J. Digestive Diseases Nutrition, 8, 346 (1941).

¹⁷⁵ See Appendix.

¹⁷⁶ Sulfonamides in the urine will interfere since they likewise react with Ehrlich's aldehyde reagent. If they are present, acidify the urine and shake with petroleum ether. Shake the petroleum ether extract with aqueous alkali and carry out the test on the final neutralized aqueous extract.

¹⁷⁷ Miller, Singer, and Dameshek: Arch. Internal Med., 70, 722 (1942).

¹⁷⁶ For a similar procedure requiring a smaller volume of urine, see Powers and Levatin: *J. Biol. Chem.*, 154, 207 (1944).

The procedure as described provides for urine containing protein as well as protein-free urine. If the urine is known to be free from protein, the treatment with trichloroacetic acid may be omitted. The urine is diluted so as to contain from 1 to 2 mg. per cent of sulfonamide, and then 50 ml. of this diluted urine, plus 5 ml. of 4 N hydrochloric acid are diluted to 100 ml. with water. Free sulfonamide is determined on a 10-ml. portion of this final dilution as with a blood filtrate. Total sulfonamide is determined on a 10-ml. portion, heated without further addition of acid, made up to volume, and the analysis continued as above.

Interpretation. As with blood, the sulfonamide content of urine may vary between wide limits. The procedure as described is satisfactory for urines containing from 50 to 500 mg. per cent. If smaller or larger amounts than this are present, other suitable dilutions must be made.

Sulfonamides found in the urine may be either in the form of the free drug, its acetylated derivative, 169 or oxidized forms possibly combined with glucuronic acid. 170 Only the acetylated derivative does not respond to the colorimetric procedure; the difference between free and total sulfonamide therefore represents acetylated sulfonamide. The proportion of free drug to its various derivatives depends upon a number of factors, of which the nature of the sulfonamide itself is perhaps most important; sulfanilamide is relatively little acetylated as compared to sulfadiazine, for example. Clinically, the sulfonamide content of the urine is of importance in at least two respects; these include the possible formation of urinary calculi by the insoluble and precipitated drug, and the possibility of renal damage and hematuria associated with the deposition of crystalline sulfonamide or acetylsulfonamide in the renal tubules. Studies on these two possible manifestations of sulfonamide excretion have shown that the various sulfonamides and their derivatives differ significantly in their solubility in urine and in their propensity to precipitate out, either in the renal tubules or in the urine itself; in general, the therapy consists of maintaining an alkaline urine, since the compounds responsible are more soluble at alkaline reaction. Thus far, only the free drug and its acetylated product appear to be involved here; other excretory forms of the sulfonamides, where they have been recognized, are quite soluble.

UROBILINOGEN

Method of Wallace and Diamond:¹⁷¹ Principle. A series of dilutions of urine is carried to the point where the red color resulting from the reaction between urobilinogen and Ehrlich's aldehyde reagent is just discernible. This method is regarded as more accurate than the spectroscopic method of Wilbur and Addis.¹⁷² A more extended, and probably more accurate, method for the determination of urobilin and urobilinogen in urine and feces is described by Watson.¹⁷⁸ According to White, Meikle-

¹⁰⁰ Marshall, Bratton, and Litchfield: Science, 88, 597 (1938).

¹⁷⁰ Scudi: Science, 91, 486 (1940); also Scudi and Jelinek: J. Pharmacol., 81, 218 (1944).

¹⁷² Watson: Am. J. Clin. Path., 6, 458 (1936). See also Watson and Bilden: Arch. Internal Med., 63, 740 (1941).

john, Deutsch, and Kark,¹⁷⁴ the method of Watson is superior for research purposes to the Wallace and Diamond method described here, but not necessarily so for routine clinical purposes under the proper conditions.

Procedure: One ml. of Ehrlich's aldehyde reagent¹⁷⁵ is added to 10 ml. of undiluted urine and allowed to stand one to three minutes. An idea as to the quantity of urobilinogen is gained by noting the rapidity and intensity of color development. Dilutions are not carried out if the color remains a light red (normal values). For higher concentrations, prepare a series of dilutions of the urine from 1:10 to 1:200 or higher, as indicated by the preliminary test. Tap water may be used, but should not be too cold. Add 1 ml. of the reagent to each dilution and after three to five minutes note the highest dilution that shows a faint pink discoloration. Express the result in terms of this dilution. The test is best performed in daylight but in the absence of bright sunlight.

Interpretation. The appearance of the color in dilutions up to 1:20 may be regarded as normal. Constipation may produce a temporary rise in urobilinogen. This substance is believed to originate by reduction of the bile pigment. The latter may be extrahepatic as well as hepatic in origin (see p. 544). Excessive amounts of urobilinogen are, therefore, excreted in diseases of the liver and biliary tract, including toxemias of pregnancy, infectious diseases, and alcoholic intoxication, and in hemolytic diseases, including poisoning by lead, sulfonal, mushrooms, and hemolytic poisons in general. 176 It is claimed that urinary urobilinogen affords no accurate index to blood decomposition; according to Miller, Singer, and Dameshek, 177 however, the fecal output of urobilinogen is of value in this connection.

OXALIC ACID

Dakin Modification of Salkowski-Autenrieth and Barth Method: Principle. The oxalic acid is precipitated by means of CaCl₂. From the solution of this precipitate in hydrochloric acid the oxalic acid is extracted with ether and reprecipitated as calcium oxalate.¹⁷⁸

Procedure: To a 24-hour specimen of urine (or as large a quantity as is available) add HCl to make about a 5 per cent solution and heat on the water bath for 20 minutes to break up oxaluric acid. Add an excess of calcium chloride and make fairly strongly alkaline with ammonia. Let stand in a warm place overnight. Filter off on a folded filter and wash the precipitate well with boiling water. Observe the filtrate for a short time. If calcium oxalate sediments, filter again. Transfer the precipitates to a beaker and warm with a small quantity of dilute HCl. Filter through a small folded filter. Wash the residue by digesting with successive portions of hot water. Concentrate the filtrate to 5 to 7 ml. Transfer to an extraction tube for continuous extraction with ether (see Fig. 277), and extract for five to six

¹⁷⁴ White, Meiklejohn, Deutsch, and Kark: Am. J. Digestive Diseases Nutrition, 8, 346 (1941).

¹⁷⁵ See Appendix.

¹⁷⁶ Sulfonamides in the urine will interfere since they likewise react with Ehrlich's aldehyde reagent. If they are present, acidify the urine and shake with petroleum ether. Shake the petroleum ether extract with aqueous alkali and carry out the test on the final neutralized aqueous extract.

¹⁷⁷ Miller, Singer, and Dameshek: Arch. Internal Med., 76, 722 (1942).

¹⁷⁶ For a similar procedure requiring a smaller volume of urine, see Powers and Levatin: *J. Biol. Chem.*, 154, 207 (1944).

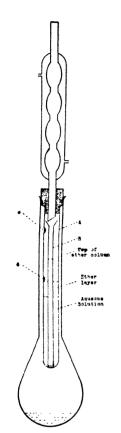

Fig. 277. Continuous extraction apparatus (Gaebler).179

hours. Add 20 ml. of water to the ether extract and distil off the ether. Filter and add an excess of calcium chloride and ammonia. Then make decidedly acid with acetic acid and let stand in a warm place overnight. Filter off the precipitate on a small paper, and wash with hot water. Titrate with potassium permanganate after treating with an excess of 5 per cent sulfuric acid and warming to 60°, or ignite to CaO and weigh.

Calculation. Since 56 parts of CaO are equivalent to 90 parts of oxalic acid, the quantity of oxalic acid in the volume of urine taken may be determined by multiplying the weight of CaO by the factor of 1.6071. In case titration is performed it should be remembered that I ml. of 0.1 N KMnO₄ equals 0.0063 g of crystallized oxalic acid or 0.0045 g. of anhydrous acid.

Interpretation. From 15 to 20 mg. of oxalic acid are excreted by a normal adult on an ordinary mixed diet. It arises from oxalates of the food ingested and from fat and protein metabolism. It is increased by the ingestion of apples, grapes, cabbage, etc., although most of the ingested oxalate is destroyed. It is increased in disturbances of metabolism associated with decreased oxidation, according to certain observers. The term "oxaluria" has been largely a misnomer.

SULFUR 150

A. Gravimetric Procedures

1. Total Sulfates: Folin's Method: Principle. The sulfuric acid of the conjugated sulfates is set free by boiling with acid. The total sulfates are then precipitated with barium chloride.

Procedure: Place 25 ml. of urine in a 200- to 250-ml. Erlenmeyer flask, add 20 ml. of dilute hydrochloric acid¹⁸¹ (1 volume of concentrated HCl to 4 volumes of water), and gently boil the mixture for 20 to 30 minutes. To minimize the loss of water by evaporation, the mouth of the flask should be

¹⁷⁹ The apparatus involves essentially the same principles as the one used by Myers and Wardell in the determination of cholesterol (p. 536). Of the apparatus as shown in the diagram, only two parts need be made -tubes A and B. A is a medium-weight pyrex 1 by 10 inch tube, with two holes, c and d, the former $8\frac{1}{2}$ and the latter $5\frac{1}{2}$ inches from the bottom. Tube B is made from ordinary glass tubing, is 9 inches in length, and has a funnel-shaped dilation at the top and bulb with four or five small holes at the bottom. A cork which fits an 800-ml. Kieldahl flask is fitted with a hole to admit a small condenser, and is cut down to one inch diameter at its lower end so that tube A can, be forced upon it. On heating, the ether vapor passes through c into the condenser, runs back through tube B, rises through the aqueous solution, and returns to the Kieldahl flask through d.

180 Under this heading are described gravimetric and volumetric methods for sulfur in urine. A colorimetric procedure for inorganic sulfate has been described by Kahn and Leiboff: J. Biol. Chem., 80, 623 (1928). For turbidimetric methods, see Medes and Stavers: J. Lab. Clin. Med., 25, 624 (1939-1940); Treon and Crutchfield: Ind. Eng. Chem., Anal. Ed., 14, 119 (1942).

181 If it is desired, 50 ml. of urine and 4 ml. of concentrated acid may be used instead.

covered with a small watch glass during the boiling process. Cool the flask for two to three minutes in running water, and dilute the contents to about 150 ml. by means of cold water. Add 10 ml. of a 5 per cent solution of barium chloride slowly, drop by drop, to the cold solution. 182 The contents of the flask should not be stirred or shaken during the addition of the barium chloride. Allow the mixture to stand at least one hour, then shake up the solution and filter it through a weighed Gooch crucible. 183

Wash the precipitate of BaSO₄ with about 250 ml. of cold water, dry it in an air bath or over a very low flame, then ignite, 184 cool, and weigh.

Calculation. Subtract the weight of the Gooch crucible from the weight of the crucible and the BaSO₄ precipitate to obtain the weight of the precipitate. The weight of S in the volume of urine taken may be determined by means of the following proportion:

Mol. Wt. BaSO₄: Wt. of BaSO₄:: Mol. wt. S: x(wt. of S in grams)

Representing the weight of the $BaSO_4$ precipitate by y and substituting the proper molecular weights, we have the following proportion:

233.43: y :: 32.06 : x(wt. of S in grams in the quantity of urine used)

Calculate the quantity of S in the 24-hour specimen of urine.

To express the result in percentage of S, simply divide the value of x, as just determined, by the quantity of urine used.

Interpretation. The total sulfate excretion (ethereal and inorganic sulfates) by a normal adult on a mixed diet is usually between 0.6 and 1.2 g. of S with an average of about 0.8 g. The sulfuric acid is derived but to a slight extent ordinarily from ingested sulfates, being mainly dependent on the sulfur of the protein metabolized, and will consequently vary widely with the level of protein metabolism. From 75 to 95 per cent of the total sulfur of the urine is ordinarily found as sulfate, the proportion being greatest on a high protein diet. The sulfate excretion is increased in all conditions associated with increased decomposition of body protein as in acute fevers and decreased whenever there is a decrease in metabolic activity.

2. Inorganic Sulfates: Folin's Method: Place 25 ml. of urine and 100 ml. of water in a 200- to 250-ml. Erlenmeyer flask and acidify the diluted urine with 10 ml. of dilute hydrochloric acid (1 volume of concentrated HCl to 4 volumes of water). In case the urine is dilute, 50 ml. may be used instead

¹⁸² A dropper or capillary funnel made from an ordinary calcium chloride tube and so constructed as to deliver 10 ml. in two to three minutes is recommended for use in adding the barium chloride.

¹⁸³ If a Gooch crucible is not available, the precipitate of BaSO₄ may be filtered off upon a washed filter paper (Schleicher and Schüll's, No. 589, blue ribbon), and after washing the precipitate with about 250 ml. of cold water the paper and precipitate may be dried in an air bath or over a low flame. The ignition may then be carried out in the usual way in the ordinary platinum or porcelain crucible. In this case correction must be made for the weight of the ash of the filter paper used.

184 Care must be taken in the ignition of precipitates in Gooch crucibles. The flame should never be applied directly to the perjorated bottom or to the sides of the crucible, since such manipulation is invariably attended by mechanical losses. The crucibles should always be provided with lids and tight bottoms during the ignition. In case porcelain Gooch crucibles, whose bottoms are not provided with a nonperforated cap, are used, the crucible may be placed upon the lid of an ordinary platinum crucible during ignition. The lid should be supported on a triangle, the crucible placed upon the lid, and the flame applied to the improvised bottom. Ignition should be complete in 10 minutes if no organic matter is present.

of 25 ml. and the volume of water reduced proportionately. Add 10 ml. of 5 per cent barium chloride slowly, drop by drop, to the cold solution, and from this point proceed as indicated in the method for the determination of Total Sulfates, p. 884.

Calculate the quantity of inorganic sulfates, expressed as S, in the 24-hour urine specimen.

Calculation. Calculate according to the directions given under Total Sulfates, above.

Interpretation. On an average, about 90 per cent of the total sulfates of the urine exists as inorganic sulfates, but the proportion of the sulfates existing in this form varies widely, being greater on a high protein diet than on a very low protein diet. The amount varies with the total sulfates (see p. 885).

3. Ethereal Sulfates: Folin's Method: Principle. The inorganic sulfates are removed with barium chloride and the conjugated sulfates then determined after hydrolysis.

Procedure: Place 125 ml. of urine in an Erlenmeyer flask of suitable size, dilute it with 75 ml. of water, and acidify the mixture with 30 ml. of dilute hydrochloric acid (1 volume of concentrated HCl to 4 volumes of water). To the cold solution add 20 ml. of a 5 per cent solution of barium chloride, drop by drop. 185 Allow the mixture to stand about one hour, then filter it through a dry filter paper. 186 Collect 125 ml. of the filtrate and boil it gently for at least one-half hour. Cool the solution, filter off the precipitate of BaSO₄, wash, dry and ignite it according to the directions given on p. 885.

Calculation. The weight of the BaSO₄ precipitate should be multiplied by 2 since only one-half (125 ml.) of the total volume (250 ml.) of fluid was precipitated by the barium chloride. The remaining calculation should be made according to directions given under Total Sulfates, p. 885.

Calculate the quantity of ethereal sulfates, expressed as S, in the 24-hour urine specimen.

Interpretation. The excretion of ethereal sulfates (expressed as S) varies ordinarily from 0.04 to 0.1 g. per day comprising from 5 to 15 per cent of the total sulfur excretion. The absolute amount of ethereal sulfate increases with increase in the protein of the diet and particularly with increase of putrefactive processes in the intestine or elsewhere. The amount excreted cannot, however, be taken as an index of the extent of intestinal putrefaction.

4. Total Sulfur: 187 Benedict's Method: 188 Principle. The urine is evaporated and ignited with a solution of copper nitrate and potassium chlorate. Organic matter is thus destroyed and all unoxidized sulfur is oxidized to the sulfate form and can be readily precipitated with barium chloride in the usual manner. The method is very convenient and accurate.

¹⁸⁵ See footnote 182, p. 885.

¹⁸⁶ This precipitate consists of the inorganic sulfates. If it is desired, this BaSO₆ precipitate may be collected in a Gooch crucible or on an ordinary quantitative filter paper and a determination of inorganic sulfates made, using the same technique as that suggested above. In this way we are enabled to determine the inorganic and ethereal sulfates in the same sample of urine.

¹⁸⁷ For determination of total sulfur in other biological material, see the method of Stockholm and Koch (p. 588). See also Pollock and Partansky: *Ind. Eng. Chem., Anal. Ed.*, **6**, 330 (1934).

¹⁸⁸ Benedict: J. Biol. Chem., 6, 363 (1909).

Ten ml. of urine are measured into a small (7 to 8 cm.) porcelain evaporating dish and 5 ml.159 of Benedict's sulfur reagent190 added. The contents of the dish are evaporated over a free flame which is regulated to keep the solution just below the boiling point, so that there can be no loss through spattering. When dryness is reached the flame is raised slightly until the entire residue has blackened. The flame is then turned up in two stages to the full heat of the bunsen burner and the contents of the dish thus heated to redness for 10 minutes after the black residue (which first fuses) has become dry. This heating is to decompose the last traces of nitrate (and chlorate). The flame is then removed and the dish allowed to cool more or less completely. Ten to 20 ml. of dilute (1:4) hydrochloric acid are then added to the residue in the dish, which is then warmed gently until the contents have completely dissolved and a perfectly clear, sparkling solution is obtained. This dissolving of the residue requires scarcely two minutes. With the aid of a stirring rod the solution is washed into a small Erlenmeyer flask, 191 diluted with cold, distilled water to 100 to 150 ml., 10 ml. of 10 per cent barium chloride solution added drop by drop, and the solution allowed to stand for about an hour. It is then shaken up and filtered as usual through a weighed Gooch crucible. Controls should be run on the oxidizing mixture.

Calculation. Make the calculation according to directions given under Total Sulfates, p. 885. Calculate the quantity of sulfur expressed as S, present in the 24-hour urine specimen.

Interpretation. The total sulfur excretion averages about 1.0 g. per day, expressed as S. It runs more or less parallel with the decomposition of endogenous and exogenous protein and a definite ratio between the excretion of total N and total S might be expected; however, no constant value can be given. See Total Sulfates.

5. Total Sulfur: Osborne-Folin Method: Principle. This method depends on the destruction of organic matter by means of sodium peroxide. It is employed particularly for the determination of sulfur in foods and feces. Benedict's procedure (see above) is simpler and fully as satisfactory for urine. For details, see the Eleventh Edition of this book.

B. Volumetric Procedures

6. Volumetric Determination of Ethereal and Inorganic Sulfates and Total Sulfur: Fiske's Modification of the Method of Rosenheim and Drummond: Principle. The sulfates of the urine are precipitated by means of benzidine solution, the precipitate of benzidine sulfate being filtered off and the sulfuric acid of the compound titrated with 0.02 N NaOH, using phenolsulfonephthalein (phenol red) as an indicator. This is possible because the benzidine is a very weak

180 If the urine is concentrated, the quantity should be slightly increased	d.
190 Crystallized copper nitrate, sulfur-free or of known sulfur content	200 g.
Sodium or potassium chlorate	50 g.
Distilled water to	1000 ml.
Denis suggested the use of the following solution:	
Copper nitrate	25 g.
Sodium chloride	25 g.
Ammonium nitrate	10 g.
Water to make	100 ml.

The procedure is the same as the above except that 25 ml. of urine and 5 ml. of reagent are taken. It gives accurate results.

¹⁹¹ Sometimes the porcelain glase cracks during heating, in which case the solution should be filtered into the flask.

base and its sulfate readily dissociates. It is necessary that excess of HCl be avoided in the precipitation process. For critical studies of this procedure, see Owen¹⁹² and McKittrick and Schmidt.¹⁹³ Kahn and Lieboff¹⁹⁴ have described a colorimetric method for sulfate based on diazotization of the benzidine sulfate with phenol in alkaline solution.

Procedure:

a. Removal of Phosphate: This step is necessary for the highest accuracy, especially where the proportion of phosphorus to sulfur may be high, as in half-hourly specimens of urine. For 24-hour specimens where the highest accuracy is not desired it may be omitted.

Transfer to a 100-ml. volumetric flask enough urine (usually 10 to 20 ml.) to contain about 10 to 20 mg. of sulfur as sulfate. Dilute to about 50 ml. with water. Add one drop of phenolphthalein solution and then concentrated ammonium hydroxide drop by drop to a faint pink color. Add 10 ml. of 5 per cent ammonium chloride and about 1.5 g. of finely powdered magnesium carbonate. Make to mark, stopper, mix thoroughly by shaking for one minute, and let stand for 30 minutes. Using a dry filter, filter into a dry flask. This filtrate is used for the three following determinations.

b. Inorganic Sulfate: Pipet 5 ml. of the filtrate into a large pyrex test tube with flaring lip. Add 2 drops of a 0.04 per cent alcoholic solution of

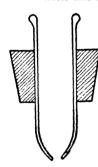

Fig. 278. Filtration tube for sulfur determination (Fiske). 196

bromphenol blue and 5 ml. of water. Add approximately N HCl until the last trace of blue disappears and the solution is yellow. Add 2 ml. of benzidine solution. 195 Let stand for two minutes. Add 4 ml. of 95 per cent acetone and let stand for 10 minutes. Prepare a thin mat of paper pulp in a filtration tube (see Fig. 278). 198 This mat should first be washed with water and then sucked dry. Filter off benzidine sulfate with very gentle suction. Wash down the sides of the test tube with 1 ml. of 95 per cent acetone. transferring to filtration tube. Wash twice more with 1 ml. and finally with 5 ml. of acetone. Add about 2 ml. of water and poke the mat with a wire out through the bottom of the tube into the pyrex test tube, rinsing the wire with a few drops of water. Add 2 to 4 drops of 0.05 per cent water solution of phenol red. Titrate with 0.02 N NaOH (prepared from 0.1 N NaOH by dilution) the solution being kept hot. At the beginning of the titration the filter tube is kept suspended in the mouth of the test tube and the alkali run through the filter tube to dissolve adherent sulfate. Rinse

the inner tube with 2 to 3 ml. of water, heat the solution to boiling so that the tube is further washed with condensed steam, and finally rinse the inner tube with a few ml. more of water and remove. Titrate to a definite pink color that remains after boiling.

Calculation. The sulfate titrates like free sulfuric acid. One ml. of 0.02 N NaOH is equivalent to 0.32 mg. of S. Multiply the buret reading by 0.32 to get mg. of inorganic S in 5 ml. of filtrate.

¹⁹² Owen: Biochem. J., 30, 352 (1936),

¹⁰² McKittrick and Schmidt: Arch. Biochem., 6, 411 (1945).

¹⁹⁴ Kahn and Lieboff: J. Biol. Chem., 80, 623 (1928).

¹⁹⁵ Made by shaking 4 g. of benzidine in about 150 ml. of water in a 250-ml. flask adding 50 ml. of approximately N HCl, shaking until dissolved, and diluting to mark. Filter if necessary.

¹⁸⁶ Made from glass tubing of 15 mm. diameter shrunken at one end to leave an opening 3 mm. in diameter, cut to a length of 7 cm., and flanged at the cut end. A somewhat elon gated tip is desirable.

- c. Total Sulfate (Inorganic and Ethereal): To 5 ml. of filtrate in a 100-ml. beaker add 1 ml. of approximately 3 N HCl. Heat on a water bath to dryness and for 10 minutes longer. Transfer to a pyrex tube with lip using five 2-ml. portions of water, add 2 ml. of benzidine solution, and proceed as in the method for inorganic sulfate. The calculation is the same.
- d. Ethereal Sulfate: Subtract inorganic from total sulfate. The difference is ethereal sulfate.
- e. Total Sulfur: Transfer approximately 0.25 ml. of Benedict's sulfur reagent (see p. 887) and 5 ml. of filtrate to a small evaporating dish (6 cm.). Evaporate carefully to dryness on wire gauze or hot plate. Gradually increase heat, finally igniting at red heat for two minutes over free flams. Let cool for five minutes. Add 1 ml. of 3 N HCl and evaporate to dryness at low heat. The mixture will turn from green to brown. Transfer to a pyrex tube with a lip with the aid of five 2-ml. portions of water. Add 1 drop of N HCl and 2 ml. of benzidine solution. Complete the determination as in the methods above but in place of the first 1-ml. portion of acetone, in washing use 2 ml. of 50 per cent acetone. The calculation is the same as above.
- f. Neutral Sulfur: Subtract from the total sulfur the total sulfate as determined above. The difference is neutral or unoxidized sulfur.

Interpretation. The neutral sulfur of the urine is made up of cystine and related substances, thiocyanate, oxyproteic acids, etc. It makes up ordinarily from 5 to 25 per cent of the total sulfur of the urine, or on the average 0.08 to 0.16 g. per day calculated as S. The absolute amount is fairly constant for a given individual through wide variations of protein intake, indicating that its origin is mainly endogenous, that is, that it arises principally from the decomposition of tissue protein. On this account the percentage of the total sulfur excretion existing in the neutral form may rise to 25 per cent on a very low protein diet and decrease to 5 per cent on a high protein diet, the absolute amount remaining nearly constant. In fasting, percentages as high as 70 have been noted. In many disorders, as tuberculosis, cancer, cystinuria, etc., the amount may be relatively and in some cases absolutely increased, but no fixed relations have been determined for the various conditions.

PHOSPHORUS

1. Determination of Inorganic Phosphate: Method of Fiske and SubbaRow:¹⁹⁷ Principle. Phosphate reacts with molybdic acid to form phosphomolybdic acid. On treatment with 1,2,4-aminonaphthol-sulfonic acid, phosphomolybdic acid is selectively reduced¹⁹⁸ to produce a deep blue color ("molybdenum blue"), which is probably a mixture of lower oxides of molybdenum. This color is then compared in a colorim-

¹⁹⁷ Fiske and SubbaRow: J. Biol. Chem., 66, 375 (1925).

¹⁹⁸ Various other reducing agents have been proposed (see discussion on p. 578), of which stannous chloride has perhaps found most favor. A method using stannous chloride is described in the Eleventh Edition of this book. Stannous chloride has the advantage of being more stable than aminonaphtholsultonic acid solution, and of giving a more intense color, thus permitting the use of smaller volumes of urine. This latter appears to be of little value in urine analysis, and a disadvantage of stannous chloride is that the color produced changes in intensity on standing and may not obey Beer's law, thus requiring careful technical control, particularly in photometric measurement.

eter or photometer with that obtained from a suitable standard phosphate solution treated in the same way.

Procedure: 199 Measure into a 100-ml. volumetric flask enough urine 200 to contain between 0.2 and 0.8 mg. of inorganic phosphorus (usually 1 or 2 ml.). Add water to bring the total volume to about 70 ml., followed by 10 ml. of Molybdate I reagent. Mix by gentle shaking and add 4 ml. of aminonaphtholsulfonic acid reagent. Again mix, dilute to the mark with water, mix several times by inversion, and allow to stand five minutes.

At the same time, transfer to a similar flask 5 ml. of standard phosphate solution, containing 0.4 mg. of phosphorus, 65 ml. of water, and the same reagents that were added to the urine sample, mixing as above. Dilute to the mark with water, mix well by inversion, and allow to stand five minutes. For photometric measurement, prepare a blank solution by treating 70 ml. of water in a 100-ml. flask with the same reagents that are used for the standard and unknown, dilute to the mark with water, and mix by inversion.

For colorimetric measurement, match the standard against itself at 20 mm. and compare the unknown against the standard. For photometric measurement, determine the density of the standard and of the unknown in a photometer at 660 to 720 my, setting the photometer to zero density with the blank.

Calculation. For colorimetric measurement:

```
Reading of Standard Reading of Unknown × 0.4 = mg. of inorganic phosphate (as P) in the volume of urine used
```

An unknown reading between 5 and 40 mm. is acceptable with the standard at 20 mm.; if the unknown reads outside this range, repeat the analysis on a smaller or larger volume of urine. Results are usually expressed in terms of grams (or mg.) of inorganic P per 24-hour volume of urine.

For photometric measurement:

```
Density of Unknown Density of Standard × 0.4 = mg. of inorganic phosphate (as P) in the volume of urine used
```

In a 1-cm. cuvette, and at 660 m μ , the density of the standard is approximately 0.500 (see Fig. 182, p. 580). Under these conditions, up to 0.8 mg. of phosphorus may be accurately determined. If larger amounts are present, or if a deeper cuvette is used, the determination is carried out on a smaller portion of urine (and standard, if necessary) and the calculations are corrected accordingly.

Interpretation. The excretion of phosphoric acid is extremely variable but on the average the total output for the 24 hours is about 1.1 g. expressed as P, mainly in the form of phosphates. The greater part of the phosphate excretion arises from the ingested food, either from the preformed phosphates or more especially from the organic combinations as phospho- and nucleoproteins. The excretion is consequently very largely dependent upon the phosphorus content of the diet. Some of the phosphoric acid results from the breakdown of the tissues of the body, and this endogenous phosphoric acid excretion is increased in conditions of

199 The resgents required, and the standard phosphate solution, are described on p. 579 in connection with the determination of blood inorganic phosphate.

²⁰⁶ If albumin is present and the addition of molybdate produces a turbidity, treat the urine with 4 volumes of 10 per cent trichloroacetic acid, stopper, shake and filter, and repeat the determination using 2 to 10 ml. of filtrate. If very low in phosphate so that more than 10 ml. of filtrate must be used, follow the method for blood filtrates (see p. 579).

increased metabolism as in fevers. The findings in pathological conditions have been somewhat contradictory due to lack of control of diet. The so-called "phosphaturias" nearly always represent decreased acidity and not increased phosphate content of the urine. Such conditions are, however, significant as indicating a possible tendency to the formation of phosphatic calculi.

2. Total Phosphates: Uranium Acetate Method: Principle. Standard uranium acetate is run into a measured quantity of urine until all of the phosphate has been precipitated as insoluble uranium phosphate. An excess of uranium is indicated by a reddish coloration with potassium ferrocyanide. This method is accurate and gives practically the total phosphorus of urine inasmuch as the latter exists generally almost entirely as phosphates.

Procedure: To 50 ml. of urine in a small beaker or Erlenmeyer flask add 5 ml. of a special sodium acetate solution²⁰¹ and heat the mixture to the boiling point. From a buret, run into the hot mixture, drop by drop, a standard solution of uranium acetate²⁰² until a precipitate ceases to form and a drop of the mixture when removed by means of a glass rod and brought into contact with a drop of a solution of potassium ferrocyanide²⁰³ on a porcelain test tablet produces instantaneously a brownish-red coloration. Take the buret reading and calculate the P content of the urine under examination.

Calculation. Multiply the number of ml. of uranium acetate solution used by 0.002 to determine the number of grams of P in the 50 ml. of urine used. To express the result in percentage of P, multiply the value just obtained by 2, e.g., if 50 ml. of urine contained 0.074 g. of P, it would be equivalent to 0.148 per cent.

3. Total Phosphorus: Principle. Although urine phosphorus exists almost entirely as inorganic phosphate and the determination as such is usually sufficient, a strictly total phosphorus determination requires the destruction of organic matter. This is brought about by heating with sulfuric acid and hydrogen peroxide. The determination is otherwise the same as for the colorimetric determination of inorganic phosphate.

Procedure: Place sufficient urine to contain between 0.2 and 0.8 mg. of total phosphorus (usually 1 to 2 ml.) in a large pyrex test tube (200 by 25 mm.), add 10 ml. of 5 N sulfuric acid (or 5 ml. of 10 N acid), and a quartz chip to prevent bumping. Heat over a micro-burner or on an electric hot plate

²⁰¹ The sodium acetate solution is prepared by dissolving 100 g. of sodium acetate in 800 ml. of distilled water, adding 100 ml. of 30 per cent acetic acid to the solution, and making the volume of the mixture up to 1 liter with water.

water with the aid of heat and 3 to 4 ml. of glacial acetic acid. Let stand a few days and filter. Standardize against a phosphate solution containing 0.002 g. of P per ml. For this purpose dissolve 13.480 g. of pure air-dry sodium ammonium phosphate (NaNH,HPO4 + 4H₂O) in water to make a liter. To 20 ml. of this phosphate solution in a 200-ml. beaker add 30 ml. of water and 5 ml. of sodium acetate solution (see above) and titrate with the uranium solution to the correct end-reaction as indicated in the method above. If exactly 20 ml. of uranium solution are required 1 ml. of the solution is equivalent to 0.002 g. of P. If stronger than this, dilute accordingly and check again by titration.

²⁰³ A 10 per cent solution of potassium ferrocyanide is satisfactory. Cochineal in 30 per cent alcohol may be used as an indicator. It is added directly to the urine after the uranium acetate titration produces no further precipitate. A green color is the end-reaction. The use of cochineal is more convenient but rather less accurate than the procedure involving

the use of the ferrocyanide.

until the water has been driven off and a dark brown fluid remains. Add 30 per cent hydrogen peroxide²⁰⁴ by drops as necessary to complete oxidation of organic matter and leave a colorless solution, heating to boiling momentarily between drops. The hydrogen peroxide should be allowed to drop directly into the tube contents and not run down the sides of the tube. When oxidation is complete, cool slightly, add 2 to 3 ml. of water, and boil for two to three minutes to ensure hydrolysis of meta- or pyrophosphate. Cool, and transfer quantitatively with rinsings to a 100-ml. volumetric flask. Make up to about 70 ml. with water and add 10 ml. of a 2.5 per cent solution of ammonium molybdate in water. Mix and add 4 ml. of the aminonaphtholsulfonic acid reagent used for the determination of inorganic phosphate (p. 889). Dilute to 100 ml. with water and mix. The remaining procedure (including standard and calculations) is exactly as described for the determination of inorganic phosphate.

4. Total Phosphorus: Neumann's Procedure: Principle. The organic matter is destroyed by digestion with a mixture of sulfuric and nitric acids or some other oxidizing agent. The phosphorus is then precipitated as the phosphomolybdate and determined gravimetrically or volumetrically.

Preparation of the Solution: Pipet 10 ml. of urine (or an amount of substance containing about 10 mg. of P) into a Kjeldahl flask. Add 10 ml. of a mixture of equal parts of concentrated H₂SO₄ and concentrated HNO₃. Digest over a low flame until red fumes cease to come off. If the mixture darkens due to the charring action of the sulfuric acid, add nitric acid from a separatory funnel a few drops at a time and continue the digestion. When the mixture remains clear on evaporation to the point where white sulfuric fumes come off, the digestion is completed by heating for 10 to 15 minutes longer. Cool and transfer the solution to a 400-ml. Erlenmeyer flask with the aid of enough water to make a total volume of about 75 ml.²⁰⁵

Instead of oxidizing the material as described above it may be ignited with magnesia to destroy organic matter. About 2 g. of the solid substance or 25 ml. of urine (previously evaporated nearly to dryness) are mixed with a little more than an equal bulk of magnesium oxide in a porcelain dish of about 30 ml. capacity. Five ml. of magnesium nitrate solution (see Appendix) are added and the mixture heated very gently at first, then gradually to bright redness. The mixture is cooled and transferred with water to a 250-ml. flask. An excess (20 to 30 ml.) of HCl are added and the mixture boiled a few minutes. Remove from the flame and add at once enough barium chloride solution to precipitate any sulfate present. Cool, make to mark, filter, and take an aliquot for analysis.

Precipitation of the Phosphomolybdate: Neutralize the solution with ammonia, make slightly acid with nitric acid, and add 15 g. of ammonium nitrate in substance (or 25 ml. of a 60 per cent solution). Heat on a water bath to 60° to 65° C. (not higher) and add 30 to 40 ml. of molybdate solution, 206 stir and let stand for about 15 minutes at 60° to 65°. Filter at once through a small paper, 207 washing the precipitate twice by decantation

²⁰⁴ Merck's Blue Label or "Special" Reagent is satisfactory.

²⁰⁵ In the case of urine it is possible to neutralize this acid solution with ammonia, make it acid with acetic acid, and titrate with uranium acetate as in the preceding method.

²⁰⁶ Made by adding 5 ml. of concentrated HNO₃ to 100 ml. of the ordinary molybdate solution (see Appendix).

³⁰⁷ It is better to use a special filter tube of about 1½ inches diameter (similar to a Gooch filtering tube) in which is placed a perforated porcelain plate 1½ inches in diameter, covered with a layer of asbestos ½ inch thick. Filtration is carried out with suction and is very rapid. Ordinary Gooch crucibles lined with asbestos may also be used but are not so satisfactory. The asbestos used should be specially prepared (see Appendix). For a good discussion of the details of procedure and sources of error of this volumetric method, see Hibbard: J. Ind. Bng. Chem., 5, 998 (1913).

with 1 per cent potassium nitrate solution, using about 25 ml. each time, stirring up the precipitate well in each case, and allowing to settle. Transfer the precipitate to the filter and wash with 1 per cent potassium nitrate solution until two fillings of the filter (collected separately) do not greatly diminish the color produced with phenolphthalein by 1 drop of the standard alkali.

Titration of the Phosphomolybdate: Transfer the precipitate and filter back to the original beaker and dissolve in a small excess of 0.2 N NaOH (about 2 to 3 ml. more than required to completely dissolve the yellow precipitate). Add about 100 ml. of boiled and cooled water and a few drops of phenol-phthalein as an indicator (a red color should be observed indicating excess of NaOH) and titrate the excess of NaOH with 0.1 N acid.

Calculation. Divide the number of ml. of 0.1 N acid required by 2 and subtract from the number of ml. of 0.2 N NaOH used. This gives the number of ml. of 0.2 N NaOH required. Multiply by 0.270 (the equivalent of 1 ml. of 0.2 N NaOH in P) and obtain the number of mg. of P in 10 ml. of the urine analyzed. Calculate the daily output of P in this case from the 24-hour volume.

Interpretation. Nearly all of the phosphorus of the urine exists as inorganic phosphates. Consequently the total phosphorus of urine varies in the same way as total phosphates (q.v.). A small portion of the phosphorus of the urine may exist in organic combination, though never in a reduced form. This organically bound phosphate may amount to from 1 to 1 per cent of the total phosphorus excretion. Little is known with regard to the compounds in which it occurs. Possibly some glycerophosphoric acid may occur either free or as lecithin.

Gravimetric Modification: The phosphorus may be determined somewhat more accurately by substituting a gravimetric procedure for the above titration. In this case the washed phosphomolybdate precipitate is dissolved on the filter paper with ammonium hydroxide and hot water to make a volume of not more than 100 ml. Nearly neutralize with HCl, cool, and add about 10 ml. of magnesia mixture (see Appendix) from a buret. Add slowly (about 1 drop per second), stirring vigorously. After 15 minutes add 12 ml. of ammonium hydroxide solution (sp. gr. 0.90). Let stand for some time (two hours is usually enough), then filter and wash the precipitate with 2.5 per cent ammonia until practically free from chlorides. Ignite to whiteness or to a grayish-white ash and weigh. Multiply the weight of magnesium pyrophosphate thus obtained by 0.279 to get the weight of P.

Calculation. Calculate as explained above.

CHLORIDES

1. Volhard-Arnold Method: Principle. The urine is acidified with nitric acid and the chlorides precipitated with a measured excess of standard silver nitrate solution. The silver chloride formed is filtered off and in the filtrate the excess silver nitrate is titrated back with standard ammonium thiocyanate solution. Ferric ammonium sulfate is used as an indicator. A red color due to the formation of ferric thiocyanate indicates that an excess of thiocyanate is present and that the end-point has been reached.

Procedure: Place 10 ml. of urine in a 100-ml. volumetric flask, add 20 to 30 drops of nitric acid (sp. gr. 1.2) and 2 ml. of a cold saturated solution of ferric alum. If necessary, at this point a few drops of 8 per cent solution of potassium permanganate may be added to dissipate the red color. Now slowly

run in a known volume of the standard silver nitrate³⁰⁸ solution (20 ml. is ordinarily used) in order to precipitate the chlorine and insure the presence of an excess of silver nitrate. The mixture should be continually shaken during the addition of the standard solution. Allow the flask to stand 10 minutes, then fill it to the 100-ml. graduation with distilled water and thoroughly mix the contents. Now filter the mixture through a dry filter paper, collect 50 ml. of the filtrate, and titrate it with standardized ammonium thiocyanate solution.²⁰⁹ The first permanent tinge of red-brown indicates the end-point. Take the buret reading and compute the weight of sodium chloride in the 10 ml. of urine used.

Calculation. The number of ml. of ammonium thiocyanate solution used indicates the excess of standard silver nitrate solution in the 50 ml. of filtrate titrated. Multiply this reading by 2, inasmuch as only one-half of the filtrate was employed, and subtract this product from the number of ml. of silver nitrate (20 ml.) originally used, in order to obtain the actual number of ml. of silver nitrate utilized in the precipitation of the chlorides in the 10 ml. of urine employed.

To obtain the weight in grams of the sodium chloride in the 10 ml. of urine used, multiply the number of ml. of the standard silver nitrate solution actually utilized in the precipitation, by 0.010. If it is desired to express the result in percentage of sodium chloride, move the decimal point one place to the right; for results in terms of grams of sodium chloride per liter of urine, move the decimal point two places to the right.

In a similar manner the weight, or percentage of chlorine may be computed using the factor 0.006 instead of 0.010.

To express results in terms of milliequivalents of chloride per liter of urine, multiply the number of milliliters of standard silver nitrate required for the chloride in 10 ml. of urine by the factor 17.1.

Calculate the quantity of sodium chloride and chlorine in the 24-hour urine specimen.

Interpretation. From 10 to 15 g. of chlorine, expressed as sodium chloride (170 to 250 milliequivalents of chloride), are excreted per day, on the average, by normal adults. The amount is, however, closely dependent upon the chloride content of the food ingested. In fasting, the chloride excretion falls rapidly to a very minimal quantity. On high water ingestion it is increased. In pneumonia and certain other acute infectious diseases the excretion of chlorides may be markedly diminished, particularly during the periods in which exudates are forming. In convalescence and with resolution of the exudates the chlorine excretion rises again. A decrease has also been noted in nephritis associated with edema.

2. Volhard-Harvey Method: Principle. This procedure²¹⁰ differs from the Volhard-Arnold method in that the excess of silver nitrate is

²⁰⁸ Standard silver nitrate solution may be prepared by dissolving 29.061 g. of silver nitrate in 1 liter of distilled water. Each ml. of this solution is equivalent to 0.010 g. of sodium chloride or to 0.006 g. of chlorine.

³⁰⁹ This solution is made of such a strength that 1 ml. of it is equal to 1 ml. of the standard silver nitrate solution used. To prepare the solution dissolve 13 g. of ammonium thiocyanate, NH₃CN, in a little less than a liter of water. In a small flask place 20 ml. of the standard silver nitrate solution, 5 ml. of the ferric alum solution, and 4 ml. of nitric acid (sp. gr. 1.2), add water to make the total volume 100 ml., and thoroughly mix the contents of the flask. Now run in the ammonium thiocyanate solution from a buret until a permanent red-brown tinge is produced. This is the end-reaction and indicates that the last trace of silver nitrate has been precipitated. Take the buret reading and calculate the amount of water necessary to use in diluting the ammonium thiocyanate in order that 10 ml. of this solution may be exactly equal to 10 ml. of the silver nitrate solution. Make this dilution and titrate again to be certain that the solution is of the proper strength.

*10 For details, see the Eleventh Edition of this book.

titrated directly without filtering and hence in the presence of the silver chloride. The procedure is thus more rapid but the end-point is more difficult to determine, and the results are not so exact. It is therefore not recommended.

3. Method of Sendroy, Modified by Van Slyke and Hiller:²¹¹ Principle. This is an application to urine of the blood chloride method described on p. 575. The urine is shaken with solid silver iodate; chloride present forms insoluble silver chloride and an equivalent amount of soluble iodate. After removing insoluble material, the iodate in solution is converted to free iodine, which is then titrated with standard thiosulfate. The method is recommended because of its simplicity and accuracy.

Procedure: ²¹² Treat 1 ml. of urine with 25 ml. of phosphoric-tungstic acid reagent and shake with silver iodate, exactly as described for the analysis of 1 ml. of plasma or serum on p. 576. After filtration or centrifugation, treat 10 ml. of the filtrate or centrifugate with sodium iodide and titrate the liberated iodine with 0.02308 N thiosulfate solution, likewise as described on p. 576.

Calculation. The thiosulfate is of such strength that, at the dilution of urine employed, 1 ml. is equivalent to 10 milliequivalents of chloride per liter of urine. Therefore,

Ml. of 0.02308 N thiosulfate required × 10 = milliequivalents of chloride per liter of urine

To express results in terms of grams of sodium chloride per liter, since 1 milliequivalent of chloride equals 0.0585 g. of sodium chloride, multiply the results of the above calculation by 0.0585.

If the chloride content of the urine is so low that less than 5 ml. of thiosulfate are required for the titration, repeat the analysis, using 5 ml. of urine and 25 ml. of phosphoric-tungstic acid reagent. Shake with iodate and titrate a 10-ml. portion of filtrate as before, and calculate as follows:

Ml. of 0.02308 N thiosulfate required × 2.31 = milliequivalents of chloride per liter of urine

Multiply the result by 0.0585 as above to express in terms of grams of sodium chloride per liter.

Interpretation. See p. 894.

TOTAL FIXED BASE

Method of Fiske:²¹³ Principle. The fixed bases sodium, potassium, calcium, and magnesium are converted into sulfates and the combined sulfuric acid titrated by the benzidine method.

Procedure: Measure into a large lipped test tube (200 by 20 mm.) a sample of urine containing preferably between 10 and 25 mg. of NaCl but not more than 5 mg. of inorganic phosphorus. Add 1 ml. of approximately 4 N sulfuric acid and 0.5 ml. of concentrated nitric acid, and boil down until white fumes appear. If the residue does not soon become colorless after this stage

²¹² Reagents Required: See method for blood chlorides, p. 576.

²¹¹ Personal communication.

²¹³ Fiske: J. Biol. Chem., 51, 55 (1922). See also method of Stadie and Ross: J. Biol. Chem., 65, 735 (1925) and comment of Brown and Shohl: J. Biol. Chem., 91, 745 (1931). A simple and accurate method for the determination of total fixed base by electrolysis is described by Consolazio and Talbot: J. Biol. Chem., 132, 753 (1940).

has been reached, cool slightly, add a few more drops of nitric acid, and continue the heating. When the remaining drop of sulfuric acid has become clear and colorless, let cool for a few minutes, and wash into a test tube which is marked at 25 ml., with four 2-ml. portions of water. Add a drop of saturated alcoholic solution of methyl red. Neutralize with powdered ammonium carbonate until the color of the indicator just begins to change, and restore the pink color by adding 4 N sulfuric acid 1 drop at a time. Heat to boiling and add more acid to restore the pink color if this is necessary. Add a 10.5 per cent solution of ferric chloride crystals in 0.2 N HCl in the proportion of 0.1 ml, for each mg, of inorganic phosphorus present, shake and run in 1 ml. of a 5 per cent solution of ammonium acetate. Add sufficient water to make the total volume 10 or 11 ml., heat again to boiling, and dilute to the 25-ml. mark with cold water. Insert a rubber stopper and mix by inverting a few times. Filter at once through a dry 9-cm. ashless paper into a dry test tube. Keep the filter nearly filled with liquid as long as possible and collect only 20 ml. Stopper the tube containing filtrate and cool. The phosphate has now been removed.

Transfer 5 ml. of filtrate to a small platinum dish, add 1 ml. of approximately 4 N sulfuric acid, and evaporate on the water bath until nearly dry. Place the dish on a metal triangle and heat cautiously at first over a microburner, gradually raising the flame until fumes have ceased to come off. Let cool, sprinkle over the residue a little powdered ammonium carbonate, and ignite again, finally raising the flame to its maximum and moving the triangle about until each part of the dish has been momentarily subjected to a dull red heat. When the dish has cooled, add 2 ml. of water. Agitate until the residue has dissolved, using a rubber-tipped rod to assist in solution if necessary. Transfer the contents of the dish to a large lipped pyrex test tube, rinsing four times with 2-ml. portions of water. Determine the sulfate according to the benzidine method (see p. 887).

Calculation. An aliquot of one-fifth of the original urine was used for the determination and 0.02 N NaOH in the titration. Therefore the titration reading is equivalent to the number of ml. of 0.1 N fixed base in the sample of urine used. Subtract a correction of 1 per cent for the contraction of the warm solution during the filtration stage. Results are usually expressed in terms of milliequivalents of total fixed base per liter; this is obtained by dividing by 10 the number of ml. of 0.1 N base per liter.

Interpretation. The total fixed base excretion, combining as it does the sodium, potassium, calcium, and magnesium excretions, (q.v.), will be influenced by factors affecting any of these. In acidosis, volatile base (ammonia) plays a large part in neutralization but the fixed base excretion is also increased in varying degrees.

CALCIUM

Determination of Calcium: Method of Shohl and Pedley:²¹⁴ Principle. The urine is oxidized with ammonium persulfate. Calcium is precipitated as oxalate and titrated with potassium permanganate. The method is more rapid than the gravimetric.

Procedure: To 100 ml. of unfiltered urine in a 250-ml. Erlenmeyer flask add 5 ml. of concentrated HNO₂ or H₂SO₄ and one spoonful (containing 3 to 4 g.) of ammonium persulfate. Insert a funnel in the flask to prevent spattering. Boil and keep near the boiling point on a hot plate or over a low flame for

²¹⁴ Shohl and Pedley: J. Biol. Chem., 50, 537 (1922). For references to various other procedures upon which the determination of calcium may be based, see the section on blood calcium methods in Chapter 23.

1 hour or until reduction of the persulfate is complete, as evidenced by an absence of frothing when the flask is agitated. The solution at this point is pale green in color. Add 10 ml. of 2.5 per cent oxalic acid. Cool to room temperature. Neutralize with ammonium hydroxide, using one drop of methyl red as an indicator. Cool to room temperature. If the color is now red, add a few drops of ammonia to bring to intermediate color between red and yellow (pH 4.8 to 5.2). Let stand overnight. Filter. Whatman No. 50 hardened filter paper 12.5 cm. is satisfactory. Wash precipitate and flask three times with distilled water,215 filling the filter two-thirds full each time and allowing to drain. Break a hole in the filter paper and wash back the precipitate into the original flask, first with distilled water and then with hot dilute sulfuric acid, bringing the volume to about 100 ml. Add 10 ml. of concentrated sulfuric acid and heat to 70° to 80° C. Titrate with 0.05 N potassium permanganate, taking as an end-point the first color that persists 15 to 30 seconds. One ml. of 0.05 N KMnO₄ = 0.0010 g. of Ca.

Interpretation. The average urinary excretion of calcium by normal adults lies between 0.1 to 0.3 g. (expressed as Ca) per day. This corresponds to 5 to 15 milliequivalents of calcium ion. Calcium excretion in the urine is dependent very largely upon the amount of calcium in the diet. From 10 to 40 per cent of the ingested calcium ordinarily is excreted by this channel, the greater part being eliminated by the feces. The proportion is dependent particularly on the amount of calcium in the food. If the calcium ingestion is very high, the per cent of the total excretion taking place by way of the kidneys will be low, and vice versa. As excretion takes place by way of the intestine as well as by the kidneys, no conclusions can be drawn from urinary analyses alone. The excretion of calcium may be greatly increased in certain bone disorders as osteomalacia. In others, as in rickets, the urinary excretion may be very low. For further discussion, see p. 752.

The calcium content of the urine is of clinical significance in connection with the formation of certain calcium-containing stones. According to Shorr,²¹⁶ measures designed to decrease the amount of calcium (and of phosphate) in the urine, or to increase the solubility of calcium as by promoting the urinary excretion of citrate (which forms a soluble complex with calcium) should prove to be of value in the management of nephrolithiasis due to stones of the calcium-carbonate and calcium-phosphate types.

CALCIUM AND MAGNESIUM

McCrudden's Methods: Principle. Urine contains magnesium, phosphates, and a small amount of iron, each of which will interfere with the accurate determination of its calcium content if proper conditions of acidity are not maintained during the precipitation. In the following method the proper acidity is attained through the use of sodium acetate and hydrochloric acid, and this with slow addition of the ammonium oxalate reduces the danger of occlusion of magnesium oxalate, calcium phosphate, or ferric phosphate in the calcium oxalate precipitate.

²¹⁶ See footnote 223, p. 590.

^{\$16} Shorr: J. Urol., 53, 507 (1945).

The calcium oxalate precipitate is either ignited and weighed as CaO or determined volumetrically by titration with potassium permanganate. Magnesium is determined in the filtrate from the calcium determination after destruction of the organic matter. It is determined in the usual way by ignition of the magnesium ammonium phosphate precipitate and weighing as the pyrophosphate.

Procedure for Calcium: If the urine is alkaline, make it neutral or slightly acid and filter. Take 200 ml. of the filtered urine for analysis. If it is only faintly acid to litmus paper, add 10 drops of concentrated hydrochloric acid (sp. gr. 1.20). If the urine is strongly acid, it may be made just alkaline with ammonia and then just acid with hydrochloric acid, after which the 10 drops of concentrated hydrochloric acid are added. Then add 10 ml. of 2.5 per cent oxalic acid. Run in slowly with stirring 8 ml. of 20 per cent sodium acetate. Allow to stand over night at room temperature or shake vigorously for 10 minutes. Filter off the precipitate of calcium oxalate on a small paper, and wash free from chlorides with 0.5 per cent ammonium oxalate solution. The precipitate may then be dried, ignited to constant weight, and weighed as calcium oxide, or it may be manipulated volumetrically as described below.

Volumetric Procedure: If free from uric acid, the calcium oxalate precipitate may be washed three times with distilled water, filling the filter about two-thirds full and allowing it to drain completely before adding more. A hole is made in the paper and the calcium oxalate washed into a clean flask. The volume of the fluid is brought up to about 50 ml. and 10 ml. of concentrated sulfuric acid added. Titrate with standard potassium permanganate solution to a pink color which endures for at least a minute.

Calculation. In the gravimetric procedure, convert the weight of CaO into terms of Ca by multiplying by 0.715. In the volumetric procedure, one ml. of 0.1 N permanganate solution is equivalent to 2.0 mg. of Ca. Calculate the daily output of calcium.

Procedure for Magnesium: Transfer the filtrate from the determination of calcium as above to a porcelain dish, add about 20 ml. of concentrated nitric acid, and evaporate to dryness. Heat the residue over a free flame until the ammonium salts are destroyed and the residue fuses. After cooling, take the residue up with water and a little hydrochloric acid and filter if necessary. Dilute to about 80 ml., nearly neutralize with ammonia, and cool. Add a slight excess of sodium acid phosphate and then ammonia drop by drop with constant stirring until the solution is alkaline, and then add enough more slowly with constant stirring to make the solution contain one-fourth its bulk of dilute ammonia (sp. gr. 0.96). Allow to stand overnight. Filter and wash free from chlorides with alcoholic ammonia solution (1 part alcohol, 1 part dilute ammonia, 3 parts water). The precipitate with filter paper is incinerated slowly and carefully with a good supply of air to prevent reduction, in the usual manner, and ignited and weighed as the pyrophosphate.

Calculation. To obtain the weight of Mg, multiply the weight of magnesium pyrophosphate by 0.2184.

Interpretation. The daily excretion of magnesium by way of the urine usually amounts to between 0.05 and 0.2 g. (expressed as Mg). This amount corresponds to 4 to 20 milliequivalents of magnesium ion per day. The amount depends mainly upon the diet. Usually less than 50 per cent of the excreted magnesium is eliminated by the kidneys, the major portion passing out in the feces. The proportion varies, however, and it is impossible to draw any conclusions from the urinary output alone. There

may be a retention of magnesium in certain bone disorders accompanying a loss of calcium; in osteomalacia for example. Thus the excretions of calcium and magnesium do not necessarily run parallel.

Determination of Calcium in Ash of Foods or Feces: 217 Ignite the material in a crucible to a white ash and dissolve the ash with the aid of a little hydrochloric acid. Bring the volume of the ash solution to 75 to 150 ml. Make just alkaline with strong ammonia added drop by drop (using litmus paper or alizarin as an indicator). Add concentrated HCl drop by drop until just acid to litmus. Then add 10 drops of concentrated HCl (sp. gr. 1.20), and 10 ml. of 2.5 per cent oxalic acid. Either of two procedures may then be followed. (a) The solution is boiled until the precipitated calcium oxalate is coarsely crystalline, and then an excess of 3 per cent ammonium oxalate is slowly added to the boiling solution and the boiling continued until any further precipitate is coarsely crystalline. (If but little calcium is present. nothing will precipitate at this point and it is not necessary to add oxalate.) Or (b) the flask closed with a rubber stopper is shaken vigorously for 10 minutes. An excess of 3 per cent ammonium oxalate is then added. Cool to room temperature. Add 8 ml. of 20 per cent sodium acetate solution. (In case of ash of feces add 15 ml.) The solution may either be (a) allowed to stand overnight or (b) stoppered and vigorously shaken for 10 minutes, The calcium oxalate is filtered off on a small ash-free paper and washed free from chlorides with 0.5 per cent ammonium oxalate solution. Either of two procedures may next be followed. (a) The precipitate and filter are dried, and burned in a platinum or porcelain crucible to constant weight as CaO. (b) The precipitate is washed three times with cold distilled water. as given under the method for urine and the oxalate titrated with potassium permanganate.

Magnesium is determined in the filtrate from calcium just as given above.

SODIUM AND POTASSIUM

Determination of Combined Sodium and Potassium:218 From 50 to 100 ml. of urine, depending upon the specific gravity, are oxidized in a Kjeldahl flask with nitric and sulfuric acids as in the Neumann procedure for total phosphorus (see p. 892). To remove the sulfuric acid as completely as possible, transfer with the aid of a little water to a platinum dish219 and evaporate to dryness over a free flame. (The alkalies are in the form of sulfate and do not volatilize.) Dissolve the residue in hot water with the aid of a little dilute hydrochloric acid. Heat to boiling and add barium chloride solution until no more precipitate forms. While still hot, add an excess of ammonia and ammonium carbonate. The barium chloride precipitates the sulfates and part of the phosphates; the ammonia in the presence of excess barium precipitates the rest of the phosphates, and the carbonate precipitates the calcium and most of the magnesium, as well as the excess barium. Filter and wash the precipitate well with hot water containing a few drops of ammonia. Evaporate the filtrate and washings to dryness and heat the residue to dull redness for a moment. Redissolve

²¹⁷ For another procedure for the determination of calcium in tissues and other biological materials, see p. 593. (Corley and Denis: *J. Biol. Chem.*, 66, 601 (1925).) For determination of Ca, Mg, and P in materials such as hay and cow feces which contain much acid-insoluble material, see Morris, Nelson, and Palmer: *Ind. Eng. Chem.*, Anal. Ed., 3, 164 (1931).

²¹⁸ For a method for direct quantitative determination of sodium, potassium, calcium, and magnesium in urine and feces, see Tisdall and Kramer: J. Biol. Chem., 49, 1 (1921). The "flame photometer" (see p. 482) of Barnes, Richardson, Berry, and Hood (Ind. Eng. Chem., Anal. Ed., 17, 605 (1945)) is being successfully used in many laboratories for the simple and accurate separate determination of urinary sodium and potassium.

319 Wilson (J. Biol. Chem., 50, 301 (1922)) suggests the use of inexpensive tin dishest instead of platinum.

instead of platinum.

in water and treat again with ammonia and ammonium carbonate to remove any remaining alkaline earth metals. Filter and wash as before. Transfer the filtrate and washings to a weighed platinum dish, add a few drops of hydrochloric acid, and evaporate to dryness. Heat the residue gently to remove ammonium salts and then to dull redness for a moment. Desiccate and weigh. Reheat to constant weight which represents the combined chlorides of sodium and potassium. The reagents used in the determination must be tested and found free from alkali metals or a correction made for the alkali metals present in the reagents used. The sodium is determined by difference after potassium has been estimated by the method given below.

Potassium: Dissolve the alkali chlorides from the preceding determination in a little water and add a slight excess of 10 per cent platinic chloride over that necessary to precipitate all of the alkali present calculated as sodium chloride (about 17 ml. being required for each gram of sodium chloride). Evaporate to a syrupy consistency on the water bath and add about 50 ml. of 80 per cent alcohol. Stir occasionally for a few minutes. This operation must be carried out in the absence of ammonia vapors. Filter through a weighed Gooch crucible, washing the precipitate with 80 per cent alcohol first thoroughly by decantation and then on the filter, for some time after the filtrate is colorless. Dry at 110° to 115° C. and weigh.

Calculation. Multiply the weight of potassium platinic chloride by 0.1608 to obtain the amount of K present. Express as KCl by using instead of this factor the factor 0.3067. Subtract from the weight of total alkali chlorides as determined in the preceding method, the weight of potassium chloride as calculated and obtain the amount of sodium chloride present. To convert sodium chloride into sodium, multiply by 0.3934. To express the sodium (or potassium) content in terms of milliequivalents, divide the weight of NaCl (or KCl) in grams by 0.05845 (or 0.07455).

Interpretation. The average alkali excretion of an adult on a mixed diet is about 1.5 to 2.5 g. of potassium expressed as K (40 to 65 milliequivalents), and 3.0 to 4.5 g. of sodium expressed as Na (130 to 200 milliequivalents). The ratio of Na to K is thus about 5:3. Both the ratio and the absolute amounts of these elements excreted are, however, largely dependent upon the salt content of the diet. The urine during fasting contains more potassium than sodium salts, because of the noningestion of sodium chloride and the accompanying destruction of potassium-containing body tissues. The excretion of the bases, particularly K, may be increased in fevers and in acidosis.

IRON

Methods of Elvehjem and Kennedy. The urine is ashed, the ash dissolved, and the iron present determined colorimetrically as thiocyanate.

Procedure: Evaporate and ash 100 ml. of urine and carry out iron determination according to Elvehjem or Kennedy (see p. 600).

IODINE

Method of Von Fellenberg:²²⁰ Principle. For discussion of the principle, see the determination of iodine in blood. McCullagh²²¹ has suggested a simpler procedure for iodine determinations in blood and other materials (see p. 605).

²³¹ McCullagh: J. Biol. Chem., 107, 35 (1934).

²²⁰ The method given is a modification by Lunde: Biochem. Z., 193, 94 (1928).

Procedure: To 10 to 40 ml. of urine add 1 to 3 ml. of a saturated solution of iodine-poor K₂CO₃ and evaporate in a low iron dish (about 10 cm. diameter). Heat gently without igniting, moisten with water, and ignite, not bringing the bottom of the dish to redness. Extract the charred mass with a little water and filter. Ignite the paper and residue, then add the filtrate (only faintly yellow) and a few drops of 10 per cent NaNO₃ and complete ignition. The residue should be pure white. Extract four times with 2 to 3 ml. of alcohol. Evaporate the alcoholic solution in a gold or platinum dish (about 6 cm. diameter) on a water bath to dryness, after adding a few drops of saturated K₂CO₃ solution. Ignite gently. Extract again with 95 per cent alcohol and evaporate and ignite, this time adding no K₂CO₃. The bottom of the dish must not turn red. Dissolve the residue in 0.3 ml. of water and titrate iodine according to the method of McCullagh (p. 605) or according to the procedure of v. Fellenberg.²²² The amount of iodine eliminated in 24 hours may be from 10 to 200 γ (1 γ = 0.001 mg.).

For the determination of urinary 17-ketosteroids, see Chapter 26. For the determination of various vitamins in urine, see Chapter 35. See also the references to methods for blood analysis (Chapter 23) since many of these are equally suitable for urine.

TESTS FOR KIDNEY EFFICIENCY

1. Blood Urea Clearance: Method of Möller, McIntosh, and Van Slyke:²²³ Principle. By blood urea clearance is meant the efficiency with which the kidney excretes urea. Results are expressed either in terms of the volume of blood in ml. which is completely cleared of urea per minute, or more commonly as the percentage of the average normal value which this volume represents. The necessary data include the concentration of urea in blood and urine and the volume of urine excreted in unit time.

Procedure: The patient is permitted to eat a moderate meal (usually breakfast) without coffee. Vigorous exercise is avoided and after breakfast the patient is kept at rest during the two-hour test period. At the beginning

²²² Von Fellenberg: Ergeb. Physiol., 25, 176 (1926); Biochem. Z., 224, 170 (1930). Lunde, Closs, and Pedersen: Biochem. Z., 206, 261 (1929).

²²³ Möller, McIntosh, and Van Slyke: J. Clin. Invest., 6, 427 (1928). See also Van Slyke and Cope: Proc. Soc. Exptl. Biol. Med., 29, 1169 (1932).

of the test period, the bladder is emptied and the urine discarded. The patient is given a glass of water to drink, and the urine is collected in two succeeding periods of one hour each. At the beginning of the second period, the patient is given another glass of water, and a sample of blood is drawn for urea determination. At the close of the test, the volumes of urine passed during each period are accurately measured in graduated cylinders, and the urea content of each determined separately.

The two collection periods need not be exactly one hour long, but may be longer if convenient. It is important, however, that the *time* of the period be accurately known, to the nearest minute, and that the entire volume of urine formed during this period be obtained, since only in this way can the volume of urine flow per minute be calculated. The two periods serve as checks on one another; if results calculated on the basis of each separate period differ significantly, error is indicated. If the urine volume is less than 25 ml. per hour, the sample is discarded.

Calculation. The maximum clearance (C_m) indicates the maximum efficiency of urea excretion with high urine volumes and is calculated if the urine volume observed

in an adult, or if the corrected volume $V \times \frac{1.73}{\text{sq. m. surface area}}$ in a child, exceeds 2 ml. per minute. The standard clearance (C_a), or the efficiency with which the

with the standard centarity (C_n), of the enterley with which the kidneys excrete urea when the urine volume is at the average normal level of 1 ml. per minute, is calculated if the urine volume, corrected in the case of a child, is less than 2 ml. per minute. Both clearances are best calculated in percentage of the average normal C_n or C_m .

Percentage of average normal
$$C_m = \frac{100~\mathrm{UV}}{75\mathrm{B}} = 1.33~\frac{\mathrm{UV}}{\mathrm{B}}$$

Percentage of average normal
$$C_n = \frac{100~U\sqrt{V}}{54B} = 1.85~\frac{U\sqrt{V}}{B}$$

U = Urea concentration of urine (mg. of urea N per 100 ml.)

B = Urea concentration of blood (mg. of urea N per 100 ml.)

V = ml. of urine excreted per minute

The following table is convenient in calculating standard clearance. It gives values of \sqrt{V} .

V ml. per minute	√v	V ml. per minute	√v	V ml. per minute	√v	V ml. per minute	\sqrt{v}
0.2	0.45	0.7	0.84	1.2	1.10	17	1.30
0.3	0.55	0.8	0.89	1.3	1.14	1.8	1.34
0.4	0.63	0.9	0.95	1.4	1.18	1.9	1.38
0.5	0.71	1.0	1.00	1.5	1 23	2.0	1.42
0.6	0.78	1.1	1.05	1.6	1.27	2.1	1.45

Interpretation. In patients with diminishing renal function, the blood urea clearance shows evidence of diminution sooner than does the blood creatinine content, the blood urea content considered without relation to urea excretion, or the phenolsulfonephthalein excretion. The blood urea clearance usually falls below 50 per cent of normal values before any of

the other three show abnormality. Only after the blood urea clearance indicates less than 20 per cent of normal renal function are all values for blood urea, creatinine, and phenolsulfonephthalein found outside the limits of normal variation. The maximum clearance is normally about 40 per cent greater than the standard clearance, the mean values being 75 ml. (variations 64 to 99 ml.) of blood per minute for the maximum and 54 ml. (variations of 40 to 68 ml.) for the standard. The method is based on the view that with abundant urine the urea excretion per minute equals the urea contained in a constant volume of blood.

2. Phenolsulfonephthalein Test: Principle. This test for renal function was devised by Rowntree and Geraghty. It depends upon the injection into the tissues of a dyestuff which is eliminated rapidly by the normal kidneys, and can be easily estimated quantitatively in the urine.

This dyestuff, phenolsulfonephthalein, is nonirritative to the body either when taken by mouth or when injected into the tissues, so that it does no harm to an already weakened kidney.

The patient upon whom the test is to be performed is given 300 to 400 ml. of water 20 to 30 minutes previously, in order to assure a free flow of urine. Just before the start of the test, the bladder is emptied and the urine discarded.

Procedure: One ml. of a solution containing 6 mg. of phenolsulfonephthalein²²⁴ per ml. is injected intramuscularly in the lumbar region, the time
of injection being noted. The patient is then catheterized and the urine
as it forms thereafter allowed to drop into a beaker containing 2 drops of
25 per cent NaOH. The appearance of a red color in the alkalinized urine
indicates beginning excretion of the drug, the normal time being within
5 to 10 minutes after its injection. Urine is now collected in one-hour
samples. In patients with obstruction to the flow of urine from the bladder,
the retention catheter is stoppered and the urine drawn off at the end of
each hour. Other patients may simply be allowed to urinate at the hourly
periods.

To each hour sample of urine is added 25 per cent NaOH, drop by drop, until the maximum intensity of color appears. This color will remain constant for an indefinite period of time. Each sample is then placed in a 1000-ml. volumetric flask and diluted to the mark with distilled water.

Compare the color intensity of each sample either colorimetrically or photometrically against a standard. To prepare the standard, place a sufficient amount of the phenolsulphonephthalein solution to contain 3 mg. of the dye (i.e., one-half of the amount administered) in a beaker, dilute with a little water, and add 25 per cent NaOH dropwise to maximum color intensity. Transfer quantitatively to a 1000-ml. volumetric flask, dilute to the mark with water, and mix.

For colorimetric comparison, match the unknowns against the standard in the usual way. It is convenient to set the standard at 10 mm. For photometric measurement, determine the densities of standard and unknown in a photometer at 520 m_µ, setting the photometer to zero density with water.

²²⁴ This solution is prepared by adding 0.6 g. of phenolsulfonephthalein and 0.84 ml. of 2 N NaOH to enough 0.75 per cent NaCl solution to make 100 ml. This gives the monosodium or acid salt which is slightly irritant locally when injected. It is necessary to add two to three drops more 2 N NaOH which changes the color to a Bordeaux-red. This preparation is nonirritant. Suitable preparations of the dye in sterile ampules may be obtained from pharmaceutical supply houses.

of the test period, the bladder is emptied and the urine discarded. The patient is given a glass of water to drink, and the urine is collected in two succeeding periods of one hour each. At the beginning of the second period, the patient is given another glass of water, and a sample of blood is drawn for urea determination. At the close of the test, the volumes of urine passed during each period are accurately measured in graduated cylinders, and the urea content of each determined separately.

The two collection periods need not be exactly one hour long, but may be longer if convenient. It is important, however, that the *time* of the period be accurately known, to the nearest minute, and that the entire volume of urine formed during this period be obtained, since only in this way can the volume of urine flow per minute be calculated. The two periods serve as checks on one another; if results calculated on the basis of each separate period differ significantly, error is indicated. If the urine volume is less than 25 ml. per hour, the sample is discarded.

Calculation. The maximum clearance (C_m) indicates the maximum efficiency of urea excretion with high urine volumes and is calculated if the urine volume observed

in an adult, or if the corrected volume $V \times \frac{1.10}{\text{sq. m. surface area}}$ in a child, exceeds

2 ml. per minute. The standard clearance (C_a) , or the efficiency with which the kidneys excrete urea when the urine volume is at the average normal level of 1 ml. per minute, is calculated if the urine volume, corrected in the case of a child, is less than 2 ml. per minute. Both clearances are best calculated in percentage of the average normal C_a or C_m .

Percentage of average normal
$$C_m = \frac{100~\mathrm{UV}}{75\mathrm{B}} = 1.33~\frac{\mathrm{UV}}{\mathrm{B}}$$

Percentage of average normal
$$C_n = \frac{100 \text{ U} \sqrt{V}}{54 \text{B}} = 1.85 \frac{\text{U} \sqrt{V}}{\text{B}}$$

U = Urea concentration of urine (mg. of urea N per 100 ml.)

B = Urea concentration of blood (mg. of urea N per 100 ml.)

V = ml. of urine excreted per minute

The following table is convenient in calculating standard clearance. It gives values of \sqrt{V} .

V ml. per minute	\sqrt{v}	V ml. per minute	√v	ml. per minute	√v	V ml. per minute	$\sqrt{\mathrm{v}}$
0.2	0.45	0.7	0.84	1.2	1.10	1 7	1.30
0.3	0.55	0.8	0.89	1.3	1.14	1.8	1.34
0.4	0.63	0.9	0.95	1.4	1.18	1.9	1.38
0.5	0.71	1.0	1.00	1.5	1.23	2.0	1.42
0.6	0.78	1.1	1.05	1.6	1.27	2.1	1.45

Interpretation. In patients with diminishing renal function, the blood urea clearance shows evidence of diminution sooner than does the blood creatinine content, the blood urea content considered without relation to urea excretion, or the phenolsulfonephthalein excretion. The blood urea clearance usually falls below 50 per cent of normal values before any of

the other three show abnormality. Only after the blood urea clearance indicates less than 20 per cent of normal renal function are all values for blood urea, creatinine, and phenolsulfonephthalein found outside the limits of normal variation. The maximum clearance is normally about 40 per cent greater than the standard clearance, the mean values being 75 ml. (variations 64 to 99 ml.) of blood per minute for the maximum and 54 ml. (variations of 40 to 68 ml.) for the standard. The method is based on the view that with abundant urine the urea excretion per minute equals the urea contained in a constant volume of blood.

2. Phenolsulfonephthalein Test: Principle. This test for renal function was devised by Rowntree and Geraghty. It depends upon the injection into the tissues of a dyestuff which is eliminated rapidly by the normal kidneys, and can be easily estimated quantitatively in the urine.

This dyestuff, phenolsulfonephthalein, is nonirritative to the body either when taken by mouth or when injected into the tissues, so that it does no harm to an already weakened kidney.

The patient upon whom the test is to be performed is given 300 to 400 ml. of water 20 to 30 minutes previously, in order to assure a free flow of urine. Just before the start of the test, the bladder is emptied and the urine discarded.

Procedure: One ml. of a solution containing 6 mg. of phenolsulfonephthalein²²⁴ per ml. is injected intramuscularly in the lumbar region, the time
of injection being noted. The patient is then catheterized and the urine
as it forms thereafter allowed to drop into a beaker containing 2 drops of
25 per cent NaOH. The appearance of a red color in the alkalinized urine
indicates beginning excretion of the drug, the normal time being within
5 to 10 minutes after its injection. Urine is now collected in one-hour
samples. In patients with obstruction to the flow of urine from the bladder,
the retention catheter is stoppered and the urine drawn off at the end of
each hour. Other patients may simply be allowed to urinate at the hourly
periods.

To each hour sample of urine is added 25 per cent NaOH, drop by drop, until the maximum intensity of color appears. This color will remain constant for an indefinite period of time. Each sample is then placed in a 1000-ml. volumetric flask and diluted to the mark with distilled water.

Compare the color intensity of each sample either colorimetrically or photometrically against a standard. To prepare the standard, place a sufficient amount of the phenolsulphonephthalein solution to contain 3 mg. of the dye (i.e., one-half of the amount administered) in a beaker, dilute with a little water, and add 25 per cent NaOH dropwise to maximum color intensity. Transfer quantitatively to a 1000-ml. volumetric flask, dilute to the mark with water, and mix.

For colorimetric comparison, match the unknowns against the standard in the usual way. It is convenient to set the standard at 10 mm. For photometric measurement, determine the densities of standard and unknown in a photometer at 520 m μ , setting the photometer to zero density with water.

²²⁴ This solution is prepared by adding 0.6 g. of phenolsulfonephthalein and 0.84 ml. of 2 N NaOH to enough 0.75 per cent NaCl solution to make 100 ml. This gives the monosodium or acid salt which is slightly irritant locally when injected. It is necessary to add two to three drops more 2 N NaOH which changes the color to a Bordeaux-red. This preparation is nonirritant. Suitable preparations of the dye in sterile ampules may be obtained from pharmaceutical supply houses.

Calculation. For colorimetric measurement:

 $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 50 = \text{percentage of administered dye in sample}$

For photometric measurement:

 $\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 50 = \text{percentage of administered dye in sample}$

Interpretation. The amount of the drug eliminated normally is 40 to 60 per cent during the first hour and 20 to 25 per cent during the second hour, or a total of 60 to 85 per cent for two hours. The amount of the drug excreted has been found to be independent of the quantity of urine obtained. Ordinarily, two one-hour samples are sufficient; in case of delayed excretion the collection of hourly samples may be continued until practically all of the drug has been recovered in the urine.

If it is desired to test the function of each kidney separately, ureteral catheterization must be resorted to, the experiment otherwise being performed as above described.

The phenolsulfonephthalein test may be used to indicate the amount of derangement in quantitative functional disturbance of the kidneys, as in chronic interstitial and chronic parenchymatous nephritis or uremia.

It is claimed that the rate of excretion of phenolsulfonephthalein is affected by certain extrarenal factors; namely, the albumin and hydrogen-ion concentrations of the blood.

3. Mosenthal Test for Kidney Function:²²⁵ Principle. The patient under examination is placed for a day on a more or less definite diet.²²⁶ The urine is collected in six two-hour periods during the day and one 12-hour night period. These urine specimens are analyzed for volume, specific gravity, total nitrogen, and chlorides.

Procedure: On the day of the test have the patient empty the bladder at 8 A.M. and start the diet for the day which, if desired, may contain approximately 13 to 14 g. of nitrogen, 8 to 9 g. of salt, 1700 to 1800 ml. of fluid, and considerable purine material in meat, soup, tea, and coffee. 227 No solid food nor fluid of any kind must be taken between meals and especial care must be observed that nothing is eaten or drunk after the evening meal. The meals should start at 8 A.M., 12 noon, and 5 P.M., respectively.

Collect the urine punctually at the end of every two-hour period until 8 P.M., and place in separate bottles. Collect the night urine from 8 P.M. to 8 A.M. of the following day in another bottle. Measure the volume of each specimen of urine and determine in each case the specific gravity, total nitrogen, and total chlorides.

227 See footnote 226.

^{***} Mosenthal: Boston Med. Surg. J., 170, 245 (1914); Ohio State Med. J., 18, 348 (1922). ***

*** A diet suitable to ordinary hospital conditions is given by Kahn: "Functional Diagnosis," p. 260, New York, W. F. Prior Co., 1920. It is not essential, as was formerly believed, to prescribe a diet abundant in diuretic foods or beverages, since the foods found in the ordinary household contain sufficient diuretic materials for the proper carrying out of the test. In private practice it is only necessary that the patient eat three full meals a day and write down the approximate quantities, as—1 cup of coffee, 2 slices of toast, 2 table-spoonfuls of oatmeal, etc.

Interpretation. The test is of particular value apparently as giving earlier indications of diminished kidney efficiency than is true of some other tests used. It is sometimes difficult to interpret the results obtained in terms of renal involvement because of the influence of possible extrarenal factors. In general, however, the normal response is one in which the specific gravity figures vary at least 9 points (less if too little water is taken) from the highest to the lowest and the volume of the *night* urine is 400 ml.²²⁸ or less. If the percentage of nitrogen and sodium chloride in the night urine or in the highest of any of the day specimens is 1 per cent, a normal condition is indicated. Values under 1 per cent, however, may or may not be abnormal.

mina at 1) and	Urine		Sodium Chloride		Nitrogen	
Time of Day	ml.	Sp. gr.	Per Cent	Grams	Per Cent	Grams
8 -10	153	1.016	1.32	2.02	0.89	1.26

Intake	1760			8.50		13.40
Balance	+270			-3.22		+1.47

When kidney function becomes involved, the first signs are usually demonstrated in the night urine. The quantity becomes increased and the specific gravity and the nitrogen concentration are lowered. One or all of these changes from the normal may occur. In severe cases of chronic nephritis an advanced degree of functional inadequacy of the kidney is indicated by a markedly fixed and low specific gravity, a diminished output of both salt and nitrogen, a tendency to total polyuria, and a night urine showing an increased volume, low specific gravity, and low concentration of nitrogen. Such functional pictures are, however, not confined to nephritis. They are found frequently in many other conditions: pyclitis, cystitis, hypertrophied prostate, marked anemia, pyclonephritis, polycystic kidney, and diabetes insipidus. The table above taken from Mosenthal shows the response of a normal individual.

Carbohydrate, Fat, and Protein Metabolism

GENERAL

The components of a normal mixed diet which supply all the requirements of the animal body for growth and maintenance include proteins, fats, carbohydrates, the various vitamins, water, and certain inorganic elements. In the present chapter are considered some of the nutritional requirements for proteins, fats, and carbohydrates, and the changes which these substances undergo subsequent to their digestion and absorption into the animal body. The energy metabolism of these substances has been considered in Chapter 25. Brief discussions concerning certain metabolic phases are also found in the chapters dealing with the urinary constituents and in other connections. The questions of mineral metabolism, water, and the vitamins are discussed in subsequent chapters.

Throughout the discussions which follow, frequent mention will be made of the use of isotopes, which have proved such valuable tools in the study of intermediary metabolism and nutrition. The isotopes themselves and their use in biology are discussed in the following chapter. Adequate entrance to the voluminous literature of intermediary metabolism and nutrition is afforded by the footnote references and the reviews and special articles listed in the bibliography at the end of this chapter.

CARBOHYDRATE METABOLISM

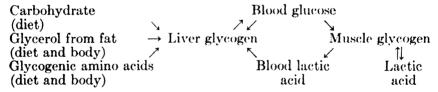

Carbohydrates supply the major portion of the daily energy requirements of the normal individual; on an ordinary diet over half of the total daily calories usually come from this source. In addition to being oxidized as a source of energy, carbohydrates may be transformed to glycogen or converted into fat. Of these various processes, glycogen formation and breakdown appears to occupy a central position.

Glycogen Formation and Breakdown (Glycogenesis and Glycogenolysis). Glycogen is found in practically all of the tissues of the body, but in varying amounts; the glycogen content of the brain for example, is so low as to require special care for its detection. The muscles and liver contain most of the glycogen of the body, largely because of their bulk relative to that of the other tissues. Glycogens from various tissues—e.g., muscle glycogen, liver glycogen—appear to be chemically identical but to have markedly different physiological significance. Thus the glycogen content of muscle is relatively constant in the absence of exhaustive muscular contraction, and is little affected by starvation or the nature of

the diet, which may produce variation in the liver glycogen content from a mere trace to upward of 8 per cent of the weight of this organ.

Glycogen, therefore, may have both a functional and a storage significance. The capacity of the animal to store carbohydrate as glycogen is relatively limited, however, as contrasted to its capacity to store fat. The adult human body may contain about 300 g. of glycogen, of which only that fraction found in the liver (normally about one-half of the total) represents a significant source of carbohydrate for general metabolic purposes. Fasting for a few days is usually sufficient to deplete the animal of all available stored carbohydrate. Any carbohydrate metabolism in a fasting animal after the exhaustion of stored carbohydrate is due presumably to synthesis of carbohydrate from noncarbohydrate precursors (gluconeogenesis).

Major precursors of liver glycogen within the animal body include the glucose, fructose, and galactose (but not pentose) produced by carbohydrate digestion in the intestinal tract; the glucose and lactate of the blood; the glycerol portion of the fats of either the diet or the body; and certain amino acid constituents of the proteins of either the diet or the tissues which are capable of being converted into glucose and hence into glycogen. Precursors of muscle glycogen include the glucose of the blood and, to an extent which is still debatable, the lactic acid produced from glycogen itself during muscle contraction. These various interrelationships with regard to liver and muscle glycogen may be summarized in the following diagram, adapted from Cori:

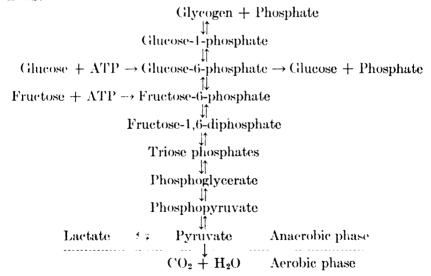

Knowledge that a particular substance is a precursor of liver glycogen, for example, usually has been obtained by demonstrating that an increased liver glycogen content follows the feeding of the test substance. Perfusion of the isolated organ, and incubation with surviving liver slices, also have been used. It generally has been assumed that if glycogen formation occurred, the test substance was directly incorporated into the newly formed glycogen. There is considerable evidence that this is not entirely true. For example, Conant, Cramer, et. al., fed lactate containing radioactive carbon in the carboxyl group to fasted rats, and isolated the liver glycogen which was undoubtedly the result of the lactate feeding. Although the extra glycogen corresponded to 32 per cent of the fed lactate, it contained only 1.6 per cent of the radioactivity. Further experiments by the same group showed that radioactive carbon dioxide itself (in the form of bicarbonate) was incorporated in the glycogen resulting from glucose or lactate feeding. Similar results have been obtained with

¹ Conant, Cramer, Hastings, Klemperer, Solomon, and Vennesland: J. Biol. Chem., 137, 557 (1941).

the glucogenic amino acid glycine labeled with isotopic carbon in the carboxyl group.² If glucose is administered to a fasting or fed rat whose body contains isotopic hydrogen (deuterium) in the form of D₂O, the deuterium content of the glycogen subsequently isolated from the animal tissues is sufficiently high to preclude the possibility of more than a few per cent of the isotope-free dietary glucose having been directly incorporated into the newly formed glycogen.³ These and other results indicate that glycogen formation and breakdown is a complicated and continuous process within the body, (according to Stetten the "half life" of rat liver glycogen is but one day) and that the accumulation of glycogen in the presence of an apparent precursor may be due only in part to the precursor itself, or may even represent a "sparing" action on glycogen metabolism, without any direct connection with the latter.

Knowledge concerning the intermediate steps in glycogen formation and breakdown has been obtained largely with tissue preparations or isolated enzyme systems. Much of this work has been done with either muscle or liver; it is believed that conclusions drawn from such studies are generally applicable, in principle if not in specific detail. The various reactions known to be concerned in glycogen formation and breakdown may be divided into two phases, anaerobic and aerobic, summarized as follows:

Many of these reactions already have been discussed in detail in Chapter 10 in connection with the chemistry of lactic acid formation in muscle, and the chemical structures of the various intermediate compounds also will be found there.

It will be noted that the immediate chemical precursor of glycogen is the compound glucose-1-phosphate (the "Cori ester"). The enzyme catalyzing the reversible reaction between glycogen, inorganic phosphate, and

Olsen, Hemingway, and Nier: J. Biol. Chem., 148, 611 (1943).
 Stetten and Boxer: J. Biol. Chem., 155, 231, 237 (1944).

glucose-1-phosphate is known as phosphorylase. The equilibrium in this reaction is such that glucose-1-phosphate predominates; the direction of reaction appears to be determined largely by the concentration of inorganic phosphate. In the presence of excess inorganic phosphate, glycogen breakdown occurs; for glycogen synthesis, it is necessary to keep the inorganic phosphate content low. This apparently is done in the cell by oxidative processes which incorporate the phosphate into phosphate esters, some of which are intermediates in the series of reactions shown. There is thus in effect a "phosphate cycle" (Cori), whereby inorganic phosphate liberated by glycogen formation is used to phosphorylate other compounds which, in turn, can give rise to glycogen and inorganic phosphate again.

For free glucose (or fructose) to be converted into glycogen by the reactions shown, phosphorylation is necessary. This phosphorylation—leading to the formation of either glucose-6-phosphate or fructose-6-phosphate, as the case may be—requires the presence of the "high energy phosphate" of adenosine triphosphate(ATP), and of the enzyme hexokinase. This enzyme, or at any rate its activity, is apparently under the control of certain hormones, as discussed on p. 919, and knowledge concerning this control may prove to be of fundamental importance in understanding certain phases of carbohydrate metabolism.

After phosphorylation, glucose becomes available for either glycogen formation, reconversion to glucose, or breakdown to lactic acid anaerobically or complete oxidation aerobically. Reconversion to glucose is due to the enzyme phosphatase, which catalyzes hydrolysis of glucose-6-phosphate to glucose and inorganic phosphate. This is believed to be the origin of the glucose of the blood from the glycogen of the liver (and possibly also of the kidneys). In muscle tissue, which contains no phosphatase, glucose-6-phosphate is either converted to glycogen or degraded to form lactic acid anaerobically or completely oxidized aerobically. The formation of lactic acid from glycogen requires no oxygen; the oxidation of triosephosphate to phosphoglycerate is coupled with the simultaneous reduction of pyruvate to lactate, through the mediation of coenzyme I which is alternately reduced and oxidized, as described in Chapters 10 and 35.

Aerobic Oxidation of Carbohydrate. The precise mechanism whereby carbohydrate is completely oxidized to CO_2 and H_2O is still a subject of controversy. It is probable that a number of different pathways exist, differing from one tissue to another, and there are a number of experimental facts which as yet do not fit into any recognized general scheme. It nevertheless is felt by many that a reasonable answer to the mechanism of aerobic carbohydrate oxidation is afforded by the cyclic process first described in its essential principles by Krebs and called by him the "citric acid cycle," later modified by Krebs and others and now more generally known as the "tricarboxylic acid cycle."

According to this concept, carbohydrate is considered to be degraded to the stage of pyruvic acid, CH₃COCOOH, by the series of reactions just described for the anaerobic breakdown, but whereas under anaerobic

conditions pyruvic acid is converted to lactic acid as the chief end-product of the process, under aerobic conditions the pyruvic acid undergoes a different series of reactions. These reactions of the tricarboxylic acid cycle are summarized in the accompanying diagram, which for purposes of clarity has been considerably simplified, as will be pointed out.

The first step in the aerobic oxidation of pyruvic acid appears to be condensation with oxalacetic acid already present in the cell to form ultimately a 6-carbon tricarboxylic acid, such as cis-aconitic acid. Whether this condensation occurs directly to form a 7-carbon intermediate of unknown nature which is then decarboxylated to give the 6-carbon compound, or whether pyruvic acid is decarboxylated to form a reactive

2-carbon compound ("active" acetic acid?) which then reacts with oxalacetic acid, is not known. The subject of acetic acid formation in this connection is discussed further on p. 927.

Aconitic acid once formed is readily hydrated in the presence of the tissue enzyme aconitase to form isocitric acid. Citric acid may also be formed here but appears to play no direct part in the cycle except as a possible precursor of aconitic acid by reversal of the reaction just described. Isocitric acid then undergoes oxidation by dehydrogenation, in the presence of isocitric dehydrogenase, to yield oxalosuccinic acid, which is then decarboxylated to give α -ketoglutaric acid. This latter compound is readily converted by decarboxylation and dehydrogenation (probably through the stage of succinic aldehyde) to give the C₄ dicarboxylic acid succinic acid. Most animal tissues contain an enzyme, succinic dehydrogenase, which catalyzes the oxidation of succinic acid by dehydrogenation to form fumaric acid. This latter readily undergoes hydration in the presence of the enzyme fumarase to form malic acid, which on oxidation, catalyzed by the enzyme malic dehydrogenase, yields oxalacetic acid. At this point the entrance of another molecule of pyruvic acid permits the entire cycle to be repeated.

Thus the net result of the cycle is the complete disappearance of one molecule of pyruvic acid, giving rise to three molecules of CO_2 in the process and requiring the ultimate presence of five oxygen atoms $(2.5\mathrm{O}_2)$ to accept the 10 hydrogen atoms removed by the various dehydrogenation reactions. It is believed that the mechanism of hydrogen transport to oxygen is by way of the di- and triphosphopyridine nucleotides (coenzymes I and II), the flavoproteins, and the cytochromes, as described in Chapter 12 on Enzymes.

The overall reaction is therefore:

$$C_3H_4O_3 + 2.5O_2 = 3CO_2 + 2H_2O$$

Pyruvic acid

with a respiratory quotient (R.Q.) of 3/2.5 = 1.2. By the combination of reactions described, involving the formation of pyruvate from carbohydrate and the participation of pyruvate in the tricarboxylic acid cycle, it is possible therefore to account for the complete oxidation of carbohydrate to CO_2 and H_2O . To obtain an R.Q. of 1.0, which is the R.Q. of carbohydrate oxidation, the transfer of two more hydrogen atoms to an oxygen atom must enter into the picture. According to some, this takes place by the aerobic oxidation of lactate to form pyruvate, the lactate being assumed to be the normal end-product of glycolytic breakdown. Another view is that aerobically pyruvate is not reduced to lactate, the two hydrogen atoms normally used in this reaction anaerobically being transferred to oxygen aerobically by some as yet unspecified means. Whichever view is correct, the appearance of pyruvate as an intermediate requires the extra oxygen consumption which results in an R.Q. of 1.0 rather than 1.2 for the entire process of carbohydrate oxidation.

The major evidence in favor of such a cyclic process as that described

may be summarized as follows: the various postulated intermediates usually increase the respiratory rate of suitable tissue preparations (e.g., minced muscle) when added in catalytic amounts; many of the individual enzymes concerned have been isolated and shown to function as indicated; certain of the postulated intermediates have been isolated from tissue systems in the presence of specific poisons such as malonate and arsenite; and critical examination of the theory by the use of isotopes as "markers" for specific portions of the various molecules concerned as yet has not revealed any major discrepancies.

The reactions of the tricarboxylic acid cycle afford an explanation for the participation in the processes of carbohydrate oxidation of the various intermediates shown, even though such intermediates are not carbohydrates or may arise from noncarbohydrate precursors. The implications of this relationship to the metabolism of fats and amino acids will be evident from the subsequent discussion in this chapter.

All of the reactions of the tricarboxylic acid cycle are reversible with the exception of the condensation reaction between pyruvic and oxalacetic acids. Thus an explanation is afforded for the synthesis of carbohydrates from noncarbohydrate precursors which are, or give rise to, components of the cycle, provided a means is available for their further conversion to pyruvate which avoids the irreversibility of the condensation reaction. There is ample evidence that such formation of pyruvate occurs in animal tissues. Pyruvic acid may arise by the direct decarboxylation of oxalacetic acid:

$\begin{array}{c} {\rm COOH \cdot CH_2 \cdot CO \cdot COOH \rightarrow CH_3 \cdot CO \cdot COOH + CO_2} \\ {\rm Oxalacetic\ acid} & {\rm Pyruvic\ acid} \end{array}$

This reaction is known to occur in animal tissues. Once formed, pyruvic acid is readily phosphorylated in the presence of ATP:⁴

Pyruvate
$$+$$
 ATP \rightleftharpoons Phosphopyruvate $+$ ADP

Phosphopyruvate then can serve as a direct precursor of the hexoses and glycogen by the reversal of the glycolytic reactions already described on p. 909. Kalekar has shown that phosphopyruvate itself is formed during the aerobic oxidation of the C₄ dicarboxylic acids by tissue extracts; this may arise by the decarboxylation of phosphooxalacetic acid (Lipmann):

$$\begin{array}{c} {\rm COOH\cdot CH:CO(PO_3H_2)\cdot COOH} \to {\rm CH_2:CO(PO_3H_2)\cdot COOH} + {\rm CO_2} \\ {\rm Phosphooxalacetic\; acid} \\ {\it (enol\; form)} \\ \end{array} \\ \begin{array}{c} {\rm Phosphopyruvic\; acid} \\ {\it (enol\; form)} \end{array} ,$$

Other reactions doubtless remain to be discovered, but at any rate it is clear that the pathways of carbohydrate synthesis from noncarbohydrate precursors are open by the reactions described.

The reversibility of the decarboxylation reactions of the tricarboxylic acid cycle affords an explanation for CO₂-fixation, *i.e.*, the utilization of the carbon of carbon dioxide for metabolic purposes. CO₂-fixation was first described for bacteria, but has now been shown to be applicable to

⁴ Lardy and Ziegler: J. Biol. Chem., 159, 343 (1945).

mammalian tissues as well. Two reactions of CO₂-fixation have thus far been demonstrated in animal tissues: (1) The reaction between pyruvic acid and CO₂ to form oxalacetic acid (Wood and Werkman), and (2) the reaction between ketoglutaric acid and CO₂ to form oxalosuccinic acid (Ochoa):

 $\begin{array}{c} \mathrm{CH_3 \cdot CO \cdot COOH} + \mathrm{CO_2} \rightleftarrows \mathrm{COOH \cdot CH_2 \cdot CO \cdot COOH} \\ \text{Pyruvic acid} & \text{Oxalacetic acid} \\ \mathrm{COOH \cdot CO \cdot CH_2 \cdot CH_2 \cdot COOH} + \mathrm{CO_2} \end{array}$

 \rightleftarrows COOH·CO·CH(COOH)·CH₂·COOH

α-Ketoglutaric acid

Oxalosuccinic acid

Proof that CO_2 -fixation occurs in animal tissues was afforded by Evans and Slotin⁵ using bicarbonate containing radioactive carbon; the α -keto-glutarate synthesized by pigeon liver preparations in the presence of pyruvate and the isotopic bicarbonate was found to contain a significant amount of the isotopic carbon. The carbon of radioactive sodium bicarbonate administered to rats is also found in the glycogen subsequently isolated from the liver.⁶ Using the stable carbon isotope C^{13} , the position of the fixed carbon is found to be in positions 3 and 4 of the glucose molecule,⁷ a result in accordance with the uptake of CO_2 by pyruvic acid to form oxalacetic acid, followed by subsequent conversion of the phosphorylated oxalacetic acid to phosphopyruvic acid as discussed previously, and ultimate synthesis of hexose from phosphopyruvic acid by the reversal of the glycolytic mechanism already described.

The significance of CO₂-fixation in animal tissues remains obscure. It may represent merely the demonstration of the reversibility of decarboxylation reactions; the extent of fixation is usually quite small, since the equilibrium conditions usually favor decarboxylation. On the other hand, it has been suggested that CO₂-fixation provides for the constant presence of the catalytic amounts of oxalacetic acid necessary for the continuous operation of the tricarboxylic acid cycle.

Despite the extensive knowledge which has been obtained concerning intermediary carbohydrate metabolism, there is much that is still obscure. The aerobic oxidation of lactic acid, for example, usually is considered to occur by way of conversion to pyruvic acid which is then oxidized by the processes just described. There is some evidence that other as yet unknown and possibly important pathways exist. In certain tissues, glucose can be shown to be oxidizable to form gluconic or phosphogluconic acid, reactions which do not fit into any recognized general scheme of glucose metabolism. The conversion of carbohydrate to pyruvate and the reactions of the tricarboxylic acid cycle have been studied largely in one tissue, i.e., muscle, and the conclusions derived are not necessarily applicable *in toto* to other tissues. Certain discrepancies are known, for example, between muscle and liver tissue, and for brain. Yet

⁷ Wood, Lifson, and Lorber: J. Biol. Chem., 159, 475 (1945).

Krebs has pointed out that the various animal tissues thus far investigated possess enzymes similar in general to those required for the tricarboxylic acid cycle for example, so that while individual differences between tissues doubtless occur, the basic reactions could be fundamentally similar in all tissues.

Formation of Carbohydrate from Amino Acids. The reactions of the tricarboxylic acid cycle afford a reasonable explanation for the ability of certain amino acids to give rise to glucose or extra glycogen in the animal body. Thus the amino acids glutamic acid, aspartic acid, and alanine, by metabolic deamination, give rise to α -ketoglutaric acid, oxalacetic acid, and pyruvic acid, respectively. These three latter compounds are recognized components of the tricarboxylic acid cycle.

glutamic acid $\rightarrow \alpha$ -ketoglutaric acid aspartic acid \rightarrow oxalacetic acid alanine \rightarrow pyruvic acid

After deamination, therefore, these three amino acid constituents of the protein molecule become indistinguishable from carbohydrate metabolites. Since the reactions of the tricarboxylic acid cycle are reversible, a mechanism is available for either the synthesis of carbohydrate or metabolism via carbohydrate pathways for these amino acids, and for any others which are convertible into these amino acids by metabolic processes. That pathways exist other than those described is quite probable, but they remain to be discovered.

Conversion of Carbohydrate to Fat. The fattening of farm animals and the development of obesity in man on high carbohydrate diets suggest that carbohydrate must be converted to fat in the animal body. In feeding experiments in which a control animal is killed and analyzed for fat while a litter mate is fed a high carbohydrate diet, it can be shown that the latter may, after a time, contain more fat than could be derived from all of the fat and protein fed. In the same way, milch cows without loss of fat from their bodies may secrete in their milk much more fat than can be accounted for by fat and protein ingested. Studies of the respiratory quotient yield similar evidence with regard to the conversion of carbohydrate into fat (see Chapter 24).

The glycerol for fat synthesis may arise very easily from carbohydrate, possibly directly from phosphoglyceraldehyde, a normal intermediate in carbohydrate metabolism in tissues:

The mode of synthesis of the fatty acid portion of the fat molecule is not yet clear. Earlier views inclined toward the belief that acetaldehyde

was formed from pyruvic acid by decarboxylation, a reaction which is known to occur readily in yeast:

$$\begin{array}{c} \mathrm{CH_3 \cdot CO \cdot COOH} \rightarrow \mathrm{CH_3 \cdot CHO} + \mathrm{CO_2} \\ \text{Pyruvic acid} & \text{Acetaldehyde} \end{array}$$

The acetaldehyde was then considered to undergo an aldol condensation:

$$\begin{array}{c} \mathrm{CH_3 \cdot CHO} \, + \, \mathrm{CH_3 \cdot CHO} \to \mathrm{CH_3 \cdot CHOH \cdot CH_2 \cdot CHO} \\ \text{Acetaldehyde} & \text{Aldol} \end{array}$$

By oxidation of the aldehyde group of aldol, the compound β -hydroxy-butyric acid, which is a normal intermediate in fatty acid oxidation, is formed. This could conceivably be converted into butyric acid by dehydration followed by reduction:

$$\begin{array}{c} CH_3\text{-}CHOH\text{-}CH_2\text{-}COOH \to CH_3\text{-}CH\text{-}CH\text{-}COOH \\ \text{\mathfrak{g}-Hydroxybutyric acid} \end{array}$$

 $\begin{array}{c} \rightarrow \mathrm{CH_3\text{-}CH_2\text{-}CH_2\text{-}COOH} \\ \text{Butyric acid} \end{array}$

By repeated condensations of the same type, the higher fatty acids could be produced by similar reactions.

This theory is attractive and has the merit of explaining the fact that naturally occurring fatty acids almost always have an even number of carbon atoms in the molecule, as well as accounting for the synthesis of unsaturated fatty acids. Unfortunately, there is little direct evidence from animal experiments for the participation of acetaldehyde in such reactions as those described. A more likely course of acetaldehyde metabolism is thought to involve the reaction with pyruvate to form acetoin, possibly through the intermediate stage of biacetyl:

$$\begin{array}{c} \mathrm{CH_3\text{-}CHO} + \mathrm{CH_3\text{-}CO\text{-}COOH} \to \mathrm{CH_3\text{-}CO\text{-}CO\text{-}CH_3} \\ \textbf{Acetaldehyde} & \textbf{Pyruvic} & \textbf{Biacetyl} \\ & & & & & & & & & & \\ \textbf{acid} & & & & & & & & \\ & & & & & & & & & \\ & & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & \\ & & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & \\ & & & \\ & & & \\ & & \\ & & & \\ & & \\ & & & \\ & \\ & \\ & & \\ &$$

Nothing is known concerning the further metabolism of acetoin, or its possible role in the synthesis of fatty acids. Concerning the possibility of crotonic acid formation, Jowett and Quastel⁸ are of the opinion that crotonic acid cannot be an intermediate between butyric acid and β -hydroxybutyric acid.

An alternate concept of fatty acid synthesis involves the possibility that acetic acid is an intermediate in the process. Rittenberg and Bloch⁹ fed to animals acetic acid containing isotopic hydrogen in the methyl group and isotopic carbon in the carboxyl group. The fatty acids subsequently isolated from the body fat contained sufficient isotopic hydrogen and carbon throughout the entire chain to indicate that acetic acid molecules had been utilized directly in the synthesis of the fatty acid molecule.

How such synthesis from acetic acid may be related directly to the

[•] Jowett and Quastel: Biochem. J., 29, 2143 (1935).

⁹ Rittenberg and Bloch: J. Biol. Chem., 154, 311 (1944).

formation of fat from carbohydrate is not entirely clear. It has been shown by Lipmann that in certain bacteria the oxidation of pyruvate in the presence of inorganic phosphate leads to the production of acetic acid, through the intermediate formation of acetyl phosphate:

$$\begin{array}{c} \text{CH}_3\text{·CO·COOH} + \text{H}_3\text{PO}_4 \xrightarrow{-2\text{H}} \text{CH}_3\text{·CO·OPO}_3\text{H}_2 + \text{CO}_2 \\ \text{Pyruvic acid} & \text{Acetyl phosphoric acid} \\ & \text{CH}_3\text{COOH} + \text{H}_3\text{PO}_4 \\ & \text{Acetic acid} \end{array}$$

There is no conclusive evidence that such formation of acetate from pyruvate occurs in animal tissues, although the process appears likely. The possible relationship of acetic acid to carbohydrate and fat metabolism is further discussed on p. 926.

The Blood Sugar. The sugar of the blood is glucose, present normally at a concentration of about 80 mg. per 100 ml. of blood, or 0.08 per cent. This level is maintained constant within relatively narrow limits under all ordinary circumstances; significant variations from the normal range usually indicate some aberration of carbohydrate metabolism. The constancy of the blood sugar level apparently is due to a balance between the rate at which glucose enters the blood and the rate at which it leaves the blood. Blood glucose appears to originate chiefly in the liver; the rapid fall in blood glucose level after hepatectomy indicates that other tissues cannot contribute materially to the blood sugar content, although there is some evidence that the kidneys may play a minor role in this respect. The glycogen of the liver usually is considered to be the major source of the blood glucose, but the maintenance of a normal blood sugar level in the fasting animal long after liver glycogen stores are exhausted indicates that carbohydrate synthesis in the liver may also play an important part in this connection.

Factors which lead to a removal of glucose from the blood include oxidation by the tissues, conversion to glycogen in liver and muscle, and to a minor extent in other tissues, storage as fat, and under certain conditions excretion in the urine. Increased oxidation in the tissues and increased conversion to liver and muscle glycogen each tend to lower the blood sugar level; when these two factors operate together, as after the administration of insulin, the resulting hypoglycemia may be profound. In the absence of insulin, as in diabetes mellitus, the inability to store glycogen in the liver coupled with decreased oxidative utilization in the peripheral tissues generally is believed to be responsible for the elevated blood sugar values seen in this condition. An alternate explanation for the hyperglycemia of diabetes mellitus is accelerated gluconeogenesis ("overproduction") rather than impaired oxidative utilization ("underconsumption"). Evidence in favor of the overproduction theory is limited.

Increased glycogenolysis in liver (but not in muscle), as after the ad-

ministration of adrenaline or during ether anesthesia, likewise causes an elevation of the blood sugar. The glycogen of muscle is not a direct factor in the maintenance of the blood sugar level, but operates only indirectly insofar as the muscles remove glucose for glycogen formation or contribute lactic acid to the blood which is then carried to the liver, where blood lactate may be a significant source of liver glycogen and hence blood glucose.

Storage of carbohydrate as fat (discussed on p. 915) is apparently a property of most of the tissues of the body. Loss of glucose from the blood because of excretion in the urine will occur whenever the rate of reabsorption of glucose by the renal tubular cells falls behind the rate of entrance of glucose into the glomerular ultrafiltrate—i.e., when the level of plasma glucose exceeds the renal threshold concentration. Ordinarily, the renal threshold concentration corresponds to a plasma glucose level of 150 mg. per cent or so, and this is only transitorily exceeded after ingestion of a large amount of carbohydrate, during emotional stress, etc. In the rare condition known as renal diabetes the renal reabsorption of glucose is so diminished that significant amounts escape into the urine. and after poisoning with the drug phlorizin the renal reabsorption of glucose is almost completely abolished ("phlorizin diabetes," see p. 937). The excretion of blood glucose in the urine in diabetes mellitus is due more to the elevated concentration in the blood than to any significant alteration in the renal threshold. In none of the various conditions described which lead to excretion of glucose in the urine is the loss from the blood ordinarily sufficient to appreciably affect the level of the blood sugar concentration.

Hormonal Control of Carbohydrate Metabolism. The metabolism of carbohydrate in the animal body is under the control of hormones from several of the endocrine glands, of which the pancreas, the anterior pituitary gland, and the adrenal cortex appear to be of major importance. Some aspects of this hormonal control have been indicated in the preceding pages; the endocrine glands themselves are discussed in Chapter 26.

Knowledge concerning the relation between the pancreas and carbohydrate metabolism began with the classical demonstration by Von Mering and Minkowski in 1889 that removal of the pancreas in the dog was followed by development of the symptoms of diabetes mellitus. In 1921 Banting, Best and Macleod obtained the active principle of the pancreas in this connection, the hormone insulin. Administration of insulin to a normal animal leads to a profound hypoglycemia which may result in convulsions or unconsciousness (insulin shock). In the diabetic, a maintained administration of insulin will completely alleviate the condition. Opinions differ as to the mechanism of insulin action; some feel that insulin accelerates carbohydrate oxidation, while others regard its function as primarily concerned with the synthesis of carbohydrate from noncarbohydrate precursors (gluconeogenesis) or possibly with the conversion of carbohydrate to fat. The significance of insulin in the "bexokinase reaction" is discussed below.

A further notable advance in knowledge concerning the hormonal control of earbohydrate metabolism was the demonstration by Houssay that removal of the pituitary gland abolished the symptoms of diabetes in the pancreatectomized dog. Removal of the adrenal cortex is likewise effective in ameliorating the symptoms of pancreatic diabetes (Long and Lukens). These and other results suggest that control of carbohydrate metabolism by the hormones of the pancreas, the anterior pituitary gland, and the adrenal cortex is essentially a balance between opposing forces, with the effect of insulin opposed by either or both the pituitary and adrenal cortex principles. Striking confirmation of this concept is afforded by the work of the Coris and their associates, 10 who have found that the ability of tissue extracts to phosphorylate glucose by the hexokinase reaction (see p. 910) is inhibited by a fraction of anterior pituitary extract, and also by adrenal cortical extract; this inhibition is overcome by insulin. Tissue extracts from diabetic animals showed an inhibited hexokinase activity which was overcome in vitro or in vivo by insulin. This first demonstration of the hormonal control of a specific enzymatic reaction of carbohydrate metabolism should open the way to a more complete knowledge of carbohydrate metabolism under normal and abnormal conditions.

Knowledge concerning relationships between the various other hormones of the body and carbohydrate metabolism is relatively meager and difficult to evaluate. The thyroid hormone influences the rate of metabolism in the tissues, but no specific relation to carbohydrate metabolism has been demonstrated, although a role in gluconeogenesis has been postulated. A role in gluconeogenesis has likewise been delegated to certain of the steroid hormones of the adrenal cortex. The various "effects" of anterior pituitary principles on carbohydrate metabolism ("glycostatic," "glycotropic," etc.) are summarized in Chapter 26. The subject is rendered difficult by the lack of purity of the hormone preparations in some instances, and by the possibility that a postulated action or lack of action may in reality involve the mediation of some other gland or hormone in addition to the one thought to be concerned.

FAT METABOLISM

The fats of the diet and of the animal body represent largely a concentrated form of energy, for metabolic or storage purposes, but there is adequate evidence that fats may subserve important noncaloric metabolic functions as well. In this connection, Burr and Barnes conclude that "there are ample reasons for recommending that the fat intake be not reduced much below the normal established by habit." Thus the fat content of the diet may influence such diverse processes as the digestibility and absorbability of other foodstuffs in the gastrointestinal tract, and the rate of calcification of the bones; fatty acids represent important constituents of the lipid structural components of tissues; the fats of the diet serve as a vehicle for the fat-soluble vitamins; and the presence in the diet of certain highly unsaturated fatty acids which cannot be syn-

¹⁰ Price, Cori, and Colowick: J. Biol. Chem., 160, 633 (1945); Price, Slein. Colowick, and Cori: Fed. Proc., 5, 150 (1946)

thesized by the animal body has been shown to be necessary for normal growth and tissue metabolism.

The proportion of total calories furnished by dietary fat may vary widely from one group of individuals to another, and depends chiefly on such factors as availability, cost, and established nutritional customs. The recommendation of the National Research Council is that fat be present in the diet to the extent of furnishing 20 to 25 per cent of the total calories (30 to 35 per cent at higher levels of calorie expenditure) and that 1 per cent of the total calories be in the form of the essential unsaturated fatty acids (see p. 922).

Comparative Nutritive Value of Fats. The variety of fats found in nature has stimulated investigation into their relative nutritional merits, for economic as well as nutritive reasons. These studies have failed to reveal any significant nutritional differences between the common animal and vegetable food fats and oils other than those attributable to slight variation in digestibility or in content of fat-soluble vitamins. Deuel. et al. 11 have furnished experimental evidence to refute the concept that butter fat possesses certain saturated fatty acids, not present in other fats, which are essential for growth. While rats prefer a diet containing butter to one in which the fat is corn, cottonseed, olive, peanut, or soybean oil, or margarine, this preference is apparently due to flavor alone; margarine fat and butter fat promote similar growth responses when fed to weanling rats under controlled conditions. ¹² Deuel has reported that adequate growth and reproduction have been maintained in rats through 13 generations on a diet in which skimmed milk powder and margarine fat replaced the whole milk powder of Sherman's well-known whole milk powder-ground whole wheat basal diet. These and other results lead to to the conclusion that butter fat possesses no special nutritive powers as compared to vegetable fats, and that properly fortified margarine is an adequate substitute for butter and has substantially equivalent nutritional value. 13 Fortification of the first American margarine was carried out in the laboratory of the senior author, who also demonstrated that margarine so fortified was the nutritive equivalent of butter. 13a

Studies on the digestibility of natural fats and oils have shown that all of the common cooking oils as cottonseed, corn, peanut, and olive oils, as well as butter, lard, and various margarines, are equally completely (95 per cent) digestible. Beef and mutton tallow are somewhat less digestible. Among the fatty acids themselves, myristic and lauric acids are practically completely digestible by the rat when fed in olive oil, stearic acid has a low digestibility, and palmitic acid occupies an intermediate position.¹⁴ The triglycerides of these acids behave in the same manner.

Relation Between Diet Fat and Body Fat. Prior to the work of Schoenheimer and Rittenberg on fat metabolism as studied with the aid of fats labeled with isotopic hvdrogen (deuterium), it had been believed generally that the fats of the diet were directly metabolized and only the excess above energy requirements was stored in the fat depots of the body. Schoenheimer and Rittenberg¹⁵ showed that even when fat is fed at a low level, some of this fat is first deposited in the tissues instead of being subjected to direct combustion. The experimental details are of interest. Normal mice were kept on a diet low in fat, and containing 2 per cent of linseed oil which had been partially hydrogenated with deuterium. Later postmortem examination of the body fat for the presence of the deuterio fat indicated that, even though the total amount of depot fat remained constant, 44 per cent of the dietary fat had been incorporated in the depot fat. Thus the animals were burning an approximately equal mixture of depot fat and food fat, in spite of the fact that the fat content of the diet was below that needed for energy purposes if completely burned.

Depot fat is therefore not inert storage material but is constantly involved in metabolic processes. The admixture of dietary and tissue fat shown by such experiments as that just described is, however, subject to some modifying control, since the animal tends to produce a body fat of fairly uniform composition and succeeds moderately well as long as the fat of the diet is not altered to too great an extent. If, however, large amounts of fats containing foreign types of fatty acids are taken in, some of these may be deposited in the tissues unchanged and modify the character of the body fat. Thus the melting point of the body fat of the dog has been raised from the usual 20° C. to 40° C. by feeding mutton tallow and has been decreased to 0° C. by feeding linseed oil. Anderson and Mendel fed rats diets of skimmed milk powder and added fat, and found that the iodine number of the body fat could be varied from 122 to 35 by feeding soybean and coconut oils with iodine numbers of 132 and 7.7, respectively. This matter is of commercial importance since the giving to hogs of rations too high in liquid fats gives rise to a soft body fat yielding a soft lard. In such cases, feeding for some time of a diet high in carbohydrate has a "hardening" effect, since the fat formed from carbohydrate has a higher melting point and tends to gradually replace a portion of the lower melting point fats.

Some modification of ingested fat may occur during absorption and resynthesis in the intestinal wall. That the various saturated fatty acids found in the mixed triglycerides of animal body fats are in synthetic equilibrium with one another is shown by the fact that after the feeding of a particular fatty acid labeled with deuterium, i.e., deuterio-palmitic acid, a significant amount of the deuterium is subsequently found incorporated in the other saturated fatty acids of the body fats. Deuterium is also found in the oleic and palmitoleic acid fractions, thus proving that these mono-unsaturated acids may be synthesized from dietary com-

¹⁵ Schoenheimer and Rittenberg: J. Biol. Chem., 111, 175 (1935).

ponents.¹⁶ This synthesis may be by direct dehydrogenation, but it appears more probable that the fed fatty acid entered into degradation reactions which produced smaller fragments from which the oleic acid was then synthesized. No deuterium is found in the linoleic acid fraction, thus confirming the original observations of Burr and Burr discussed below that the animal is unable to synthesize these highly unsaturated fatty acids.

Essential Fatty Acids. The inability of the animal body to synthesize certain highly unsaturated fatty acids essential for its normal nutrition was first demonstrated by Burr and Burr¹⁷ in 1929. These investigators found that rats placed on a diet devoid of fat but otherwise apparently complete failed to grow and developed characteristic lesions of the skin and tail (see p. 984 and Fig. 287 for complete description of this condition). Addition to the diet of the normal saturated fatty acids or of oleic acid did not render the diet complete, but when small amounts of highly unsaturated fatty acids such as linoleic or linolenic acid were added to the diet the deficiency did not develop. Further study has confirmed these findings: the deficiency is apparently not concerned with the formation of fat from carbohydrate, or fat storage; arachidonic acid is more effective than the other unsaturated fatty acids in promoting growth; and in the deficient animal the arachidonic acid content of the liver is maintained at the expense of continuous depletion of the other tissues. 18 This would imply that the presence of highly unsaturated fatty acids in liver, at one time thought to be a characteristic of fat metabolism in this organ, is in reality due to selection and retention of these compounds from the blood.

Oxidation of Fats. The glycerol portion of the fat molecule is undoubtedly oxidized in the body by pathways of carbohydrate metabolism, probably after preliminary phosphorylation to form phosphoglycerol, which then by oxidation could give rise to either phosphoglyceric aldehyde or phosphoglyceric acid, both of which are recognized intermediates in carbohydrate breakdown (see p. 909). The fatty acids are oxidized in quite a different way.

 β -oxidation. It is generally agreed that the major method whereby fatty acids are oxidized in the animal body is by the process known as β -oxidation. According to this concept, the fatty acid chain is oxidized at the carbon atom β to the carboxyl group, with the splitting off of a 2-carbon fragment and the production of a fatty acid having two less carbon atoms than the original. This process continues along the chain until the entire fatty acid molecule has been broken down to 2-carbon fragments by the removal of two carbon atoms at a time.

The first biological evidence for β -oxidation was afforded by the experiments of Knoop. This investigator found that on feeding animals fatty acids of varying chain length but in each case with the ω -carbon (the one farthest removed from the carboxyl carbon) substituted with a phenyl

group, there could be isolated from the urine either benzoic acid or phenylacetic acid, in the form of the conjugated derivatives hippuric acid and phenaceturic acid, respectively. Benzoic acid was obtained when the fatty acid chain contained three or five carbon atoms; phenylacetic acid when it contained two (i.e., phenylacetic acid itself) or four carbon atoms. These results led Knoop to conclude that the carbon atoms could not be removed one by one during oxidative breakdown of the fatty acid, but must come off in pairs, i.e., by oxidative removal at the β -carbon.

The nature and fate of the 2-carbon fragment produced by β -oxidation of fatty acids has been the subject of considerable study. Current evidence indicates that it is acetic acid, CH₃·COOH, possibly in an "active" form, e.g., acetyl groups, or acetyl phosphate; this subject is further discussed on p. 927. It appears to have been shown beyond any doubt that in liver at any rate the 2-carbon fragments condense with one another to form the 4-carbon compound acetoacetic acid, CH₃·CO·CH₂·COOH, and that acetoacetic acid is the end-product of fatty acid oxidation in this tissue. Thus Weinhouse, Medes and Floyd¹⁹ incubated liver slices with octanoic acid labeled with isotopic carbon in the carboxyl group, and determined the distribution of the isotopic carbon in the acetoacetic acid produced by exidation of the fatty acid. The isotope was found approximately evenly distributed between the carboxyl carbon and the carbonvl (β) carbon of acetoacetic acid, indicating that the two halves of the acetoacetate molecule are both derived to the same extent from the 2-carbon fragments of β -oxidation.

The same investigators showed that incubation of liver slices with acetic acid itself labeled with isotopic carbon in the carboxyl group resulted in the formation of isotopic acetoacetate by coupling of acetic acid molecules. Lehninger²⁰ has succeeded in obtaining liver suspensions which under the proper conditions readily oxidize all of the normal saturated fatty acids containing from 4 to 18 carbon atoms to yield acetoacetic acid as end-product. The oxidation of octanoic acid, for example, by β -oxidation in liver may therefore be represented as follows:

Weinhouse, Medes and Floyd: J. Biol. Chem., 155, 143 (1944); 158, 411 (1945).
 Lehninger: J. Biol. Chem., 161, 437 (1945).

There is some evidence that butyric acid may be oxidized directly to acetoacetic acid as well as through the stage of acetic acid formation shown; the bulk of acetoacetic acid formation from fatty acid oxidation is, however, by acetic acid condensation. The acetoacetic acid thus formed in liver is not further utilized by this organ, except possibly to a slight extent in fasting. Other tissues, however, readily metabolize acetoacetic acid to CO₂ and H₂O, nor does there appear to be an impairment in this respect in diabetes (Soskin). Whether or not acetoacetic acid is an intermediate in fatty acid oxidation in tissues other than liver is not definitely known, but it appears likely that this is the case. The further metabolism of acetoacetic acid is considered on p. 925.

The mechanism of β -oxidation is still obscure. An early theory postulated the intermediate formation of the β -keto acid, followed by splitting of the chain at this point. In the light of present knowledge, this process appears unlikely. Lehninger's work with rat liver suspensions indicates that phosphorylation of the carboxyl group, to form an acyl phosphate, is an essential part of the process:

$$\begin{array}{c} \text{R-CO-OH} \, + \, \text{H}_3\text{PO}_4 \longrightarrow \text{R-C()-OP()}_3\text{H}_2 \, + \, \text{H}_2\text{O} \\ \text{Fatty acid} & \text{Acyl phosphoric} \\ \end{array}$$

Oxidation does not occur in the absence of adenosine triphosphate (ATP) or of substances whose oxidation generates ATP; and fatty acid esters are not oxidized until after hydrolysis—i.e., until the carboxyl group is free. If the fatty acid is synthetically phosphorylated in the carboxyl group, ATP is not required for oxidation.²¹ Since this means that once the carboxyl group is phosphorylated the entire chain can be oxidized, it appears likely that the phosphate is transferred along the chain. Since Lehninger's preparations require coenzyme I as well as ATP, dehydrogenation is presumably involved along with phosphorylation. Enzyme preparations capable of dehydrogenating the higher fatty acids have been obtained from liver; in one instance the dehydrogenation is claimed to involve the formation of a double bond in the α , β position, a process which has obvious implications to the mechanism of β -oxidation.

Other mechanisms than β -oxidation for fatty acids have been proposed. Jowett and Quastel suggested that "multiple alternate oxidation" would more nearly explain their experimental results on ketone body formation from fatty acids by liver slices. According to this concept, the fatty acid chain is believed to be attacked by oxidation at every alternate carbon atom, to form a succession of ketone groups; the chain is then split at every fourth carbon to give acetoacetic acid molecules directly. This theory has little to commend it, and Jowett and Quastel's results are equally explicable on the basis of 2-carbon splitting followed by condensation to form acetoacetic acid as already described. That fatty acids may undergo ω -oxidation—i.e., oxidation beginning at the carbon atom farthest removed from the carboxyl group—to form dicarboxylic acids, is indicated by the isolation from the urine of animals of small amounts of

²¹ See Lardy and Elvehjem: Ann. Rev. Biochem., 14, 1 (1945).

certain long-chain dicarboxylic acids after feeding fatty acids. The significance, if any, of this type of oxidation in the normal metabolism of fatty acids is obscure.

Metabolism of Acetoacetic Acid. Acetoacetic acid, its equilibrium reduction product β -hydroxybutyric acid, CH₃·CHOH·CH₂·COOH, and its decarboxylation product acetone, CH₃·CO·CH₃, are the ketone bodies ("acetone bodies") which normally are found only in very small amounts in the blood and urine. Under certain conditions, as in diabetes mellitus, during starvation, or prolonged subsistence on a low-carbohydrate diet, the amount of these ketone bodies in the blood rises and considerable quantities may be excreted in the urine (see experiment on p. 984). Such a condition is known as ketosis. It was believed for some time that acetoacetic acid and its associated ketone bodies were abnormal metabolic end-products, and in particular that acetoacetic acid represented the inability of the tissues to carry fatty acid oxidation by the β -oxidation process beyond the stage of the 4-carbon compound.

It is now known that acetoacetic acid is a normal end-product of fatty acid oxidation in liver, and it is probably a normal intermediate in fatty acid oxidation in other tissues. The intensity of ketone-body production (ketogenesis) by liver appears to be largely a question of substrate availability. If adequate carbohydrate is available, the liver apparently prefers carbohydrate oxidation as a source of energy, and ketone-body production is small. Carbohydrate is therefore an "antiketogenic" substance. In the absence of carbohydrate oxidation, as in diabetes or when glycogen stores are exhausted, oxidative energy is derived almost entirely from fatty acid breakdown and ketone bodies result. They may be produced by the liver in such quantities that the peripheral tissues are unable to oxidize them as fast as they are formed, in which case they will accumulate in the blood (ketonemia) and be excreted in the urine (ketonuria).

It was felt at one time that ketogenesis was harmful and that it could be controlled by the proper ratio in the diet of ketogenic material (fats, the ketogenic portion of proteins) to antiketogenic material (carbohydrate, the glucogenic portion of protein). These views are no longer held. The major effect of ketosis on the animal body appears to be in relation to acid-base balance; excretion of large amounts of acetoacetic acid and β -hydroxybutyric acid in the urine as their alkali salts depletes the body of available base and may lead to the development of an acidosis.

That ketone bodies may arise from sources other than fatty acid oxidation is well recognized. Their origin from pyruvate under certain circumstances has been shown, and it is well established that certain amino acids such as leucine and phenylalanine are metabolized via the intermediate formation of acetoacetic acid. Presumably any metabolic source of acetic acid could also serve as a source of acetoacetic acid (see p. 927). Thus ketone body production is not a characteristic of fatty acid oxidation alone, but is rather to be considered only one of the various metabolic processes which yield energy to the organism.

Further stages in the breakdown of acetoacetic acid to CO₂ and H₂O are not well established. It is felt by some that a major metabolic pathway

is by way of the Krebs tricarboxylic acid cycle (see p. 911), possibly through reversible equilibrium with acetic acid (see diagram on p. 927). The role of the Krebs cycle in acetoacetate metabolism was first postulated by Breusch²² and by Wieland, ²³ and this has been confirmed by Buchanan, et al.. 24 using carbon-labeled isotopic acetoacetate. After incubation with kidney tissue, the isotopic carbon was found in the originally nonisotopic ketoglutaric acid, succinic acid and fumaric acid added in excess and subsequently isolated from the system; these three compounds are all intermediates in the Krebs cycle. Wieland and Breusch felt that acetoacetate was metabolized by reaction with oxalacetate to form citrate, and indeed this reaction can be shown to occur in kidney tissue; according to Buchanan, et al., citrate cannot be an intermediate in acetoacetate breakdown, so that its formation must represent a side reaction. Medes, Floyd, and Weinhouse²⁵ feel that acetoacetate, pyruvate, and acetate are all metabolized via a common intermediate, possibly acetyl phosphate or the "ketene-like" radical (—CH₂—CO—) proposed by Martius²⁶ as a plausible form of "active" acetic acid (for further discussion, see p. 927).

The possible relationship between fat and carbohydrate metabolism exemplified by the entrance of the reactions of the tricarboxylic acid cycle into acetoacetate metabolism may afford some basis for the aphorism that "fats burn in the fire of the carbohydrates," which has fallen into some disrepute in recent years, possibly because it is clearly not applicable to fat metabolism in the liver. Certainly if it can be shown that carbohydrate metabolism facilitates acetoacetate combustion (which has not as yet been done but which appears likely) the existence of a "ketolytic" as well as an antiketogenic action of carbohydrate must once again be considered, at least in reference to organs other than liver. For further discussions of ketone bodies, see Chapters 29 and 32.

Metabolism of Acetic Acid. Acetic acid is the simplest possible fatty acid with an even number of carbon atoms. It is readily metabolizable when fed to an animal, or when incubated with liver, kidney, or heart tissue (but not brain or muscle). It has been somewhat difficult to evaluate the metabolic significance of acetic acid in the past, because of its metabolic lability and the lack of precise methods for its quantitative determination. By the use of isotope labeling, acetic acid has been implicated in the synthesis of such a variety of substances as acetoacetic acid, fatty acids, cholesterol, protoporphyrin, glycogen, and the dicarboxylic amino acids, as well as in the acetylation of choline to form acetylcholine and of such substances as sulfanilamide and p-aminobenzoic acid which are excreted in part as acetyl derivatives in the urine. On the basis of the "dilution" of isotopic dietary acetate by the nonisotopic acetate of the tissues, Bloch and Rittenberg²⁷ estimate that a 100-g. rat produces about 1 g. of acetic acid per day by all metabolic processes, of which the β -oxidation of

fatty acids may be the major one, but is certainly not the only one involved. Since the animal normally excretes little if any acetic acid in the urine, all of the acetic acid produced must be further metabolized.

Available evidence concerning the metabolic pathways of acetic acid is summarized in the following diagram:

It will be noted that according to this formulation, acetic acid occupies a key position in the metabolism of not only fatty acids but also carbohydrate and certain amino acids; in fact, the diagram may be taken as a general summary of the metabolic interrelationships of carbohydrate, fat, and protein. The position of acetic acid itself in the scheme presented is, however, by no means well established. The direct formation of acetate from pyruvate, for example, has not been demonstrated in animal tissues, although it can be shown to occur in bacteria. This may indicate that ordinary acetate enters into the reactions shown (as it undoubtedly does) by an equilibrium with an "active" form of acetic acid, which in the tissues preferentially undergoes other reactions than that leading to the formation of acetic acid as end-product. Various suggestions for the "active" form of acetic acid include "acetyl groups," acetyl phosphate, a "reactive 2-carbon fragment" of unspecified nature, and a "ketene-like" radical (see p. 926). According to Lipmann, acetyl phosphate (see p. 917) fulfills the requirements for "active" acetic acid. The role of acetyl phosphate in mammalian tissue metabolism has not been unequivocally demonstrated, possibly because the compound is so unstable; in most animal tissues acetyl phosphate is rapidly hydrolyzed into acetate and phosphate. Whatever form "active" acetic acid may ultimately take, it is probable that it will occupy the position assigned to acetic acid in this discussion.

The participation of acetic acid in the formation of such compounds as acetylcholine and acetylsulfanilamide has been definitely established; ac-

cording to Lipmann and Kaplan,²⁸ both reactions require the same coenzyme, although taking place in different tissues (brain and liver, respectively). The formation of acetyl derivatives of foreign aromatic amines (sulfanilamide, p-aminobenzoic acid) and amino acids (phenylaminobutyric acid) has been studied with the aid of the various available isotopes,²⁹ and by other means; both acetic acid and pyruvic acid have been shown to be precursors of acetyl groups in this connection, with possible qualitative and quantitative differences between them. The significance of the origin of acetyl amino acids from pyruvate is further discussed on p. 933, in connection with amino acid metabolism.

Interconvertibility of Fat and Carbohydrate. That the fat of the body may arise from carbohydrate has long been known (see p. 915). The reverse process, the production of carbohydrate from fat and particularly from the fatty acid portion, has been the subject of considerable controversy. Those experimental methods based on the production of extra glucose or glycogen by which it is readily possible to demonstrate the glucogenic power of certain amino acids, for example, yield essentially negative results when fatty acids are studied. For these and other reasons, many have maintained that fats do not give rise to carbohydrate in the animal body, although this conversion can be demonstrated in certain other organisms. The opposing view, held by some, is that gluconeogenesis from fatty acids is readily possible and indeed is the major explanation for the hyperglycemia of diabetes mellitus. Much of the evidence cited in favor of this latter view is faulty. It has nevertheless been unequivocally demonstrated by the use of isotopes that the carbon of certain fatty acids can be incorporated into the glycogen of the animal body, 30 thus proving that fatty acids and carbohydrate are reversibly related, as would indeed be expected from the equilibrium relations shown on p. 927. The amount of conversion found, however, is extremely small relative to that expected if the conversion of fatty acid to carbohydrate were of any value to the organism. It has been suggested that such conversion must be uneconomical to the body in the light of current concepts of carbohydrate metabolism, since carbohydrate formation from fatty acids must inevitably be at the expense of the metabolic energy of carbohydrate breakdown. Whether or not the altered metabolic state of the diabetic facilitates or even requires the conversion of fatty acid to carbohydrate still remains to be unequivocally demonstrated.

Lipotropic Factors. On diets which are high in fats containing much saturated fatty acid and which are low in protein or in choline, there is observed a large increase in the fat content of the liver. A high cholesterol diet likewise leads to the production of a fatty liver, the lipids in this case consisting of cholesterol as well as neutral fat. In either case, an increase

²⁹ Du Vigneaud and Irish: J. Biol. Chem., 122, 349 (1937); Du Vigneaud, Cohn, Brown, Irish, Schoenheimer, and Rittenberg: J. Biol. Chem., 131, 273 (1939); Bernhard: Z. physiol. Chem., 267, 91 (1940); Bloch and Rittenberg: J. Biol. Chem., 159, 45 (1945).

³⁰ Buchanan, Hastings, and Nesbett: J. Biol. Chem., 150, 413 (1943); Wood, Lifson, and Lorber: Data presented at the Atlantic City Meeting of the American Chemical Society, 1946 (unpublished).

in choline in the diet brings about a reduction in liver fat. This is of interest in connection with the possible role of lecithin in fat metabolism, but the explanation for the so-called lipotropic action of choline is not yet established. Methionine likewise exerts a marked lipotropic action, due to its ability to promote the synthesis of choline by the transfer of methyl groups to suitable precursors (see p. 943).

Other substances which exert a lipotropic action include "lipocaic," a substance of as yet unknown nature claimed to be present in the pancreas; inositol, a member of the vitamin B complex (Chapter 35) and a constituent of certain phospholipids (Chapter 11); trytophane, and possibly glutamic acid. Whether these various substances act in an independent fashion or through the mediation of choline action is not clear. Fatty livers are also found under certain conditions in animals deficient in the essential fatty acids, in pantothenic acid or in riboflavin, or in animals which have been provided with an excess of thiamine or biotin (Chapter 35). The relation between these various dietary constituents and the deposition of liver fat is not well defined; it is felt by some that they may represent non-specific factors acting through some general change in the nutritional state.

PROTEIN METABOLISM

The proteins of the diet are considered to be completely broken down to their constituent amino acids in the digestive tract by the action of the various proteolytic enzymes present, and to be absorbed into the animal body in the form of these individual amino acids. The requirement for protein is therefore fundamentally (if not exclusively, see p. 930) a requirement for amino acids, and it should be possible to express the protein requirement of an animal in terms of the amount and kind of amino acids rather than of protein itself. The ability of amino acids to replace protein in the animal diet was first demonstrated many years ago by the use of hydrolyzed protein, supplemented with those amino acids known to be lost during the hydrolysis, in place of protein itself to supply the nitrogen requirements of the animal. This demonstration reaches its peak in the experimental procedure available today, for both human and animal experiments, whereby mixtures of highly purified amino acids, in many cases synthetic products, are used to completely replace protein in experimental diets. The availability of this type of experimental procedure, which was achieved only after the isolation and characterization of the amino acid threonine by McCoy, Meyer, and Rose in 1935, has led to major advances in the science of nutrition. It is also largely responsible for directing attention to the clinical practicality of supplying nitrogen requirements during disease and convalescence by either the oral or intravenous administration of protein hydrolysates and amino acid mixtures. an application of nutritional science which promises to be of outstanding medical value. It is an interesting commentary on scientific progress that approximately four decades elapsed between the demonstration that protein hydrolysates were of nutritional value and the extensive application of this fact in medical practice.

It must not be inferred from what has just been said that knowledge concerning the replacement of dietary protein by protein hydrolysates or amino acids has reached completion. A natural diet contains not one but many proteins, differing widely in amino acid composition which in many instances is not yet fully known. Even in the case of experimental diets where only one protein (e.g., casein) is employed, the replacement of this protein by an amino acid mixture as completely equivalent as possible in the light of present knowledge usually gives growth which is distinctly less than that obtained on the unhydrolyzed or partially hydrolyzed protein.31 Woolley has reported the existence in certain proteins of an unidentified substance called "strepogenin" which is possibly a peptide and which acts as a growth stimulant to bacteria and mice in the presence of completely hydrolyzed protein.32 This substance may contain an unidentified amino acid or it may represent a combination of known amino acids nutritionally more adequate than the individual components themselves. The possible significance of these findings in animal nutrition cannot be overlooked.

Dispensable and Indispensable Amino Acids. The amino acids supplied by the protein of the diet are needed for the synthesis of new body proteins during growth and for the continuous regeneration of the tissue proteins of the adult, as well as for many special purposes such as the formation of hormones, enzymes, purines, bile salts, creatine, and many other similar compounds. It has long been recognized that certain of the amino acids needed by the animal body for these various purposes need not necessarily be present in the proteins of the diet, since they can be synthesized within the tissues from suitable precursors. On the other hand, there are certain amino acids required by the body which cannot be synthesized under ordinary circumstances and which therefore must be present in the diet in adequate amount or nutritional failure, leading ultimately to death, will result.

Those amino acids which can be synthesized by the body from the other constituents of the ordinary diet at a rate adequate for nutritional demands are called "dispensable" or "nonessential" amino acids; those which cannot be so synthesized but must be present in the diet are called "indispensable" or "essential" amino acids. It must be clearly understood that these terms refer solely to the presence of these amino acids in the diet; as far as we know, all of the amino acid constituents of the protein molecule are essential in one way or another for the metabolic processes of the animal body. In fact, as du Vigneaud has pointed out, the so-called "nonessential" amino acids are more properly regarded as being so essential to the animal economy that it has been forced to retain the ability to synthesize them even at the expense of other constituents of the diet.

Knowledge concerning the dictary dispensability or indispensability of various amino acids has been obtained in the past largely by feeding experiments with young animals (e.g., rats) using a diet containing pro-

²¹ Womack and Rose: J. Biol. Chem., 162, 735 (1946).

²² Woolley: J. Biol. Chem., 159, 753 (1945); Sprince and Woolley: J. Am. Chem. Soc., 67, 1734 (1945).

tein known to be low or lacking in certain specific amino acids, or containing a protein hydrolysate from which certain amino acids (e.g., tyrosine, tryptophane) could be removed. Failure of the animal to grow on such a diet, followed by good growth when the diet was supplemented by the missing amino acids, afforded evidence as to the indispensability of the amino acids in question.

This procedure has certain obvious limitations and occasionally gave obscure results. A more adequate experimental basis is afforded by the use of mixtures of pure amino acids as the sole source of dietary nitrogen (Rose). To establish the nutritional significance of any one amino acid, it is only necessary to prepare the mixture without that particular amino acid and to use this deficient mixture as the source of nitrogen for the animal. Much progress has been made in this field since this experimental technique became available.

As a result of the extensive experiments of Osborne and Mendel, of Hopkins, and of Rose, using the various procedures just described, the following tentative classification of the common amino acids with regard to their dietary dispensability or indispensability for the young growing mammal has been suggested by Block:

Indispensable	Partly Ind	lispensable	Dispensable	
Histidine Lysine Tryptophane Phenylalanine Methionine Threonine Leucine Isoleucine Valine	Group A Cystine Tyrosine	Group B Arginine Glycine	Glutamic acid Aspartic acid Alanine Serine Proline Hydroxyproline	

As one might expect, the division between the various groups of amino acids is not entirely a sharp one. Thus, although methionine in sufficient amount will supply the needs of the animal for cystine, cystine is an important constituent of the diet in that it is able to spare that portion of methionine which otherwise would be converted into cystine. A similar situation holds true with respect to the conversion of phenylalanine into tyrosine.

The amino acids in Group B, arginine and glycine, apparently can be synthesized by young mammals but often at a rate insufficient to permit maximum growth. On the other hand, both of these amino acids are necessary for normal growth of chicks. This is an instance where an amino acid may be dispensable for one species of animal and indispensable for another.

Knowledge concerning the amino acid requirements of man is somewhat limited.³³ Of the amino acids listed above as indispensable for the young animal, histidine is apparently dispensable from the diet of the adult human,³⁴ at least as judged by the criterion of maintenance of nitrogen equilibrium (see p. 935). It is quite probable that as more specific criteria than growth or nitrogen balance are used, a somewhat different picture will be obtained than that described here. The conservative policy in human nutrition would indicate the presence in the diet of adequate amounts of all the amino acids listed in the first three columns on p. 931, even though experiments covering a short period in the life span may indicate that all of them are not needed for the period tested.

Two suggestions concerning the recommended daily intake of indispensable amino acids for human nutrition have been made. One is calculated from Rose's data on the minimum daily intake of each amino acid required to induce maximum weight in rats, and the other by Block and Bolling, calculated from the estimated annual per capita consumption of the principal protein foods in the United States between 1937 and 1941. These suggestions are summarized below.

RECOMMENDED DAILY CONSUMPTION OF INDISPEN-SABLE AMINO ACIDS (AVERAGE FOR ENTIRE POPULATION)

Amino Acid	Calculated from Rose (g. per day)	Block and Bolling (g. per day)
Arginine	1.2	4.7
Histidine	2.4	2.0
Lysine		5.2
Tryptophane		1.1
Phenylalanine		4.7
Methionine		4.1*
Threonine	2.9	3.6
Leucine	4.7	10.0
Isoleucine		3.7
Valine	4.1	3.9

^{*} Includes cystine.

Origin of Amino Acids. Although plants are able to synthesize all of the known amino acids when supplied with a source of nitrogen, inorganic as well as organic, the higher animals at least are able to synthesize only a little more than one-half of the common amino acids from the ordinary constituents of the diet or tissues. The limiting factor in the case of those amino acids which cannot ordinarily be synthesized appears in many instances to be the carbon chain or ring structure and not the nitrogen, since it is frequently found experimentally that the synthetic keto- or

²² For review see Melnick: J. Am. Diet. Assn., 19, 685 (1943).

³⁴ Rose, Haines, Johnson, and Warner: J. Biol. Chem., 148, 457 (1943).

hydroxy-acid analog of the amino acid will substitute for the latter in the diet:

Sometimes, but not always, both keto acid and hydroxy acid are effective in this respect; the hydroxy acid presumably gives rise to the keto acid by oxidation. Replacement of a dietary amino acid by its corresponding keto acid indicates that metabolism of the amino acid proceeds reversibly through the keto-acid stage.

Synthesis of an amino acid from a keto acid usually is considered to involve a reversible equilibrium with ammonia; this may proceed through the intermediate formation of the imino acid:

$$\begin{array}{c} +2H \\ +2H \\ -2H \\ \hline \textbf{Amino acid} \\ & -2H \\ \hline \textbf{Amino acid} \\ & -H_2() \\ & \leftarrow \rightarrow \\ +H_2() \\ \hline \textbf{Keto acid} \\ \end{array}$$

The biological formation of the amino acid from the keto acid may also involve acetylation (Du Vigneaud and Irish³⁵):

Another mechanism for the formation of amino acid from keto acid is by the transamination reactions described on p. 948. It is not possible at the present time to evaluate the relative significance of these various processes in the synthesis of amino acids within tissues.

The amino acids found in animal tissues are all of the l configuration (see Chapter 4). In the case of certain amino acids it has been found that the "unnatural" or d configuration is convertible into the natural form

³⁶ Du Vigneaud and Irish: J. Biol. Chem., 122, 349 (1937). See also Bloch and Borek: J. Biol. Chem., 164, 483 (1946).

by the body. This presumably involves loss of the asymmetry around the α carbon by conversion of the amino acid to the keto acid, followed by asymmetric synthesis of the amino acid in its natural configuration. Enzymes capable of converting d amino acids to keto acids are found in many animal tissues. In supplying the amino acid needs of an animal or human with the synthetic dl amino acid, however, it is usually assumed that the d component will be unavailable and twice as much of the dl mixture is supplied as compared to the requirement for the l form. For some amino acids the d form is largely excreted in the urine unchanged, but there are instances (e.g., serine) where the d amino acid has been shown to produce toxic manifestations.

Daily Protein Requirement. The amount of protein required by the individual per day is a nutritional factor of obvious practical significance. A variety of conditions will clearly influence estimations of the protein requirement, Among these may be mentioned growth, pregnancy, or other special demands of the individual; digestibility and absorbability and amino acid composition of the protein; possibly economic availability, individual idiosyncrasy, etc. Estimates of the protein requirement of man usually have been based on studies of the nutritional status of groups of individuals on varying kinds and amounts of protein, and on the extension of the results of animal feeding experiments to man. The Food and Nutrition Board of the National Research Council has recommended that the protein intake of an adult be 1.0 g, per kilo per day, of good quality protein, for adequate nutrition. This corresponds to about 70 g. per day for an average adult human, and will result in a daily urinary nitrogen excretion of about 10 g. The recommended protein allowance for the female is increased during pregnancy and lactation; and for children it varies with age.

The efficiency with which a given protein supplies the nitrogen requirements of an animal may be defined in terms of its so-called "biological value." Although the methods used in the past for the determination of biological value may be subject to revision in the light of changing concepts of protein metabolism (see p. 961), the concept itself retains its usefulness. Broadly speaking, a protein of high biological value is one which has a high digestibility and absorbability and which supplies the organism with adequate amounts of those amino acids which it needs. The amino acids will include not only those which cannot be synthesized by the animal, but also sufficient of the "dispensable" amino acids to minimize the requirements for their synthesis. The presence of low or inadequate amounts of even one of the "indispensable" amino acids may be the limiting factor in the biological value of a protein. For example, if one such amino acid were present in a protein in such low amount that at ordinary levels of ingestion of the protein only half the animal's requirement for this amino acid were met, a nutritional deficiency would result unless the protein intake were raised considerably above the usual level, thus leading to a lowered efficiency with respect to utilization of the other amino acids present. In general, animal proteins are found to have a higher biological value than plant proteins because of the more satisfactory distribution in kind and amount of the various amino acids present. Endosperm proteins of the cereal grains (corn, wheat, rice) are lower in certain of the indispensable amino acids, particularly lysine, than are the commonly consumed proteins of animal origin. This has led to the erroneous generalization that all plant proteins are incomplete or poorly balanced with respect to their essential amino acid composition; as a matter of fact, many vegetable proteins, such as those of oats, beans, yeasts, wheat and corn embryos, leafy vegetables, and grasses, are almost as suitable sources of the amino acids as many of the more expensive animal products. It, is sometimes recommended that at least half the protein of the diet be of animal origin. This is not necessarily an adequate criterion per se, and several proteins of low biological value individually may so complement one another with regard to amino acid composition as to provide a mixture of high biological value.

Since the absence of any one of the indispensable amino acids will result in incomplete retention (utilization) of the remainder, it has been proposed^{35a} that the biological value of certain proteins may be related not only to their content of indispensable amino acids but to the relative rates of their release in and absorption from the intestinal tract. For example, the biological value of soy protein is increased when the raw soybean meal is autoclaved, while that of casein is diminished by baking: in neither case is any difference in indispensable amino acid content observed by analysis. Nevertheless it has been demonstrated that the processing of soy protein increases the rates of release of methionine. leucine, and lysine during enzymatic digestion but at relatively different rates. The effect of differential rates of absorption in vivo would be to furnish incomplete mixtures of absorbed amino acids at the early stage of absorption followed by the too late release and absorption of the supplementary amino acids needed for most efficient utilization. It is well known that ingested amino acids do not accumulate in the blood stream. Hence the proteins of highest biological value are those that not only contain the essential amino acids in adequate amounts but make them available for absorption at relative rates consistent with most efficient utilization for protein synthesis and retention.

Nitrogen Balance and Nitrogen Equilibrium. The relation between the amount of nitrogen entering the body from the diet in the form of amino acids, and the amount of nitrogen excreted from the body in the form of metabolic end-products (chiefly as urea, but to some extent as uric acid, creatinine, etc.) is known as the nitrogen balance. The nitrogen balance is positive if intake exceeds output, negative if output exceeds intake, and, if intake and output are essentially equal, nitrogen equilibrium results. The young growing animal must be in positive nitrogen balance, since a certain portion of the ingested nitrogen is retained as newly formed body proteins and nonprotein nitrogenous compounds. During fasting, or illness associated with wastage of tissues, a negative nitrogen balance exists. The normal healthy adult is ordinarily in a state of nitrogen equilibrium. That is, if the dietary intake of nitrogen is, say, 15 g. per day, the total nitrogen excreted by all channels (urine, feces, skin) will be approxi-

⁸⁵ Melnick, Oser, and Weiss: Science, 103, 326 (1946).

mately 15 g. Of this excreted nitrogen, the urine ordinarily contributes about 90 per cent.

Nitrogen equilibrium may be established at almost any desired level of nitrogen intake, from as low as 2 g. per day to 25 or 30 g. or even more. This apparently is because within these limits the intensity of nitrogen metabolism is determined by the rate of entrance of nitrogen into the body. It was thought at one time that equality of nitrogen intake and excretion represented essentially a disposal of dietary nitrogen in excess of the needs of the animal; that is, a small portion of the entering nitrogen was considered to be utilized by the body for the replacement of nitrogen loss due to "wear and tear" on the body tissues, but the bulk of dietary nitrogen was essentially surplus material and was promptly utilized for energy-yielding purposes without contributing to the nitrogen metabolism of the tissues. This was the basis for the classical distinction of Folin between "endogenous" and "exogenous" nitrogen metabolism; according to this concept, the bulk of excreted nitrogen was of exogenous origin and did not arise by the metabolism of tissue protein.

It is now known that this concept is not true, and that in general the nitrogenous constituents of the diet promptly enter into the varied nitrogen and protein metabolism of the body tissues, becoming indistinguishable from similar substances already present, and the equality between nitrogen intake and output is due primarily to the fact that the rate at which a certain amino acid is metabolized is determined largely by the rate at which that amino acid becomes available to the tissues. In other words, the entrance of a given amount of amino acid into the metabolic processes of the tissue brings about the metabolism of an equal amount of the amino acid molecules which are already present. Thus the distinction between "endogenous" and "exogenous" breakdown disappears, and must be replaced by the concept of a continuous and dynamic nitrogen metabolism the rate of which is determined, as are all chemical reactions, by the concentration of reactants present at a particular time. The only biological exception to this thus far discovered is in connection with purine metabolism; apparently dietary purines cannot penetrate the cell nucleus and thus enter into the endogenous metabolism of nuclear purines.³⁶

This overthrow of the classical distinction between endogenous and exogenous metabolism is due largely to the pioneer work of Schoenheimer and his associates, based upon the application of isotopes to biological problems. The details of some of this work are instructive. Various amino acids (e.g., leucine, glycine) were synthesized in the presence of isotopic nitrogen (N¹⁵) so that the amino acid contained a significant amount of the isotope. These amino acids were then incorporated in small amount in the diet of rats. The urine was collected over a three-day period, after which the animals were sacrificed and the body nitrogen fractionated into protein and nonprotein portions. These, as well as the excreta, were then analyzed for the presence of the isotopic nitrogen. According to the classical concept of endogenous and exogenous metabolism, the urinary urea should have contained most of the dietary nitrogen and therefore most of

²⁶ Plentl and Schoenheimer: J. Biol. Chem., 153, 203 (1944).

the isotopic nitrogen should have appeared promptly in the urine. This did not happen. Less than one-half of the isotopic nitrogen of the glycine was excreted, and less than one-third of that of the leucine. The bulk of the unexcreted isotopic nitrogen was found in the tissue proteins. Later experiments have shown that the labeled amino acid is to a certain extent incorporated directly into the tissue proteins, and likewise contributes its nitrogen to various other amino acids of the body, since both the fed amino acid and other amino acids isolated from the tissue proteins were proved to contain the isotope.

In general, therefore, one may state that the amino acids of the diet enter rapidly into biological equilibrium with the amino acids of the body, becoming incorporated into newly formed protein or entering into reactions which supply nitrogen for the synthesis of other amino acids or other nitrogenous constituents of the tissues. These reactions occur rapidly and independently of the nutritional state of the animal; labeled amino acids are found incorporated into the animal body proteins both when there is an abundance of that particular amino acid in the diet, and when on a nitrogen-free diet the tissue proteins are being extensively broken down for energy purposes.

Conversion of Protein to Carbohydrate and Fat. It has been well established that after metabolic removal of nitrogen, the carbon chain of certain of the amino acids may be utilized by the animal for the formation of carbohydrate. The classical basis for demonstrating this formation entails the use of the drug phlorizin. If an animal is treated with phlorizin, the renal threshold for glucose is lowered to such a degree that administered glucose, or that formed within the animal body by metabolic processes, is excreted almost quantitatively in the urine ("phlorizin diabetes"). A fasting phlorizinized animal will continue to excrete glucose in the urine long after all carbohydrate stores have been exhausted. It is usually (but not invariably) found that such an animal excretes about 3.6 g. of glucose for every gram of urinary nitrogen. The ratio of urinary glucose (dextrose) to urinary nitrogen is known as the D/N ratio, which in this instance is 3.6.

A D/N ratio of 3.6 usually is interpreted to mean that out of every 100 g. of body protein metabolized by the fasting animal, which would correspond to the excretion of 16 g. of urinary nitrogen, about 58 g. of glucose are formed, since ${}^{58}{}_{16} = 3.6$. The remaining 26 g. of protein (i.e., 100 - (58 + 16)), presumably represents that portion which is metabolized via fatty acid or ketone body formation. It should be noted here that there are some who disagree with this interpretation of the significance of the D/N ratio.

If to a fasting phlorizinized animal either protein or certain amino acids are administered, extra glucose is found in the urine, along with extra metabolic nitrogen. By quantitative measurement it is believed possible to evaluate the ability of either protein or amino acids to yield glucose in the animal body. Using this method, it has been found, for example, that various proteins yield from about 50 to as high as 80 per cent of their weight as glucose, and that certain amino acids are glucose-formers while

others are not. Those amino acids which have been shown to be glucogenic by this procedure include glycine, alanine, cysteine, methionine, nor-leucine, proline, serine, valine, arginine, aspartic acid, and glutamic acid. Those amino acids which do not yield extra glucose in the phlorizinized animal include isoleucine, leucine, lysine, phenylalanine, tyrosine, and tryptophane.

The ability of protein to yield glucose would thus appear to be related to the relative proportion of glucogenic amino acids in the molecule and wide variation among proteins may be expected. It is interesting to note that there is a rough parallelism between the glucogenic amino acids and those capable of being synthesized within the animal body. In the light of current knowledge concerning intermediary carbohydrate and protein metabolism, it is not surprising that such amino acids as alanine, glutamic acid, and aspartic acid are glucogenic, since after metabolic removal of their nitrogen there remain the substances pyruvic acid, ketoglutaric acid, and oxalacetic acid respectively, and these latter compounds are recognized intermediates in carbohydrate breakdown and synthesis.

Other methods of studying the conversion of amino acids to carbohydrate include the use of perfusion through isolated organs; the ability of the compound to lead to increased liver glycogen content when administered to the fasting rat; and the ability of the amino acid to reduce an experimentally induced ketosis. Results by the various methods described are not always concordant for a particular amino acid. Tryptophane, for example, will reduce an experimental ketosis but will not lead to an increased liver glycogen content or an increased excretion of glucose in the phlorizinized dog; and other examples might be cited. It is possible that these various procedures measure metabolically independent functions rather than the same general property of carbohydrate formation, but more must be learned about the individual reactions concerned before the subject will be better understood.

The conversion of amino acids to fats or fat metabolites is less well understood than that of carbohydrate formation. Certain of the amino acids (e.g., tyrosine, phenylalanine, leucine) appear to be oxidized directly by way of the formation of acetoacetic acid, and this may in turn give rise to the synthesis of fatty acids. Since proteins can be converted into glucose, and glucose into fat, some fat may arise from protein in this fashion. The significance of this in normal nutrition is uncertain.

Protein Storage. There is as yet no evidence for the existence within the animal body of a storage form of protein analogous to the storage of carbohydrate as glycogen, or of fat. Yet there does appear to be a "reserve" protein supply which can be drawn upon to furnish the fundamental nitrogen requirements of the animal when the protein intake is inadequate. This reserve protein appears to be drawn from the tissues themselves; such organs as the liver and kidney, and the blood plasma, appear to be capable of undergoing a considerable depletion of protein content to supply the needs of other parts of the body for nitrogen during fasting. Other organs—e.g., muscle—are more resistant to protein depletion.

Specific Dynamic Action of Protein. When protein is fed, more heat is produced in the body than can be accounted for by the combustion of the protein ingested. One view is that this action is due to the stimulating action on the tissue cells of certain products of amino acid catabolism, perhaps hydroxy acids, leading to increased oxidation of carbohydrate by such cells. Glycine, alanine, and phenylalanine appear responsible for much of the specific dynamic action of proteins. Carbohydrates and fats also exert a specific dynamic action, but to a lesser extent than proteins and amino acids. For a further discussion of this subject, the reader is referred to Borsook³⁷ and Kriss, ³⁸

METABOLISM OF INDIVIDUAL AMINO ACIDS

Glycine. This amino acid enters into a variety of metabolic functions. In addition to its presence in many of the body proteins (collagen, for example, is rich in glycine), it is concerned in the synthesis of such non-protein compounds as (1) the glycocholic acid of the liver, (2) the creatine of muscle and other tissues, (3) the glutathione of the cells, (4) the protoporphyrin (heme) portion of hemoglobin, and (5) the hippuric acid and similar compounds found in the urine after ingestion of benzoic acid and other unoxidizable substances. Other aspects of glycine metabolism undoubtedly remain to be recognized.

Glycine is readily synthesizable by both the rat and the adult human; it is thus "dispensable" from the diet of these species. It has been shown, however, that about 1 per cent of glycine is necessary in the diet of the chick to ensure adequate nutrition (Almquist). This is one of several known examples of species specificity with regard to dietary amino acid requirements. The rate of synthesis of glycine in man has been estimated by Quick, on the basis of the rate of excretion of hippuric acid after benzoate administration, to be somewhat over 0.5 g. per hour. It has been shown by Rittenberg and Schoenheimer that synthesized glycine may be derived from sources within the body as well as from the diet. Shemin³⁹ has demonstrated that the amino acid serine is a significant precursor of glycine, and there is some indication that glutamic acid may also give rise to glycine, possibly through the intermediary formation of serine.

Knowledge concerning the metabolic degradation of glycine is limited, in spite of (or possibly because of) the relatively simple chemical composition of this amino acid. In the diabetic dog, the carbon chain of glycine can be shown to be readily convertible into glucose; the mechanism of this conversion is obscure. Studies on the metabolism of glycine by isolated tissues have yielded little definite information concerning glycine breakdown. Animal tissues contain a flavoprotein enzyme which catalyzes the oxidation of glycine to glyoxylic acid and ammonia.⁴⁰

$$\begin{array}{c|c} CH_2NH_2 & [O] & CHO \\ & \longrightarrow & | & + NH_3 \\ COOH & COOH \\ Glycine & Glyoxylic \\ & acid \end{array}$$

The significance of this reaction in glycine metabolism remains to be elucidated.

Of major interest is the part played by glycine, along with arginine and methionine, in the biological synthesis of creatine. The separate steps in the formation of creatine have been shown to be as follows:

Bloch and Schoenheimer⁴¹ demonstrated by feeding experiments using both glycine and arginine containing isotopic nitrogen that the two nitro-NH₂

gen atoms in the amidine portion (—C=NH) of creatine were derived from the amidine portion of arginine, and the third nitrogen atom came from glycine. Borsook and Dubnoff⁴² showed that kidney tissue forms guanidoacetic acid from arginine and glycine, and that liver tissue synthesizes creatine from guanidoacetic acid in the presence of methionine. Du Vigneaud and associates⁴³ proved that the methyl group of creatine originates from methionine by animal experiments using methionine in which the methyl group was labeled with isotopic hydrogen (deuterium). The creatine isolated from the animal body after feeding isotopic methionine contained sufficient isotope in the methyl group to establish the origin of the latter from methionine.

Guanidoacetic acid itself, the intermediate in creatine synthesis, is found normally only in small amounts in animal tissues, but readily gives rise to extra creatine formation when fed. The complicated pathway from glycine to creatine is presumably responsible for the variation in the literature concerning the effectiveness of glycine as a precursor of creatine. Glycine appears also to be directly concerned in the synthesis of glutathione, the tripeptide which is thought to be of importance in intracellular oxidation and reduction. Waelsch and Rittenberg⁴⁴ showed that when

isotopic glycine was fed to an animal, the labeled glycine appeared so rapidly in the glutathione of the animal body as to indicate the direct participation of glycine in the synthesis of this compound. Involvement of glycine in the synthesis of hemin by the adult human is also indicated by the use of isotopic glycine. After prolonged administration of labeled glycine to an individual, the hemin isolated from the red blood cells contains sufficient isotopic carbon to indicate a major role of glycine in the synthesis of the pyrrole ring of the hemoglobin molecule. ⁴⁵ Acetic acid also has been implicated in this synthesis (see p. 936).

Relatively little work has been done on the role of glycine in the synthesis of the glycocholic acid of the liver. The relationship of glycine to hippuric acid formation is discussed in detail in Chapter 20. The ability of certain tissues to synthesize hippuric acid *in vitro* has been used as a means of establishing possible precursors of glycine.

Alanine. This 3-carbon amino acid is readily synthesized by the animal body and hence is dispensable from the diet. Metabolism and synthesis usually are considered to involve the reversible equilibrium of oxidative deamination (see p. 933).

$$\begin{array}{c|cccc} CH_3 & CH_3 \\ | & (ox.) & | \\ HCNH_2 & \longleftrightarrow CO & + NH_3 \\ | & (red.) & | \\ COOH & COOH \\ Alanine & Pyruvic \\ & acid \\ \end{array}$$

There is little evidence that this reaction actually occurs in the tissues; the *l*-amino acid oxidase of Blanchard, *ct al.*, ⁴⁶ attacks alanine but slowly, and there is no biological evidence for the synthesis of alanine from pyruvic acid and free ammonia. A more plausible metabolic pathway is by the reactions of transamination described on p. 948, whereby synthesis would entail the transfer of the amino group of either glutamic or aspartic acid to pyruvic acid, to yield alanine and either ketoglutaric acid or oxalacetic acid, and metabolic breakdown would be the reverse of these reactions. The pyruvic acid thus formed from alanine by transamination may then follow the normal course of oxidation of carbohydrate intermediates (p. 910). Conversion to pyruvic acid presumably is the explanation for the glucogenic action of alanine. By the use of alanine labeled with isotopic hydrogen (deuterium), it has been shown that alanine may be a source of acetyl groups in the acetylation of certain foreign amino acids excreted in the urine as acetyl derivatives (see p. 928 and Chapter 20).

Serine. This hydroxy-amino acid is readily synthesizable by the animal body and is thus dispensable from the diet. It nevertheless participates in a somewhat unusual variety of metabolic reactions in the tissues. In addition to its presence in proteins, it has been found in phospholipid material, where it apparently serves in a manner analogous to choline and

⁴⁵ Shomin and Rittenberg: J. Biol. Chem., 159, 567 (1945).

⁴⁶ Blanchard, Green, Nocito, and Ratner: J. Biol. Chem., 161, 583 (1945).

ethanolamine in the structure of phospholipid molecules (see Chapter 11). In fact, studies by Stetten⁴⁷ using serine labeled with isotopic nitrogen indicate that ethanolamine arises by the decarboxylation of serine; ethanolamine can then give rise to choline by methylation. Serine is also a precursor of glycine. These relationships may be indicated as follows:

Serine is also concerned in the formation of cystine (see p. 945). Serine is glucogenic in the diabetic dog. The "unnatural" optical isomer of serine, d-serine, is toxic to rats.⁴⁸

Threonine. This amino acid cannot be synthesized by the animal body, and its presence in the diet in adequate amount is required both for growth in the young rat and for the maintenance of nitrogen equilibrium in the adult human. Threonine was the last "essential" amino acid to be discovered, in the sense that its isolation from casein and characterization by McCoy, Meyer, and Rose in 1935 first permitted the use of a mixture of pure amino acids as the sole source of nitrogen in an experimental diet.

Relatively little is known concerning the metabolism of threonine. It is glucogenic and antiketogenic. It is not attacked by the l-amino acid oxidase of rat kidney, but there may be another enzyme concerned since it has been reported to be deaminated by kidney tissue under anaerobic conditions to produce α -ketobutyric acid, $CH_3 \cdot CH_2 \cdot CO \cdot COOH$. Only the optically active form found naturally is utilizable for growth.

Methionine. This sulfur-containing amino acid cannot be synthesized by the animal body from the ordinary constituents of the diet, and must be present in adequate amount for the promotion of growth in the young animal and for the maintenance of nitrogen equilibrium in the adult human. Methionine alone will satisfy all of the sulfur requirements of the animal, since it is readily converted into cystine in the tissues, as described on p. 945.

Methionine is glucogenic in the diabetic dog. Metabolism may proceed in part by deamination through the corresponding keto acid, CH₂·S·CH₂·CO·COOH, since this latter compound is formed to considerable extent on incubating methionine with liver tissue, ⁴⁹ and the young rat will grow on a diet containing the keto acid in place of methionine. ⁵⁰ Further stages in the oxidative breakdown of methionine are obscure. On complete oxidation, the sulfur is found in the urine as sulfate, either inorganic or ester, as with cystine (p. 946).

 Cahill and Rudolph: J. Biol. Chem., 145, 201 (1942).

Transmethylation. An important metabolic function of methionine is in connection with the process known as transmethylation. It has been shown by Du Vigneaud and associates that the animal body is incapable of synthesizing methyl groups required for the methylation of certain nitrogen- and sulfur-containing compounds of the body but is dependent upon the presence in the diet of the needed methyl groups in utilizable form. Methionine, choline, and betaine (trimethylglycine) have been shown to be suitable dietary sources of such methyl groups: of these, methionine appears to be quantitatively the most important. In the biological synthesis of creatine, for example (see p. 940) the methyl group of creatine is derived by transfer from methionine. The process of methyl transfer from one compound to another is called transmethylation. A methyl group which may be so transferred is called a "labile methyl group": thus far, only methyl groups attached to either nitrogen or sulfur appear to be labile and to participate in transmethylation. The requirement of the animal body for labile methyl groups may be regarded as a nutritional principle in every respect analogous to the requirement for vitamins or "indispensable" amino acids.

The role of methionine in transmethylation has been adequately proved by the use of methionine synthesized to contain isotopic hydrogen (deuterium) in the methyl group.⁵¹ When such labeled methionine is included in the diet of an animal, the methylated compounds choline and creatine subsequently isolated from the animal tissues prove to contain sufficient isotope to justify the conclusion that methyl groups have been transferred from the methionine to the other compounds in question. The ability of methionine to furnish methyl groups for the synthesis of choline from suitable precursors explains the lipotropic effect of this amino acid (see p. 928). The transfer of methyl groups from methionine to choline is reversible, most probably through the intermediate formation of the amino acid homocysteine (see below); methylation of guanidoacetic acid to form creatine is irreversible, and the constant exerction of body creatine as urinary creatinine represents a loss of methyl groups from the body. The daily requirement for methyl groups, however, appears to be considerably in excess of such urinary loss, so that other pathways of methyl group degradation must be present; relatively little is known about this at the present time. Most of the evidence for transmethylation has been obtained with the rat, but the process has also been shown to occur in the adult human.

After removal of the methyl group from methionine, the amino acid homocysteine results. Homocysteine, HS·CH₂·CH₂·CH(NH₂)·COOH, and its disulfide form homocystine (analogous to the relation between cysteine and cystine) are synthetic amino acids which have not as yet been isolated from natural sources. Their biological availability is such, however, as to lead to the belief that they represent normal intermediates in methionine metabolism. If an animal is placed on a diet containing no methionine but adequate amounts of homocysteine or homocystine, to
10 Vigneaud, Cohn, Chandler, Schenck, and Simmonds: J. Biol. Chem., 140, 625

(1941).

gether with a source of labile methyl groups such as choline, or betaine, the animal will synthesize the methionine it needs for normal growth. If the methyl groups of the dietary choline are labeled with deuterium, the methionine subsequently isolated from the tissue proteins proves to contain the isotope in its methyl group. The animal body is therefore capable of transferring methyl groups from choline to homocysteine, to form methionine; as has already been pointed out, this transfer is reversible. Since the reversible exchange of methyl groups between methionine and choline can be demonstrated not only on the homocysteine diet but also when the diet contains adequate amounts of methionine and choline, it is believed to represent a normal metabolic process of the tissues. The implication of homocysteine in the formation of cystine from methionine is discussed on p. 945. The general metabolic relation between methionine, homocysteine, and related compounds may be represented as follows:

$$CH_{3}$$

$$CH_{3} \longrightarrow V$$

$$CH_{2} \longrightarrow CH_{2} \longrightarrow CH_{2}$$

$$CH_{2} \longrightarrow CH_{2}$$

$$CH_{3} \longrightarrow Creatine$$

$$CH_{2} \longrightarrow CH_{2}$$

$$CH_{3} \longrightarrow CH_{2}$$

$$CH_{2} \longrightarrow CH_{2}$$

$$CH_{3} \longrightarrow CH_{3}$$

$$CH_{3} \longrightarrow CH$$

In addition to its known metabolic functions, methionine appears to play a specific part in protecting the liver from damage by such poisons as carbon tetrachloride, phosphorus, arsenic, and chloroform. The mode of action here is unknown.

Cystine and Cysteine. These two sulfur-containing amino acids usually are considered to be metabolically equivalent since one may be so readily converted into the other by oxidation or reduction. There is some evidence, however, that there may be biological differences between cysteine and cystine, particularly in specific organs such as the liver and kidney. In the rare metabolic abnormality known as "cystinuria," individuals regularly excrete significant amounts of cystine in the urine. This excretion continues during fasting, and is not increased by the oral administration of cystine itself; the feeding of cysteine or of methionine does, however, augment cystine excretion. Thus the cystinuric distinguishes

between orally administered cystine and cysteine, and the normal individual may do so in specific tissues as well.

It was thought for a long time that cystine was an indispensable amino acid, but Jackson and Block⁵² showed in 1932 that methionine could replace cystine for growth purposes in the rat on a low-cystine diet, and the ability of the animal body to form cystine from methionine is now well established. In 1939 Tarver and Schmidt⁵³ demonstrated by the use of methionine containing radioactive sulfur that the sulfur of cystine was derived from the sulfur of methionine.

The mechanism of formation of cystine from methionine has been the subject of considerable study, and appears to have been finally established by the work of Du Vigneaud and his associates as follows: methionine is demethylated to form the amino acid homocysteine; this condenses with serine to form an unsymmetrical thio-ether, called cystathionine; the cystathionine undergoes enzymatic cleavage so that the sulfur remains with the serine moiety, to produce cysteine. The fate of the remaining portion of the cystathionine molecule is as yet not known. These various steps may be illustrated as follows:

Evidence for the conversion of methionine to homocysteine has already been presented (p. 943). When homocysteine and serine are incubated with liver tissue, cysteine is formed.⁵⁴ It has also been shown by Stetten⁵⁵ that when serine labeled with isotopic nitrogen is fed to animals, the cystine isolated from the tissues contains such a high proportion of the isotope as to indicate (but not prove) the direct conversion of serine to cysteine. Cystathionine, the postulated intermediate, has not as yet been isolated from tissues, but the synthetic compound undergoes enzymatic cleavage by liver tissue to yield cysteine, and also serves as a source of cystine when present in the diet.⁵⁶ If methionine is synthesized to contain both isotopic sulfur and isotopic carbon, and this doubly labeled compound is fed to rats, the cystine isolated from the hair proves to contain

as much as 80 per cent of the isotopic sulfur, but no isotopic carbon.⁵⁷ This is further evidence that it is the sulfur and not the carbon chain of methionine which is involved in the formation of cystine.

Cystine and cysteine contribute to the formation of many important sulfur-containing compounds in the animal body. Cysteine is a component of glutathione (γ -glutamyl-cysteyl-glycine); and appears to be the precursor of the taurine of the taurocholic acid of the bile, probably through intermediate oxidation to form cysteic acid:

Cysteine is likewise found in the urine in combination with certain unoxidizable substances (detoxication), to form what are called mercapturic acids (see Chapter 20). Cysteine is glucogenic in the animal body, possibly through the intermediate formation of serine. On complete oxidation of cysteine and cystine, the sulfur is found in the urine either as inorganic sulfate or to some extent as organic esters of sulfuric acid with such compounds as indoxyl, phenol, etc. This is also discussed in Chapter 20.

Leucine, Isoleucine and Norleucine. Relatively little is known concerning the metabolism of these three amino acids. Both leucine and isoleucine are not synthesizable from dietary constituents and are required in the diet for the growth of young animals and the maintenance of nitrogen equilibrium in the adult. Norleucine, concerning whose presence in proteins there is some question, must be synthesizable since its presence in the diet is unnecessary. Leucine and isoleucine are ketogenic rather than glucogenic amino acids; feeding experiments with norleucine indicate it to be glucogenic. The conversion of leucine to β -hydroxybutyric acid may possibly proceed as follows:

⁶⁷ Du Vigneaud, Kilmer, Rachele, and Cohn: J. Biol. Chem., 155, 645 (1944).

Valine. This amino acid is required in the diet in adequate amount, as evidenced both by growth studies with young animals and by the maintenance of nitrogen equilibrium in the adult human. A possible metabolic pathway involves deamination to form α -keto-isovaleric acid, since this compound will replace valine in an experimental diet.

Valine is convertible, in part at least, to glucose in the diabetic dog.

Proline and Hydroxyproline. These two amino acids can be synthesized by the animal body from dietary or tissue precursors, and proline is glucogenic in the diabetic dog. A probable precursor of proline is ornithine; since ornithine and proline are interconvertible in the organism, proline metabolism may proceed through ornithine formation. ⁵⁸ Glutamic acid has likewise been shown to arise from proline; further metabolism via this pathway would then be that of glutamic acid, and this may be the origin of the glucogenic action of proline. Hydroxyproline can be synthesized from dietary proline; there is some evidence that this reaction is not reversible, and that the further metabolism of hydroxyproline may not be similar to that of proline. ⁵⁹ These various relationships may be summarized as follows:

<sup>Stetten and Schoenheimer: J. Biol. Chem., 153, 113 (1944); Shemin and Rittenberg: J. Biol. Chem., 158, 71 (1945).
Pedersen and Lewis: J. Biol. Chem., 154, 705 (1944).</sup>

Glutamic Acid. This dicarboxylic amino acid is present in fairly large amount in many animal and vegetable proteins. It is readily synthesizable by the animal body, and is thus dispensable from the diet; it is probable, however, that the ease of synthesis within the tissues is more properly a reflection of the important part played by glutamic acid in the general processes of nitrogen metabolism within the cell rather than an indication of a "nonessential" function.

Evidence that glutamic acid may be an important intermediate in general nitrogen metabolism is afforded by the work of Schoenheimer and associates using various amino acids labeled with isotopic nitrogen (N¹⁵). When such labeled amino acids are fed to an animal, the isotopic nitrogen is found not only in the fed amino acid incorporated into the tissue proteins of the animal, but also to a significant extent in various other amino acids as well, and of these glutamic acid usually exhibits the highest concentration of isotope. It is probable that transamination (see below) is partly responsible for this; the presence of glutamic acid in glutathione may also be connected with the apparently rapid transfer of dietary amino nitrogen via glutamic acid.

Transamination. An important metabolic aspect of glutamic acid is its participation in the reactions of transamination, first discovered by Braunstein and Kritsman and further clarified by the work of Cohen, Green, and others. In the transamination reaction, the amino group of glutamic acid is transferable to either pyruvic or oxalacetic acid to produce α -ketoglutaric acid and the amino acids alanine or aspartic acid, as the case may be. These reactions are reversible so that glutamic acid may be synthesized from α -ketoglutaric acid and either alanine or aspartic acid. The following diagram illustrates the transamination reactions:

Enzymes catalyzing the upper reaction (glutamic-aspartic transaminase) and the lower reaction (glutamic-alanine transaminase) have been

isolated from animal tissues, 60 and are believed to contain a pyridoxine (vitamin B₆) derivative as prosthetic group. A third postulated reaction, between aspartic acid and pyruvic acid to produce oxalacetic acid and alanine, is, according to Green, due to the presence of both of the transaminases mentioned. It is noteworthy that no free ammonia is formed during transamination, the reaction apparently involving condensation of amino acid and keto acid through the amino and keto groups to form an intermediate which is then split in such a way that the amino nitrogen is transferred from the original amino acid to the keto acid chain.

In addition to transamination, glutamic acid likewise undergoes reversible oxidative deamination, as shown by Von Euler, et al.⁶¹

Glutamic acid $\rightleftharpoons \alpha$ -Ketoglutaric acid $+ NH_3$

The reversal of this reaction is one of the few known examples of the biological synthesis of an amino acid from the keto acid and ammonia, and may represent one of the pathways for the demonstrated (although limited) conversion of dietary ammonia nitrogen into amino acid nitrogen.

As would be expected from the equilibrium between glutamic acid and its keto acid, α -ketoglutaric acid, which is an intermediate in carbohydrate metabolism (p. 911), glutamic acid is glucogenic in the diabetic dog. Certain other amino acids such as proline, ornithine, and histidine are known to give rise to glutamic acid in metabolism, and this may also explain their glucogenic action. The other keto acids involved in transamination (oxalacetic acid and pyruvic acid) are likewise carbohydrate breakdown products, and this may represent an important link between amino acid metabolism and carbohydrate metabolism.

Glutamic acid is combined as one of the three portions of the molecule of the vitamin pteroylglutamic (folic) acid, the other two being p-aminobenzoic acid and pteroic acid; the various conjugated forms of this vitamin are due to the multiplicity of glutamic acid units present in peptide linkage—e.g., the conjugate in liver contains seven such units while that obtained from fermentation contains three. (See Chapter 35.)

Glutamic acid appears to be present in proteins largely in the form of its amide, glutamine, HOOC·CH(NH₂)·CH₂·CH₂·CONH₂ Free glutamine has been found in small amount in the blood, and according to Van Slyke and associates, ⁶² glutamine or a glutamine-like compound is of importance as a precursor of urinary ammonia. Glutamine has also been implicated in the processes of urea formation by the liver, but its role here, if any, is obscure. The reported presence in cancer tissue of the "unnatural" optical isomer of glutamic acid, d-glutamic acid, has not been confirmed, but d-glutamic acid is found in the capsule of the anthrax bacillus and in other products of bacterial origin.

Aspartic Acid. The metabolic aspects of this amino acid are less well understood than those of glutamic acid, but it appears to be similar to the

⁶⁰ Green, Leloir, and Nocito: J. Biol. Chem., 161, 559 (1945)

⁶¹ Von Euler, Adler, Günther, and Das: Z. physiol. Chem., 254, 61 (1938).

⁶³ Van Slyke, Phillips, Hamilton, Archibald, Futcher, and Hiller: J. Biol. Chem., 150, 481 (1943).

latter in certain respects. It is readily synthesizable within the body, and shares with glutamic acid in the transfer of dietary amino nitrogen as described on p. 948, but to a lesser extent. Synthesis probably proceeds via the transamination reaction involving the keto acid, oxalacetic acid, and glutamic acid as described previously. Metabolic breakdown by the reversal of this reaction to form oxalacetic acid, which is a carbohydrate intermediate, serves to explain the glucogenic power of aspartic acid as well as to indicate the pathway of further degradation. The amide of aspartic acid, asparagine, HOOC·CH(NH₂)·CH₂·CONH₂, is found in tissue proteins, but its significance is obscure.

Histidine. Histidine is required in the diet of the young growing animal but is apparently dispensable from the diet of the adult human, as established by the maintenance of nitrogen equilibrium in man on diets free of histidine. Here, as with arginine, it may be that rate of synthesis is the limiting factor, with the possibility that bacterial action in the intestinal tract may also be concerned. According to Edlbacher, 63 the chief route of histidine catabolism is through the intermediate formation of glutamic acid after splitting of the imidazole ring:

That other metabolic pathways exist is indicated by the fact that the young growing animal must require histidine for some purpose other than the synthesis of glutamic acid, and by the fact that the keto- and hydroxyacid analogs of histidine will replace this amino acid in the diet. Animal tissues contain an enzyme capable of decarboxylating histidine to yield histamine, and this is probably the biological source of the latter compound. After feeding histidine to certain species of animals, the compound urocanic acid may be isolated from the urine; the significance of urocanic acid in histidine metabolism is believed to be slight.

In addition to its presence in tissue proteins, histidine is found in the animal body in the muscle constituent carnosine (β -alanyl histidine), and it is probably a precursor of the red blood cell constituent ergothioneine, which is a betaine of thiolhistidine. Histidine is regularly found in the

⁴² Edibacher and Kraus: Z. physiol. Chem., 191, 225 (1930).

urine during pregnancy (and also in some other conditions); the significance of this is unknown. Histidine is glucogenic, possibly because of giving rise to glutamic acid during metabolism.

Lysine. This amino acid is required in the diet of the young growing animal and for the maintenance of nitrogen equilibrium in the adult human. It is not glucogenic in the diabetic dog. It is unique among all the amino acids thus far investigated in that it does not appear to be capable of obtaining its nitrogen from other dietary sources, as can be done by those other amino acids which have been studied (see discussion on p. 937). Lysine, however, can contribute its nitrogen to other amino acids after metabolic breakdown. The metabolism, therefore, may involve an oxidative deamination which for some reason is irreversible. This is borne out by the fact that neither the keto acid nor the hydroxy acid derivative of lysine can substitute for this amino acid in experimental diets. Studies with isolated tissues have failed to indicate any definite metabolic pathway for lysine.

Arginine. The question of whether or not this amino acid can be synthesized by the animal body has been the subject of considerable debate in the past. It now appears to be settled, largely through the work of Rose, using diets containing mixtures of pure amino acids, that arginine can be synthesized by the tissues of the young growing rat, for example, but not at a rate fast enough to supply the needs of the animal for optimal growth. It is thus indispensable in this sense in the diet of the young growing rat. The adult rat (and the adult human) apparently can supply arginine by synthesis from other sources at a rate adequate for nutritional needs. On the other hand, the requirements of the chick for arginine are such that this amino acid must be considered indispensable in the diet—an example of species differences with respect to amino acid requirements.

Various studies using amino acids labeled with isotopic nitrogen and hydrogen have indicated that arginine is synthesized in the body by the NH_2

addition of an amidine group (—C—NH) to ornithine, HOOC-CH(NH₂)-CH₂·CH₂·CH₂·NH₂. The origin of the amidine group is not known (a possible mechanism is by the "ornithine cycle" discussed below), but ornithine is readily synthesizable biologically—for example, from proline (p. 947). Evidence that the synthesis of arginine is reversible is not available, but it is known that the amidine portion may be transferred to glycine to form guanidoacetic acid in the synthesis of creatine (p. 940). Arginine also may be degraded to form ornithine and urea in the presence of the enzyme arginase, as described below. There is evidence that arginine may give rise via ornithine to proline, hydroxyproline, and glutamic acid, and these may represent further stages in metabolism. Both arginine and ornithine are glucogenic, possibly because of their convertibility to the amino acids just mentioned. There is some evidence that the α -amino nitrogen of arginine does not undergo oxidative deamination to form the corresponding keto acid, or if so, that this process is irreversible.⁶⁴

⁶⁴ Shemin and Rittenberg: J. Biol. Chem., 158, 71 (1945).

Interest in the metabolic function of arginine has been directed primarily toward its possible relation to the synthesis of creatine and the formation of urea. The role of arginine in creatine formation is described in detail on p. 940. Interestingly enough, an arginine analog of phosphocreatine (namely, phosphoarginine) appears to serve in place of phosphocreatine in the muscles of certain lower animal species.

The possible role of arginine in urea formation by mammalian liver has been evident for a long time because of the presence of the enzyme arginase in liver; arginase catalyzes the hydrolytic splitting of arginine into ornithine and urea. According to Krebs and Henseleit, 65 arginine enters into a cyclic mechanism, along with the amino acids ornithine and citrulline, for the conversion of ammonia into urea in the liver. The process is pictured as follows:

According to this theory, ammonia and carbon dioxide react with the amino acid ornithine (possibly through the intermediate formation of carbamino-ornithine) to produce the amino acid citrulline. On the further addition of ammonia to citrulline, arginine is formed which then undergoes action by the enzyme arginase to produce urea and to regenerate ornithine, which can then proceed through the cycle again. The original evidence for this theory was based largely on the demonstration that both ornithine and citrulline catalyzed the synthesis of urea from free ammonia by liver slices. Additional evidence tending to support the theory has come from several sources. If the liver slices are incubated in the presence of bicarbonate containing isotopic carbon, the carbon isotope is found in the urea synthesized. Schoenheimer's work on the distribution of isotopic dietary nitrogen between the amidine moiety and the ornithine moiety of arginine isolated from tissue proteins, and the isotope content of the urinary urea, led him to conclude that the results supported the

Krebs and Henseleit: Z. physiol. Chem., 210, 33 (1932).
 Evans and Slotin: J. Biol. Chem., 136, 805 (1940).

"ornithine cycle" theory. According to Gornall and Hunter, ⁶⁷ the accumulation of citrulline in liver tissue during urea formation under special conditions may be demonstrated, and citrulline may also be found in small amount in the blood. ⁶⁸ Beadle and Tatum also have presented evidence that the "ornithine cycle" mechanism functions in the red bread mold Neurospora. ⁶⁹

Despite this evidence, there is some doubt about the validity of the theory as it applies to the normal mechanism of urea formation. Incubated liver slices will produce urea in the absence of any significant amount of free ammonia, and this synthesis is not catalyzed by added ornithine. The demonstration of ornithine catalysis requires amounts of free ammonia much greater than those ever found in normal liver tissue; it is possible that the "ornithine cycle" represents a mechanism for the "detoxication" of ammonia, as indeed Krebs and Henseleit suggested, rather than the normal pathway of urea formation. The role of citrulline in the process is not clear, and alternate mechanisms have been proposed; in fact, it is more readily possible to demonstrate the synthesis of citrulline in kidney tissue than in liver tissue. Borsook and Dubnoff⁷⁰ question, on thermodynamic grounds, the entrance of ammonia and carbon dioxide as such into the cycle; and in general it would appear that a more satisfactory picture than that afforded by the "ornithine cycle" remains to be found.

Tryptophane. This amino acid is required in the diet for growth of the young animal and the maintenance of nitrogen equilibrium in the adult human. It has several metabolic pathways which appear to vary somewhat in different species of animals. One metabolic pathway involves oxidation to kynurenic acid through the intermediate formation of kynurenine:

$$\bigcap_{\substack{N\\H}} \operatorname{CH}_2 \cdot \operatorname{CH}(\operatorname{NH}_2) \cdot \operatorname{COOH} \to \bigcap_{\substack{N\\H_2}} \operatorname{CO} \cdot \operatorname{CH}_2 \cdot \operatorname{CH}(\operatorname{NH}_2) \cdot \operatorname{COOH}$$

Tryptophane

Kynurenine

Kynurenic acid
(4-hydroxyquinoline2-carboxylic acid)

Some animal species (but not others) will excrete kynurenic acid in the urine after the ingestion of large doses of tryptophane (Jackson). There

⁶⁷ Gornall and Hunter: J. Biol. Chem., 147, 593 (1943).

⁶⁸ Archibald: J. Biol. Chem., 156, 121 (1944).

⁶⁹ See Beadle: Harvey Lect., 40, 179 (1944-1945).

⁷⁰ Borsook and Dubnoff: Ann. Rev. Biochem., 12, 183 (1943).

is some basis for the belief that kynurenic acid is an end-product and not an intermediate in tryptophane metabolism. Kynurenine is claimed to be a hormone for Drosophila. Tryptophane can be converted into 4,8-dihydroxyquinoline-2-carboxylic acid (xanthurenic acid) by the rat. The red bread mold Neurospora can synthesize tryptophane from indole and serine. The reverse of this reaction, i.e., the production of indole by bacterial action on tryptophane in the intestinal tract, is believed to be the origin of the indole, skatole (methyl indole) and indican of the feces and urine. Tryptophane deficiency produces a type of cataract in the rat, and recent evidence indicates a relation between anemia, tryptophane, and vitamin B_6 (pyridoxine).

Tryptophane catabolism may proceed by oxidative deamination to the corresponding keto acid, indolepyruvic acid, since this compound (and indolelactic acid) will replace tryptophane in experimental diets. Tryptophane does not give rise to glucose in the diabetic dog, but it is apparently not ketogenic and will alleviate experimental ketonuria in the rat.

Phenylalanine and Tyrosine. These two aromatic amino acids usually are considered together because of their close metabolic relationship. Of the two, phenylalanine cannot be synthesized by the animal body (except from its corresponding keto- or hydroxy-acid, which are not ordinary constituents of the diet) and therefore must be present in the diet in adequate amounts. The needs of the animal for tyrosine, however, can be readily supplied by dietary phenylalanine, as established by growth studies with young rats and by the maintenance of nitrogen equilibrium in the adult human. Phenylalanine, therefore, is convertible into tyrosine by the organism; this conversion has been directly demonstrated by the feeding of phenylalanine labeled with isotopic hydrogen (deuterium) to rats, followed by the subsequent isolation of tyrosine from the animal's tissue proteins; such isolated tyrosine contained sufficient deuterium to establish its origin from the fed phenylalanine.⁷¹ All available experimental evidence indicates, however, that the conversion of phenylalanine into tyrosine is *irreversible*; tyrosine cannot be converted into phenylalanine in the animal body.

Knowledge concerning the intermediary metabolism of both phenylalanine and tyrosine is still far from complete. In addition to their roles as essential components of the body proteins, these two amino acids, and particularly tyrosine, appear to be concerned with the formation of a variety of physiologically important substances such as thyroxine, adrenaline, the pigment melanin, and others. Certain of the known or postulated metabolic interrelationships of tyrosine and phenylalanine are summarized in the diagram on page 955.

Both phenylalanine and tyrosine are ketogenic amino acids, i.e., they can be shown to give rise to acetoacetic acid under the proper conditions, and neither amino acid is glucogenic. It is postulated, therefore, that after the loss of nitrogen which is excreted as urea, both phenylalanine and tyrosine are normally oxidized to carbon dioxide and water through the

⁷¹ Moss and Schoenheimer: J. Biol. Chem., 135, 415 (1940).

intermediate formation of acetoacetic acid. The nature of the mechanism whereby the benzene ring is ruptured is not known. Whether or not these two amino acids follow a common metabolic pathway (i.e., phenyl-

alanine \rightarrow tyrosine \rightarrow intermediates \rightarrow CO₂ + H₂O) is a matter of dispute. Possible direct metabolites of phenylalanine other than tyrosine include phenylpyruvic and phenyllactic acids; phenylpyruvic acid is

found in the urine of animals after feeding phenylalanine.⁷² Also, in 1934, Fölling⁷³ reported that a certain proportion of individuals with mental disease regularly excrete phenylpyruvic acid in the urine. This condition has been called *oligophrenia phenylpyruvica*. If phenylalanine is administered to individuals suffering from this "metabolic abnormality," the excretion of phenylpyruvic acid is increased. Thus there is good evidence that phenylpyruvic and phenyllactic acids are produced from phenylalanine; there is equally good evidence that the reactions leading to their production are reversible; for instance, both phenylpyruvic acid and phenyllactic acid can replace phenylalanine in the diet of the growing rat.

The metabolic fate of tyrosine is somewhat better understood than that of phenylalanine; the irreversible blockage between tyrosine and phenylalanine permits a more precise estimation of the significance of possible intermediates obtained under experimental and abnormal conditions. As with phenylalanine, possible metabolites of tyrosine include the corresponding keto- and hydroxy-acids, p-hydroxyphenylpyruvic and p-hydroxyphenyllactic acids, respectively. Both of these compounds have been isolated from human and animal urine under certain conditions. Medes⁷⁴ has described a condition called tyrosinosis (only one such case has thus far been found) in which an adult human excreted significant amounts of p-hydroxyphenylpyruvic acid in the urine. The output of this compound was augmented with increased intake of protein or of pure tyrosine or phenylalanine: feeding the compound itself resulted in the unchanged excretion of most of it. Levine and associates 75 discovered that the infant human may exhibit a spontaneous defect in tyrosine metabolism characterized by the excretion of significant amounts of p-hydroxyphenylpyruvic and p-hydroxyphenyllactic acids, in the presence of a low vitamin-C intake and an excessive intake of tyrosine or phenylalanine, either in the form of protein or as the pure amino acids. Vitamin-C administration abolished the defect except in the presence of excessive amounts of phenylalanine or tyrosine. Sealock and associates have shown that the scorbutic guinea pig excretes tyrosine metabolites (p-hydroxyphenylpyruvic acid, homogentisic acid) after administration of tyrosine or phenylalanine; vitamin-C administration prevented the excretion of these compounds. It has also been shown that scorbutic guinea-pig liver is unable to oxidize tyrosine in vitro except in the presence of vitamin C. 76

It would appear from these and other findings that the keto acid of tyrosine is a normal intermediate in tyrosine metabolism, and that vitamin C is concerned in the further utilization of the keto acid. The possibility remains open, however, that oxidative deamination of tyrosine is an alternate metabolic pathway and that the major metabolism may follow some as yet unknown sequence of reactions.

⁷⁶ Sealock: Fed. Proc., 1, 287 (1942); Lan and Sealock: J. Biol. Chem., 155, 483 (1944).

Further knowledge concerning tyrosine metabolism has been afforded by the study of the metabolic abnormality known as alkaptonuria. In this relatively rare condition, individuals excrete the compound homogentisic acid (for structure see diagram on p. 955) in the urine. In the presence of alkali and oxygen, homogentisic acid forms a dark brown or black pigment, and it is the darkening of the urine under these conditions which usually leads to the discovery of alkaptonuria. Homogentisic acid is believed to be a normal intermediate in tyrosine metabolism, probably through the intermediary formation of 2.5-dihydroxyphenylpyruvic acid (see diagram, p. 955), and the metabolic defect in alkaptonuria is thought to be the lack of ability to carry the oxidation beyond the stage of homogentisic acid formation. Feeding of tyrosine or phenylalanine to an alkaptonuric increases the output of homogentisic acid, and fed homogentisic acid is excreted unchanged. The normal individual is able to oxidize homogentisic acid completely. Alkaptonuria may be produced experimentally in animals (and in man) by prolonged or excessive feeding of either tyrosine or phenylalanine, 77 and in scurvy. Vitamin-C administration will correct the alkaptonuria of the scorbutic guinea pig, but has no apparent effect on human alkaptonuria.

Certain other aspects of tyrosine metabolism are of physiological importance. Both the diiodotyrosine and thyroxine of the thyroid gland are considered to arise from tyrosine. Both of these substances have been isolated from easein treated *in vitro* with alkaline iodide solution, and the incubation of thyroid gland slices in the presence of radioactive iodide as a tracer results in the production of diiodotyrosine and thyroxine containing the radioactive material. Adrenaline is likewise thought to originate from tyrosine. It has been shown that animal tissue can decarboxylate tyrosine to yield tyramine; oxidation and methylation of this compound could produce adrenaline. An alternate possible pathway would involve the intermediate formation of 3,4-dihydroxyphenylalanine, followed by decarboxylation to yield hydroxytyramine, and oxidation and methylation to produce adrenaline.

According to Bloch and to Raper, it would appear that the pigment melanin is related to tyrosine metabolism. Melanin is not a simple chemical substance, but rather a mixture of pigments of ill-defined composition. It is a normal skin pigment, and appears to be low or lacking in the condition known as albinism. It is produced in excessive amounts by melanotic tumor cells, and may even be excreted in the urine (melanuria) under these conditions. It is also produced in excessive amount in Addison's disease ("bronzed diabetes"). Bloch showed some years ago that the skin contains an enzyme ("dopase") capable of converting the compound 3,4-dihydroxyphenylalanine ("dopa") into melanin-like material, and that this enzyme was absent from the skin of albinos. According to Raper, 79 the probable precursor of 3,4-dihydroxyphenylalanine is tyrosine.

I. GENERAL PROCEDURES IN METABOLISM EXPERIMENTS

1. Collection and Preservation of the Urine. In metabolism tests, such as those given in this chapter, accurate collection of urine for the exact 24-hour period is of the utmost importance. Proceed as follows: Empty the bladder at a given hour, e.g., 8 A.M., and discard the urine. Prepare a thoroughly clean bottle of proper size, introduce into it sufficient toluene to cover the bottom of the bottle, and use this bottle for the collection of all urine voided during the following 24 hours, including the urine obtained by emptying the bladder at the close of the 24-hour period, e.g., at 8 A.M. the next day. During the day, when not actually in use for the introduction of a urine fraction, the bottle should be kept in a refrigerator or cold room in order that the sample may not deteriorate before it is examined. Measure the volume of the sample and determine its specific gravity (see p. 718) and reaction before proceeding to the quantitative estimation of any specific urinary constituents.

For metabolism work on dogs, a cage is used which is provided with a screen bottom. Below this is a tray which slopes toward a central hole through which the urine passes into a bottle containing toluene. Each day's output is collected, filtered to remove hair, etc., and may then be diluted to a definite volume, usually 500 or 1000 ml. This procedure facilitates subsequent calculation.

To obtain the complete 24-hour secretion of urine of dogs, catheterization must be resorted to. Because of the difficulty of catheterizing male dogs, bitches (especially those who have had pups, and hence have stretched vaginas) are used for this type of experimentation. Care must be taken to have the catheter sterile, in order to avoid infection or cystitis. Rubber catheters are sterilized by boiling in water, while metal or glass catheters may be washed and kept in alcohol. The simplest procedure is to use a speculum (a nasal dilator is about the right size) to stretch the vagina and then to insert the catheter directly into the urethra, avoiding contact with the vaginal wall. The exact location of the urethral orifice can be determined with a little experience. Force should never be used. After the bladder has been emptied, it is washed out several times with warm water, the washings being collected with the urine and made up to volume as described above. Finally, if it does not interfere with the experiment, it is desirable to introduce about 50 ml. of warm saturated boric acid solution into the bladder from time to time.

The most satisfactory method for obtaining urine from a *rabbit* is to hold its head up between one's knees and to apply gentle pressure on the lower abdomen. By this process of "milking," practically all the urine may be obtained.

For the collection of urine in metabolism work on rats, a metabolism cage (see Appendix) is employed.

2. Completé Analysis of Urine: Ingest an ordinary mixed diet (or any special diet) and collect the urine accurately for a 24-hour period (see above). Measure the volume of the sample, determine the specific gravity, and preserve the urine (see above) until the following constituents have been determined (for Methods of Analysis, see Chapter 32): total solids, titratable acidity, hydrogen-ion concentration, total nitrogen, amino-acid nitrogen, ammonia, urea, uric acid, creatinine, total sulfur, ethereal sulfates, inorganic sulfates, neutral sulfur (by difference), total phosphates and sodium chloride.

Calculate the nitrogen and sulfur "partitions," i.e., the percentages of the total nitrogen and sulfur which occur in the different forms, and tabulate the data from the complete analysis. Compare your results with those listed in the tables on pp. 967 and 970.

3. Collection and Preservation of Feces and the Mixing and Weighing for Analysis. The old methods in vogue in metabolism work embraced the analysis of dried feces. Various investigators later demonstrated that the drying of feces was accompanied by losses and changes of some of the organic constituents of the

feces. Therefore the chemical examination of all stools wherever possible should be made on the *fresh* feces. If a study is being made which extends over several days and it is desired to economize time and effort in the chemical examination, the daily fecal output or an aliquot portion of each stool may be collected in a friction-top can or pail of suitable size and preserved by thymol and refrigeration. This method has been found satisfactory when the feces are to be examined for inorganic constituents or total nitrogen. For the determination of fat, carbohydrate, etc., the *fresh* stool should be employed because of the possibility of error due to hydrolysis of fat to fatty acid, etc.

In the preservation of feces for the determination of total nitrogen, the following simple procedure may be used: Introduce each stool into a weighed friction-top can or pail and place the vessel in a cold room or refrigerator preferably near or below 0° C. At the end of the period, mix the feces thoroughly and analyze weighed portions. In case individual stools are analyzed, the stool should be collected in a weighed flat-bottom porcelain dish. So After mixing the feces very thoroughly, the weight of dish, spatula, and teces is determined and the weight of the feces secured by difference. A portion of the well-mixed feces is then introduced into a large weighing bottle containing a glass hoe. Desired amounts of feces are then removed for analysis and the exact weight of such amounts obtained by difference.

The daily output of feces in dogs is quite variable, so that in metabolism work it is advisable to collect feces in periods, rather than each day. The stools are collected from the screen floor of the cage and placed in weighed pans. They are dried by adding alcohol, stirring and evaporating on the water bath, and then weighed. A few drops of sulfuric acid should be added to prevent the loss of ammonia. After drying the feces may be ground in a mill or mortar, to facilitate uniform sampling.

- 4. "Separation" of Feces. 82 In order to differentiate the feces which correspond to the food ingested during any given interval, it is customary to cause the subject under observation to ingest some substance, at the beginning and end of the period in question, which shall sufficiently differ in color and consistency from the surrounding feces as to render such differentiation comparatively easy. Two "markers" very widely used in such tests are wood charcoal and carmine. In making an actual separation of feces in a metabolism experiment, proceed as follows: Just preceding or in the early part of the first meal (usually breakfast) of the metabolism test, ingest a gelatine capsule (No. 00) containing 0.2-0.3 g. of carmine or charcoal. From this time collect all stools in flat-bottom porcelain dishes and examine for the presence of the "marker." All fecal matter containing portions of the marker may be considered as representing the diet in question. This fecal matter should be retained and preserved (see above). Just before or in the early part of the first meal (usually breakfast) following the end of the metabolism test, a second "marker" in a gelatin capsule should be ingested. The feces should be carefully inspected until the marker makes its appearance. Retain all fecal matter uncolored by the marker, and reject the remainder. Frequent difficulties are encountered in the practical separation of feces, but the character of such difficulties will be most satisfactorily impressed by the performance of actual separations.
- 5. The Use of Agar-agar to Increase Fecal Bulk. The indigestible hemicellulose agar-agar (as well as other gummy substances such as psyllium seed, bassorin, etc.) has the property of absorbing water readily and therefore when ingested it increases the bulk of the feece considerably. This fact is made use of in the determination of metabolic product nitrogen (see Exp. 11, p. 968), and clinically in some forms of constipation.

Experiment: Ingest a uniform diet for four days, or longer for greater accuracy. Divide the interval into two equal periods and "separate" the feces

80 The spatula for mixing the feces should be weighed with the dish.

¹¹ In case it is desired an aliquot part of each stool may be placed in a friction-top can or pail and preserved as a "composite sample" for the period.

12 For other practical work on feces, see p. 406, et seq.

by charcoal or carmine (see Exp. 4, above). During the second period ingest 10 g. of agar-agar at each meal. Collect the feces for each period (see Exp. 4, above), and note the increase in the daily excretion under the influence of the agar ingestion. What was the increase per gram of agar?

II. EXPERIMENTS ON NITROGEN METABOLISM

1. Time Relations of Protein Metabolism. It is a well-known physiological fact that an interval elapses between the ingestion of protein food and the appearance in the urine of certain products representing the complete catabolism of this food. The chief among these is urea. The term "nitrogen lag" has been used to designate the period elapsing between the ingestion of protein and the excretion in the urine of a quantity of nitrogen equivalent to that contained in the protein.

Experiment: Ingest a simple uniform diet whose exact composition has been determined by analysis or whose approximate composition has been estimated. (See Appendix for table showing composition of foods.) Continue this diet from one to four days. Collect the urine in two-hour periods from 7 A.M. to 11 P.M. and in an eight-hour period between 11 P.M. and 7 A.M. Analyze each specimen for total nitrogen or urea. At the end of this preliminary period add to the uniform diet, at one meal, a weighed quantity (150-250 g.) of lean meat specially prepared and analyzed. Collect the urine in periods as before and determine total nitrogen or urea. Calculate the total nitrogen or urea excretion; tabulate the data and plot curves showing the course of the nitrogen excretion on the various days of the experiment. How long was the "nitrogen lag"?

A less accurate experiment than the above but one which yields interesting data may be carried out as follows:

Ingest a simple diet whose nitrogen content can be estimated with some degree of accuracy. Collect the urine in two-hour periods from 7 A.M. to 11 P.M. and in an eight-hour period from 11 P.M. to 7 A.M. and analyze for total nitrogen or urea. The next day ingest the same diet plus 150-250 g. of lean meat whose nitrogen content has been determined by analysis or estimated. Collect the urine as upon the previous day and determine its total nitrogen or urea content. Plot curves showing the course of the nitrogen or urea excretion on each of the days. How soon after the ingestion of the large quantity of meat did you note an increase in the nitrogen or urea excretion? How many hours after the meal was the maximum quantity of nitrogen or urea excreted?

2. Digestibility and Biological Value of Protein. The term "protein utilization" or "biological value" is used to indicate the percentage of the ingested food nitrogen actually assimilated. "Absorbability" or "digestibility" indicates the percentage of the ingested food nitrogen which is absorbed.

The digestibility of food protein may be approximated by the following procedure: Ingest any diet of known nitrogen content for a period of three days (see Appendix for Composition of Foods). Longer periods are necessary for accurate work. Collect all feces from the diet, making the "separations" as directed on p. 959, using carmine as the initial "marker" and charcoal as the final "marker" or vice versa. Preserve the feces as directed on p. 959. Mix the total feces thoroughly and determine the nitrogen by the Kjeldahl method. The approximate nitrogen utilization may be calculated as follows:

$$\frac{(Food \ N - Feces \ N) \times 100}{Food \ N} = Approximate \ percentage \ N \ utilization$$

Inasmuch as the nitrogen content of the feces does not originate entirely from the food, but represents in part residual metabolic products, i.e., intestinal epithelium, bacteria, secretions, etc., a correction is usually made for metabolic nitrogen in more exact work (see p. 968). The value thus obtained is more properly designated as the "percentage digestibility" or the "coefficient of digestibility."

To determine the true percentage digestibility of food protein, proceed as follows: Ingest a nonnitrogenous diet as described on p. 968 for a period of two days, using sufficient agar-agar to insure a daily fecal output which shall approximate in weight that obtained when the regular protein diet was ingested.⁸³ Separate and preserve the feces as directed on p. 959. Mix thoroughly and analyze for nitrogen according to the Kjeldahl method. This gives the metabolic fecal nitrogen. Follow this period with a test-period during which the protein in question is included in the diet. Calculate the percentage digestibility of the protein of the diet as follows:

$$\frac{[Food N - (Fecal N - Metabolic N)] \times 100}{Food N} = Percentage digestibility$$

The estimation of protein utilization in the body must take into account not only absorption from the intestine, but also that fraction of the absorbed nitrogen which is retained.

Mitchell,⁸⁴ who has used this procedure extensively in the biological evaluation of proteins, felt that this could be done by determining the urinary nitrogen excretion on a nonnitrogenous diet ("endogenous nitrogen") and subtracting this from the urinary nitrogen on the protein-containing diet, to obtain the urinary nitrogen actually due to the metabolism of the protein. It is not clear that this procedure is entirely valid, based as it is upon Folin's classical distinction between "endogenous" and "exogenous" metabolism, which now appears not to be true (see discussion on p. 936). Nevertheless, as Cahill and Smith point out, the procedure under the conditions prescribed by Mitchell is capable of giving reasonable and consistent results, whatever may be its theoretical basis.

Procedure: Ingest a nonnitrogenous diet as described above, insuring sufficient energy to provide for the body's requirements so that oxidation of tissue for this purpose may be avoided. Feces and urine are collected as described in the early part of this chapter. By means of Kjeldahl analyses, values are determined for metabolic nitrogen of feces and "endogenous" nitrogen of the urine. Follow this period with a test period during which the protein under investigation is included in the experimental diet. The following equation represents the percentage of the absorbed food nitrogen which is retained by the body:

$$\frac{[Food \ N - (Fecal \ N - Metabolic \ N) - (Urinary \ N - "Endogenous" \ N)] \ 100}{Food \ N - (Fecal \ N - Metabolic \ N)} = "Biological \ Value"$$

3. Protein-sparing Action of Carbohydrate and Fat. The nonnitrogenous nutrients, carbohydrate and fat, have the power to diminish the extent of the catabolism of protein in the normal human body. In other words, they are said to "spare" protein. This point is illustrated in data reported by von Noorden and Dieters, which are tabulated below.

⁸⁴ Mitchell: J. Biol. Chem., 58, 873 (1924).

⁸³ It is frequently difficult to so regulate the agar-agar intake as to secure the proper fecal output. In such an event the proper value for metabolic nitrogen must be obtained by calculation. For example, if 89.1 g. of feces were exercted per day on the protein diet, and 166.5 g. per day (with a nitrogen value of 0.5 g.) when agar was employed, the actual value for metabolic product nitrogen may be obtained by the following proportion, assuming that the content of metabolic nitrogen is proportional to the weight of feces excreted 89.1:166.5:x:0.5, x=0.268 g. metabolic nitrogen per day.

PROTEIN-SPARING	ACTION	OF ('ARBOHYDRATE
-----------------	--------	------	--------------

Nitrogen Ingested	Nitrogen in Urine	Remarks
12.6 g.	10.4 g.	
12.6 g. + 200 g. sucrose	9.0 g.	13 per cent reduction in protein catabolism

It will be observed that the addition of 200 g. of sucrose to the diet was accompanied by a decrease of 13 per cent in the amount of protein catabolized. It has been established that carbohydrates are more efficient "protein sparers" than are the fats. For example, Voit found carbohydrate to produce a 9 per cent decrease in protein catabolism whereas fats produced only a 7 per cent decrease.

Experiment: Ingest a uniform diet of known or estimated nitrogen content for a period of four days. Collect and preserve the urine accurately (see p. 958) in 24-hour samples and analyze the excretion of the third and fourth days for total nitrogen. On the fifth day add 200 g. of sucrose to the diet. Analyze this urine also for total nitrogen. Calculate your results and tabulate the data as shown in the table above.

Did the sucrose influence the catabolism of protein in your body?

4. Influence of a High Caloric Nonnitrogenous Diet. When an individual fasts, a certain amount of protein tissue is consumed each day of the fast. The destruction of such tissue is rather low on the first day due to the fact that the glycogen stores of the body are being utilized to furnish the necessary energy. If an individual, instead of fasting, ingests a diet of high calorific value and very low in nitrogen the output of nitrogen in the urine of the third or fourth day will be less than on the third or fourth day in fasting. This is due to the fact that the body derives sufficient energy from the high calorie diet and there is less destruction of tissue protein than occurs in fasting. For a discussion of energy value of foods see "Determination of Fuel Value of Foods," below, and the table on the Composition of Foods in the Appendix.

Experiment: Ingest a high calorie diet which is very low in nitrogen or actually nonnitrogenous. A satisfactory diet may include sugar, butter, starch, cream, agar-agar, and water. (For energy values see below and table, Appendix.) Ingest such a diet for three days. Collect the urine in 24-hour periods, preserve, and analyze it for total nitrogen, acidity, and ammonia. Note the low nitrogen excretion on the third day as compared with the nitrogen output of the third day of fasting. If so desired, you may (at some later date) fast for three days and repeat the above analyses for comparison.

Determination of Fuel Value of Food. When organic substances are oxidized or burned in the human body, they liberate a certain amount of heat. This calorific energy or heat value varies according to the type of organic matter undergoing oxidation. Thus the proteins, fats, and carbohydrates of the diet when they are burned in the body yield different quantities of heat per unit of substance than do organic acids, alcohol, etc. The energy values of food protein, fat, and carbohydrate are as follows:

Protein = 4.1 large Calories per g. Fat = 9.3 large Calories per g. Carbohydrate = 4.1 large Calories per g.

To allow for the incomplete digestion of these nutrients these caloric conversion factors were multiplied by the coefficients of digestibility and thus rounded off to 4, 9, and 4, respectively. The calorific value of foods may be estimated by

applying these figures to the percentage composition as determined by chemical analysis. For this purpose, the "proximate" analysis includes moisture, ash, protein $(N \times 6.25)$, fat, crude fiber, and carbohydrate, the latter usually estimated by difference. Crude fiber represents the insoluble, indigestible residue remaining after alternate extractions with acid and alkali, and consists chiefly of cellulose, etc., from cell walls. Such calculations are predicated on the assumption of complete availability of the carbohydrates as estimated by

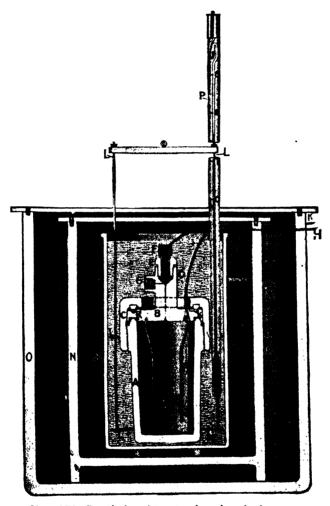

Fig. 279. Berthelot-Atwater bomb calorimeter.

difference, on the universal applicability of the factor 6.25 for converting total nitrogen to available protein, and on the assumption that the ether extract consists solely of glycerides.

In arriving at the total energy value of any given diet it is possible to burn weighed samples of the various foods in an oxygen atmosphere in an apparatus called a bomb calorimeter, illustrated in Fig. 279. By this means we may determine how much heat is liberated when the ingested food is oxidized in the body. A correction must be made for the incompletely oxidized substances of the urine and feces, e.g., organic nitrogen compounds. Thus while proteins yield

about 5.7 Calories per gram when burned in a calorimeter, correction for incompletely oxidized urea and other N compounds reduces this value in the body to 4.1. Further correction must be made for indigestible carbohydrates usually grouped together under the designation "crude fiber." There is serious question, however, whether the latter, which resists hot acid and alkaline digestion is an accurate measure of the polysaccharides which in vivo resist enzymatic digestion.

A simpler and less expensive form of apparatus for determining this calorific value of foods is the oxycalorimeter of Benedict and Fox, in which the volume of oxygen required to burn a known weight of substance is determined. A large mass of data concerning the heat value of foods has been collected and tabulated, and it is therefore possible to arrive at an approximate idea of the energy

value of a diet by calculation (see table, Appendix).

5. Influence of Purine-free and High Purine Diets. The uric acid of the body has a two-fold origin, i.e., it may arise from the metabolism of the purine (nucleoprotein, nucleotide) material of body tissue (glandular organs in particular) or it may arise from the ingestion of purine material. That uric acid which arises from the first source is called endogenous while that which arises from the second source is termed exogenous. Modern concepts hold that this distinction, made many years ago by Folin, is still valid. Secretory activity may also act to increase the endogenous uric acid output. The urine will therefore contain uric acid even though no precursor of the acid is ingested. We may also increase the uric acid output markedly by ingesting a high purine diet. However, no matter how much purine material is eaten, only a small part of it reappears in the urine as uric acid. That is, there must be some significant metabolic pathway for purine nitrogen other than excretion as uric acid. In gout there is an accumulation of uric acid in the blood. In this disease the excretion of uric acid may be low before an attack and increase considerably during an attack. The excretion of exogenous uric acid in gout is also much slower than normal.

Experiment: Ingest a purine-free diet containing about 16 g. of nitrogen and consisting of egg, cheese, milk, starch, fruit, sugar, and water for a period of two days (for purine content of foods, see table, p. 965). Determine or estimate the nitrogen content (see Appendix) and during the next two days substitute sweetbreads, thymus, or liver for all the nitrogen of the diet maintaining the calorific value of the diet the same as before. Return to the original purine-free diet for a third interval of two days. During the final period of two days feed a diet of sweetbreads or liver containing 50 per cent more nitrogen than that of the first sweetbread period. Collect the urine for each of the eight days of the experiment and determine uric

INFLUENCE OF PURINE-FREE AND HIGH PURINE DIETS NITROGEN INGESTION 10 G. DAILY (TAYLOR AND ROSE)

Urinary Constituents Determined (g. per day)	Purinc-free Diet		Purine Diet (Increased)	Purine- free Diet
Uric acid N	0.09	0.14	0.24	0.07
Total nitrogen	8.9	8.7	9.1	8.8
Urea N $(+NH_3)$		7.1	7.1	7.05
Creatinine	1.57	1.49	1.51	

acid and total nitrogen or urea. Note the rise in the uric acid output during the sweetbread periods. The uric acid output on the purine-free diet is endogenous in origin. Tabulate your results. The data shown above were secured by Taylor and Rose in a similar but much more carefully controlled test than that just outlined.

6. A Study of Endogenous Uric Acid Output. The uric acid in the urine originates from the purine material of the tissues (endogenous) and from the purine material ingested (exogenous). Mares claims that foodstuffs act to increase the endogenous uric acid output by stimulating the digestive glands to activity. A similar finding is reported by Mendel and Stehle. The foodstuff having the most pronounced influence was protein. Pilocarpine, which stimulates the digestive glands, was found to increase the endogenous uric acid output whereas alropine which inhibits secretory activity was found to decrease the output of endogenous uric acid. The influence of protein upon the endogenous uric acid excretion is shown by the chart in Fig. 280. The fasting output by the same individual is shown, for comparison, in Fig. 281.

Parine Content of Foods (after besson and schmid)

Food	Purine Nutrogen (per cent)	Food	Purine Nitrogen (per cent)
Meats:		Shellfish:	
Beef	0 037	Oysters	0 029

Anchovies.	0.145	Butter	. 0
		Milk	0
		Cheese (except cream and dairy)	0
		Cream cheese	0.005
•		Dairy cheese	0.022

Experiment: Ingest a purine-free diet consisting of milk, egg, fruit, cheese, butter, sugar, and bread for one day. Continue the diet for breakfast and luncheon the next day but eat nothing after 12 o'clock noon, until 12 o'clock noon the following day, i.e., the third day of the experiment. At that time ingest 125-150 g. of gluten or some other purine-free protein preparation. On the fourth day of the experiment eat nothing until 9 P.M.

Collect the urine each day in hour periods from 7 A.M. to 9 P.M. and

analyze for uric acid (see methods on p. 844, et seq.). Chart your data similarly to those shown in Figs. 280 and 281, and compare them with the findings there recorded.

7. The Rate of Purine Excretion. The purine material ingested by the average normal person and which is not transformed in the body will be eliminated in about 24 hours. In the case of persons afflicted with gout the purine elimination is delayed. The establishment of this delayed purine elimination is often of diagnostic assistance.

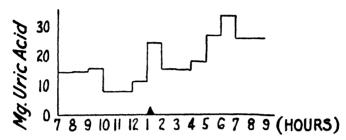

Fig. 280. Influence of protein ingestion on endogenous uric acid output. Gluten (130 g.) ingested at 1 P.M. (Courtesy, Mendel and Stehle: J. Biol. Chem., 22, 215 (1915).)

Demonstrate the rate of purine excretion as follows: Ingest a purine-free diet consisting of egg, milk, cheese, starch, sugar, fruit, and water for two days and follow this by a day in which sweetbreads, thymus, or liver is substituted for one of the meals of the day (see table, p. 965 for purine content of foods). Finish the experiment by ingesting the original purine-free diet for two days. Collect each day's urine and analyze for uric acid. How soon after the sweetbread ingestion was the original plane of endogenous uric acid elimination reëstablished? If one desires to

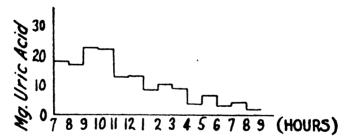

Fig. 281. Endogenous uric acid output during fasting. (Courtesy, Mendel and Stehle: *J. Biol. Chem.*, 22, 215 (1915).)

locate this time more definitely the urine may be collected in short periods (one to two hours) and the uric acid content of each specimen determined. Particularly instructive data may be collected by performing the above experiment on a gout patient and upon a normal person for comparison.

8. A Study of Creatinine Elimination. It has been established that a normal person ingesting a creatinine-free diet will excrete a uniform quantity of creatinine

from day to day. The daily excretion of an adult man of average weight ranges from 1-1.5 g. For data as to creatinine excretion of a 60-kg. man see Taylor and Rose's figures in the table on p. 964. The creatinine excretion depends primarily on the active mass of protoplasmic tissue, and therefore, it is generally true that fat men will show a lower creatinine output than lean men of like body weight. The fact that, in a given individual, the creatinine output is uniform from day to day is made use of in metabolism experiments, for checking the completeness of 24-hour collections of urine. For further discussion of creatinine see p. 730.

Experiment: Ingest an ordinary mixed diet (non-meat) for a period of three days, varying the character of the diet daily. Collect the urine and analyze for creatinine. (See p. 839 for methods of analysis.)

Did the creatinine elimination change with the change in diet?

- 9. Formation of Hippuric Acid in the Human Body. Hippuric acid is present in human urine in small amount, about 0.7 g. being excreted per day. The urine of herbivorous animals contains much larger quantities. This acid is formed in the liver in man, by the conjugation of benzoic acid and glycine; this formation is used clinically as a test of liver function. For procedure of the test, see Chapter 32.
- 10. The Partition of Urinary Nitrogen and Sulfur as Influenced by Diet. It was first shown by Folin⁸⁵ that the percentage of the total nitrogen and total sulfur of the urine which appeared in the form of any particular nitrogenous constituent or in any particular form of sulfur was regulated directly by the extent of the total nitrogen and sulfur elimination. This point is well illustrated in the following table which contains data regarding the so-called "partition" or "distribution" of the urinary nitrogen and sulfur.

THE NITROGEN AND SULFUR PARTITIONS AS INFLUENCED BY DIET85

	Norn	nal Protein	Diet	Starch-cream Diet		
Constituent of the Urine	A mount, grams	Nitrogen, grams	Per cent of total N or S	Amount, grams	Nitrogen, grams	Per cent of total N or S
Urea	31.6	14 7	87.5	4.72	2.2	61.7
Ammonia	0.6	0 49	3.0	0.51	0.42	11.3
Creatinine	1.55	0.58	3.6	1.61	0 60	17.2
Uric acid	0.54	0.18	1.1	0.27	.0.09	2.5
Undetermined N		0.85	4.9		0.27	7.5
Total N		16.8	100 0		3.6	100.0
Inorganic SO ₃	3.27		90.0	0.46		60.5
Ethereal SO3	0.19		5.2	0.10		13.2
Neutral SO ₃	0.18		4.8	0.20		26.3
Total SO ₃	3.64		100.0	0.76		100.0

It will be observed from an examination of this table that a normal protein diet which gave 16.8 g. of urinary nitrogen yielded 87.5 per cent of this nitrogen as urea, 3 per cent as ammonia, 3.6 per cent as creatinine, and 1.1 per cent as uric acid; whereas a "nonprotein diet" (starch and cream containing about 1 g. of nitrogen) which gave only 3.6 g. of urinary nitrogen yielded only 61.7 per cent

⁸⁵ Folin: Am. J. Physiol., 13, 118 (1905).

of this nitrogen as urea but gave a greatly increased percentage output in the case of each of the other nitrogenous constituents mentioned, e.g., 11.3 per cent as ammonia, 17.2 per cent as creatinine, and 2.5 per cent as uric acid. The percentage output of neutral sulfur was also greatly increased.

It will furthermore be observed that the actual daily output of certain of the constituents is uninfluenced by the amount of protein ingested. Among these are creatinine and neutral sulfur. On the other hand, the output of inorganic sulfur and urea is more or less directly proportional to the protein ingestion. The observation of such facts as these led Folin to formulate his theory of protein metabolism, which held sway for many years, but which has recently been considerably modified (see discussion on p. 936).

Experiment: During a period of two or three days ingest an ordinary mixed diet containing 100-125 g. of protein (16-20 g. of nitrogen) per day. Collect the urine accurately in 24-hour periods (p. 958), preserve it, and analyze the urine of the second and third days for total nitrogen, urea, creatinine, total sulfur, inorganic sulfates, ethereal sulfates, and neutral sulfur (by difference). For methods of analysis see Chapter 32. Follow this period by a three-day period in which a diet of starch and cream having a similar calorlic value is ingested. Analyze the urine for the second and third days as indicated above. Calculate your results and tabulate as shown in the table on p. 967. How did the change in the diet alter the metabolism of nitrogen and sulfur?

In calculating the calorific value of a diet make use of the following values: protein or carbohydrate, 4 Calories per g.; fat, 9 Calories per g.

11. "Metabolic Product" Nitrogen in Feces. A certain quota of the fecal nitrogen is due to the presence of residues of digestive secretions, epithelial cells, bacteria, etc. The nitrogen in these forms has been called "metabolic nitrogen."

To determine this form of nitrogen one method. of procedure is as follows: Ingest a nonnitrogenous diet for a period of two days. The diet may include desired quantities of starch, cream, sugar, butter, water, and sodium chloride. About 15 g. of agar-agar should be added to the diet to prevent constipation and to insure evacuation of approximately the normal quantity of feces. (For the influence of agar-agar, see Exp. 5, p. 959.) To separate the feces properly, ingest a capsule of carmine at the beginning of the test and one of charcoal at the end (see p. 959). Preserve the feces as described on p. 959. After mixing the feces thoroughly, determine the nitrogen in weighed quantities by the Kjeldahl method, according to directions given on p. 814. Calculate the quantity of nitrogen eliminated per day. Inasmuch as no nitrogen was ingested, the nitrogen present in the feces is of metabolic origin, i.e., it is made up principally of nitrogen in the form of cells, digestive secretions, and bacteria.

- 12. Influence of Defective Mastication on Food Residues in Feces. Rapid eating accompanied by defective mastication leads to the appearance of relatively large macroscopic food residues in the feces. Under some conditions, however, protein utilization (see p. 960) may be as satisfactory after "bolting" of food as when it is very thoroughly masticated. This problem may be studied by the following method:
 - a. Ingest a diet containing meat and be certain to masticate the diet very thoroughly. Collect a stool, examine macroscopically; mix carefully and examine microscopically (see pp. 402 and 407).
 - b. Ingest a diet similar to that employed in Exp. a, above. "Bolt" the food, i.e., ingest it practically without mastication. Examine the feces as above.

¹⁶ For a discussion of other methods of estimating metabolic product nitrogen see Forbes, Mangels, and Morgan: J. Agr. Research, 9, 405 (1917) and Schneider: J. Biol. Chem., 169, 249 (1935).

⁸⁷ In the oxidation process use 10 g. of potassium sulfate instead of the copper sulfate. The remainder of the procedure is the same as for urine.

Note the difference in the macroscopical and microscopical findings under (a) and (b).

If the nitrogen of food and feces is determined, we may calculate the protein utilization (see Exp. 2, p. 960). By the additional determination of urinary nitrogen, we may prepare a nitrogen balance (see Exp. 13).

13. Preparation of a Metabolic Balance. This test entails the analysis of the food ingested and of the urine and feces excreted, i.e., a study of the income and outgo. Proceed as follows:

Select a diet which is simple, i.e., consists of few constituents, and which lends itself readily to accurate chemical analysis. A good type of diet for ordinary metabolism experiments of this sort consists of crackers (graham or soda), milk, butter, water, and agar-agar (to prevent constipation). Meat, especially prepared in quantity sufficient for an entire experiment, may also be utilized. Ingest uniform quantities of these dietary constituents each day for a period of three days. Make an accurate collection of the urine passed during this interval (see p. 958). Separate the feces representing the three-day period (see p. 959), and analyze foods, urine, and feces. The balances ordinarily prepared are those for nitrogen, sulfur, phosphorus, and calcium. Analytical methods for the determination of these elements may be found in Chapter 32.

The following table includes balances obtained in a metabolism test in a case of acromegaly.

Balance of Calcium, Magnesium, Phosphorus, Sulfur, and Nitrogen in Acromlgaly

	Calcium Oxide	Magnesium Oxide	Phosphoric Anhydride	Sulfur	Nitrogen		
	Grams						
Ingestion (daily)	1.494	0.486	3.192	1.190	18.84		
Excretion (urine).	0 159	0.160	1.701	1.006	17.60		
Excretion (feces)	. 1 093	0 226	1.002	0 135	1.10		
Excretion (total).	1.252	0.386	2.703	1 141	18.70		
Retention (daily)	0.242	0.100	0.489	0.049	0.14		
Retention (per cent)	16.2	20 6	15.3	4.1	0.7		

14. The Influence of Water on Metabolism. It has been demonstrated that increased water ingestion influences favorably many of the functions and activities of the human body. The increase in protein catabolism which accompanies high water intake is shown in the following data collected from an experiment upon a normal man. In this experiment the water ingestion at meals was increased 3 liters per day during the water period.

**Hawk: The relationship of water to certain life processes and more especially to nutrition. Read before American Philosophical Society, Philadelphia, Feb., 1914. (See Biochem. Bull., 3, 420 (1914); also Water as a Dietary Constituent, from "Endocrinology and Metabolism," 3, 277 (1924), New York and London, Appleton and Co.) The so-called "water intoxication" demonstrated by Rowntree (Arch. Int. Med., 32, 157 (1923)) and later by Underhill and Sallick (J. Biol. Chem., 63, 61 (1925)) cannot be advanced as an argument against the value of a high water intake for the average individual. The observers mentioned experimented on animals and introduced as much as 50 ml. of water per kg. of body weight every half hour until a definite toxic result was obtained. A similar excessive ingestion of any standard food would probably produce fully as serious results.

INFLUENCE OF HIGH WATER INTAKE UPON URINE VOLUME

AND NITROGEN PARTITION

Day of Period	Urine Volume, ml.	Nitrogen, g.	Urea Nitrogen, g.	Ammonia Nitrogen, g.	Creatinine Nitrogen, g.	Creatin Nitrogen g.
		Prelin	minary Peri	od		
4	830	12.987	11.338	0.288	0.629	
5	920	12.084	11.476	0.305	0.619	
6	880	13.183	11.568	0.369	0.651	
		W	ater Period			
1	3440	14.161	12.596	0.486	0.610	0.063
2	3840	13.491	11.583	0.499	0.616	0 024
3	3670	12.981	11.212	0.553	0.589	0.102
4	3610	12.976	11.455	0.485	0.608	0.055
5	4020	13.138	11.879	0.456	0.589	0.128

The above data indicate an increased catabolism of protein material as shown by an increased output of total nitrogen upon the first and second days of the water period. Part of this increase may, however, have been due to a "flushing" of the tissues rather than to increased catabolism of protein structures.

a. Relation of Water Intake to Volume and Specific Gravity of the Urine: Ingest an ordinary mixed diet for two days. Collect the urine in 24-hour periods. During the first day ingest very little fluid of any kind either at meals or between meals. On the second day ingest as much water as you can without physical inconvenience. A person of average size should have no difficulty in drinking 5-6 liters per day.

Measure the volume of each day's urine and take the specific gravity. Note the pronounced increase in volume and the low specific gravity of the urine under the influence of high water ingestion.

- b. Influence on Protein Catabolism: That water stimulates protein catabolism may easily be demonstrated as follows: Ingest a uniform diet (milk, crackers, butter, peanut butter, and water) for a period of four days. During the first two days ingest your customary volume of water per day. During the last two days increase the water ingestion to 5-6 liters per day. Collect urine in 24-hour periods and analyze for total nitrogen by Kjeldahl method (see p. 814). Note the increased excretion of nitrogen under the influence of high water intake. If time permits, other nitrogenous urinary constituents may be determined (see table above).
- c. Influence of Water Deficiency: The importance of water in nutrition may be shown very satisfactorily on guinea pigs. Proceed as follows: Place two young pigs (150-200 g.) in separate cages, and give each free access to a diet of hay, oats, and lemon or orange juice which has been dried rapidly at a low temperature. Permit one pig water ad lib., and give the second pig no water. The pig receiving water will remain normal and will exhibit normal gain in body weight. The pig receiving no water will soon show pronounced losses in body weight and other signs of abnormality. The animal will die in a short time unless water is added to the diet. This experiment demonstrates very clearly that water is an indispensable dietary constituent. In fact, water is more important than food. The following experiment will show this:

- d. Food Starvation vs. Water Starvation: Place two young guinea pigs (150-200 g.) in separate cages. Give one a diet such as that described on p. 970, plus orange juice (5 ml.) but no water. Give the second pig no food, but permit free access to water. The pig receiving no water will quickly become abnormal, and it will be necessary to give it water to preserve its life. The second pig, which has access to water⁸⁹ but receives no food to eat, will live longer than the pig receiving an abundance of dry food. This little experiment impresses the important fact that man can live longer without food than without water. By restricting the amount of water in the diet of an albino rat, the animal may be kept at constant body weight for several weeks although the diet is otherwise adequate. In many respects the effect is similar to that of underfeeding. Some increased tolerance to water restriction may develop during such a test.
- 15. The Metabolism of Fasting. 90 The metabolism of a fasting man is entirely different from the metabolism of a well-nourished person. The collection and analysis of the urine during a short fast (three to seven days) will demonstrate many important facts. The following table, which contains data from fasting tests made in the senior author's laboratory, 91 illustrates some of the points in which fasting metabolism differs from normal metabolism:

METABOLISM IN FASTING

Day of Period	Body Weight, kg.	$Total\ N, \ g.$	Ammonia N, g.	Creatine N, g.	Acidity ml. 0.1 N NaOH	$rac{{{P}_{2}}{{O}_{5}}}{g_{\cdot }}$	Chloride as NaCl, g.
		Pr	climinary F	Ceeding Per	riod		
14	Av. 74.16	10.430	0.112	None	238.6	2 768	9.007

7	68.70	10.734	1.371	0.003	438.9	0.955	1.137

Abstinence from food for a few days can in no way operate to the disadvantage of a normal person. In fact, individuals affected with certain types of gastro-intestinal disorders are benefited by fasting. The fasting treatment has also been used in cases of diabetes mellitus and in the treatment of obesity.

In order to determine experimentally how the fasting metabolism differs from normal metabolism, proceed as follows: Ingest an ordinary mixed diet and collect your urine (see p. 958) for a day. Measure the volume and analyze the sample for total nitrogen, ammonia, creatine.

⁸⁹ In case the pig does not drink the water, the animal should be fed the fluid by a sound.

⁹⁰ For discussions of fasting see: Benedict: "A Study of Prolonged Fasting," Carnegie Inst. Wash. Pub. 203, 1915; Morgulis: "Fasting and Undernutrition," New York, E. P. Dutton and Co., 1923; and Jackson: "Inanition and Malnutrition," Philadelphia, P. Blakiston's Son and Co., Inc., 1925.

⁹¹ The chloride, phosphate, and acidity determinations were collected during one seven-day fast and the other data collected during a different fast on the same man.

sodium chloride, total phosphates, and acidity⁹² (for methods see Chapter 32). For the next few days (three to seven as desired) ingest nothing but water and collect the urine accurately and analyze for the constituents enumerated above. Tabulate your results and compare them with those given in the table above.

16. Influence of Protein (Amino Acid) Deficiency. Certain of the amino acids which occur in proteins cannot be synthesized in the animal body. This subject is discussed on p. 930. The importance of proper protein (amino acids) in the diet is illustrated in Fig. 282. The following experiment, which may readily be made using white rats as subjects, will clearly demonstrate the importance of the amino acid lysine.

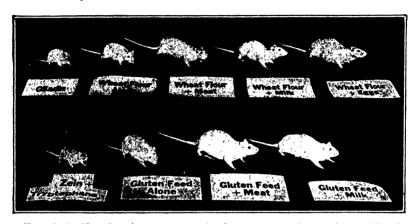

Fig. 282. Showing importance of adequate protein (amino acids) in the diet. (Courtesy, Mendel: "Nutrition—The Chemistry of Life," New Haven, Yale University Press, 1923.)

Demonstration of Lysine Deficiency: Place two young white rats (40-60 g.) in separate cages. Feed one rat Diet 1 and the other Diet 2 as listed in the following table.

Lverne	DEFICIENCY	Direct

	Diet 1 per cent	Diet 2 per cent
Rolled oats ⁹³	60	60
Gelatin ⁹³	. 00	10
Dextrin or starch	. 30	20
Salt mixture		4
Hydrogenated vegetable oil		5
Cod liver oil	. 1	1

The rat receiving Diet 2 will grow normally because of the high lysine content of gelatin. The animal receiving Diet 1 will fall to grow properly because of lysine deficiency. See Fig. 283.

⁹² A more accurate experiment may be carried out by ingesting a uniform diet of known composition (see p. 960) for a few days before the fast.

**Oat proteins are low in lysine. Gelatin is relatively high in this amino acid (see p. 109).

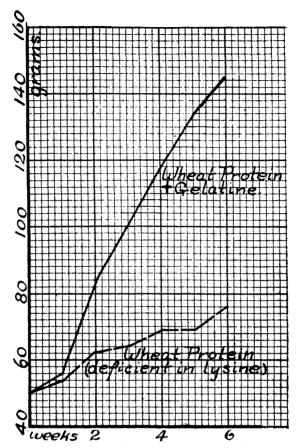

Fig. 283. Curve showing influence of a deficiency of lysine in the diet. (Unpublished data from the senior author's laboratory.)

MICROBIOLOGICAL DETERMINATION OF AMINO ACIDS

The widespread use of microörganisms for the assay of the vitamins in the B-complex group soon revealed their requirements for the amino acids. Extensive investigations followed and successful quantitative assays for 14 amino acids, using bacteria, appeared shortly. At least three amino acids may be determined with mutant strains of the mold *Neurospora* (see p. 979), and one, *l*-lysine, with a specific decarboxylase. Of the amino acids recognized as physiological constituents, only norvaline, norleucine, and hydroxyproline have not been found essential for any organism yet investigated. The fundamental principle involved in microbiological assays is to measure the response of bacteria, yeasts, or molds to graded increments of the sample and of a standard solution added to media furnishing all the nutrients required by the microörganism except the amino acid (or other nutrient) under assay. The graded response may

be measured by the increase in population of the microörganisms (i.e., turbidimetrically) or by their products of metabolism (acid or CO_2 production).

† The symbol + indicates that the amino acid is essential; ±, that some growth but not maximum

growth occurs in its absence; and -, that the amino acid is not essential.

† Asparagine and glutamine were essential for growth, and supplied the organism with these amino

Microbiological methods are advantageous in that several amino acids may be determined in a single prepared hydrolysate with the same microörganism with only slight modification of the basal medium. Only the natural or l- forms are biologically active, except in the case of aspartic acid, whose d- and l-isomers are equally available to Lactobacillus delbrūckii. However, the l-forms are more expensive than the synthetic dl-mixtures, so that the latter are used in the basal medium and in the standard series when available. When substituting one form for the other, or when the hydrochlorides are used, appropriate adjustments should be made in the amounts employed. Microbiological methods are exceedingly simple compared to the chemical isolation procedures. Moreover, they are not subject to isolation losses since determinations are made directly on the hydrolysates.

Careful attention must be given to proper methods of preparing hydrolysates for assay. Acid is known to destroy tryptophane and, in the presence of carbohydrate, tyrosine. Enzymatic digestion or hydrolysis with barium hydroxide should be employed for tryptophane assays, since hydrolysis with sodium hydroxide has been reported to give erratic results. Alkaline hydrolysis racemizes the amino acids, so that such treatment must be continued until the racemization is complete, and the values found multiplied by two. Unless complete assurance is had that

Alkali seemizes tryptophane. Though hydrolysis with sodium hydroxide has been found satisfactory by some investigators, others (Woolbey and Sebrell: J. Biol Chem. 157, 141 (1945)) have obtained erratic results. The latter prefer enzymatic digestion which avoids possible variable racemization of tryptophane or hydrolysis with barium hydroxide. Indole and anthranilic acid can replace tryptophane for L. arabinosus and should be removed from hydrolysis aby ether extraction at pH 40.

‡ Alkaline hydrolysis racemizes tyrosine. Thus, values should be multiplied by 2. Acid hydrolysis of samples containing appreciable amounts of carbohydrate should be avoided because the resultant humin formation is accompanied by a loss of tyrosine.

no amino acid loss occurs during the preliminary preparation of hydrolysates, caution should be observed in applying such analytical data to the composition of the intact protein.

The qualitative amino acid requirements of six lactic acid bacteria are shown in the table on p. 974. These microörganisms have been employed in the quantitative determination of 14 amino acids. To facilitate the application of these methods, a typical procedure is described below, and pertinent data regarding the preferred methods of preparation of the hydrolysates, the concentrations of the amino acids at half-maximum and at maximum growth, and the nature of the responses measured are summarized in the table on p. 975. References are made to the original publications for further details.

1. Microbiological Determination of Isoleucine, Leucine, and Valine. Method of Shankman:⁹⁴ Principle. Isoleucine, leucine, and valine are determined by measurement of the growth stimulation of Lactobacillus arabinosus. Samples are prepared for assay by the microhydrolytic procedure of McMahan and Snell,⁹⁵ employing 10 per cent hydrochloric acid. Each amino acid is determined separately by omitting it from the basal medium.

Preparation of the Sample: Weigh into a pyrex test tube an aliquot of the sample containing 100 mg. of protein. Add 1 ml. of 10 per cent hydrochloric acid. and seal the tube in an oxygen flame. Heat for 10 hours in an autoclave at 15 lb. pressure, or in an oven at 120°. Cool, open the tube, and wash out with approximately 95 ml. of water. Adjust with 4 N sodium hydroxide to pH 6.8 to 7.0, and dilute to a concentration. of approximately 7.5 γ of l-valine, 15 γ of l-leucine, or 10 γ of l-isoleucine per ml.

Preparation of Basal Medium: The composition of the basal medium is given in the following table:

Composition of Basal Medium for the Assay of Leucine, Isoleucine, and Valine

(The amounts shown are for the preparation of 500 ml. of basal medium)

Glucose	5 g.	l(-)-Leucine	100 mg.
Sodium acetate	3 g.	dl-Isoleucine.	100 mg.
Salt solution A	5 ml.	dl-Valine	100 mg
Salt solution B	5 ml.	l(-)-Cystine	50 mg.
Adenine	5 mg.	dl-Methionine	50 mg.
Guanine	5 mg.	l(-)-Tryptophane	17 mg.
Uracil		l(-)-Tyrosine	17 mg.
Thiamine		dl-Phenylalanine	50 mg.
Riboflavin	100 γ	l(+)-Glutamic acid	200 mg.
Nicotinic acid	100 γ	dl-Threonine	
Biotin		dl-Alanine	
Pyridoxine		l(-)-Asparagine or aspartic acid	200 mg
Pantothenic acid		l(+)-Lysine	
p-Aminobenzoic acid		l(+)-Arginine	

¹⁴ Shankman: J. Biol. Chem., 156, 305 (1943).

[&]quot; McMahan and Snell: J. Biol. Chem., 152, 83 (1944).

^{• **} Reagent grade concentrated hydrochloric acid solution contains approximately 35 per cent hydrochloric acid.

^{• **} Estimate the approximate concentrations of the amino acids present from the composition of the test material.

For use in the assay tubes, omit from the basal medium that amino acid for which analysis is being made. Adjust to pH 6.6 to 6.8 with 4 N NaOH after preparation. Store in the refrigerator and arrange storage flask with a siphon so that the amount required for the day's work may be readily obtained.

The amino acids may be weighed out directly or may be prepared as stock solutions in water, containing the desired amount in a few ml. Where necessary, a little hydrochloric acid may be used to aid in solution. Store the stock solutions in the refrigerator.

Salt solution A contains 25 g. each of potassium monohydrogen phosphate and potassium dihydrogen phosphate, in 250 ml. of water. Salt solution B has the following composition: 10 g. of magnesium sulfate heptahydrate, 0.5 g. of sodium chloride, 0.5 g. of ferrous sulfate heptahydrate, and 0.5 g. of manganese sulfate tetrahydrate, in 250 ml. of water. Add a few drops of hydrochloric acid to solution B to keep from precipitating.

Prepare stock solutions of adenine, guanine, and uracil, containing 1 mg. per ml. Solution is aided by heating in the presence of a few drops of hydrochloric acid. Store in the refrigerator, and renew at frequent intervals.

Prepare stock solutions in water of thiamine, calcium pantothenate, and pyridoxinė, containing 100 γ per ml. Store in the refrigerator and renew at frequent intervals. Prepare the riboflavin stock solution in 0.02 N acetic acid, to contain 100 γ per ml. Store as above, and in addition keep from exposure to light.

Stock solutions of nicotinic acid (100 γ per ml.) and biotin (2 γ per ml.) are prepared in 50 per cent ethyl alcohol. The stock solution of p-aminobenzoic acid (50 γ per ml.) is prepared in glacial acetic acid, and stored in a dark-glass bottle.

Procedure: Carry stab cultures of Lactobacillus arabinosus 17-5 on yeast extract-dextrose-agar (Difco) and subculture monthly. After transfer, incubate the cultures at 30° for 24 to 48 hours, and then hold in the refrigerator. Prepare the inoculum for the assay tubes by transfer from the stock culture to a sterile centrifuge tube of the complete basal medium, containing all the amino acids listed. Incubate the inoculum at 30° for 24 hours before use. Centrifuge aseptically, and wash 3 times by suspending in sterile 0.9 per cent saline and centrifuging. Finally suspend the cells in 30 ml. of saline.

Assay: Pipet into pyrex test tubes 0, 0.25, 0.50, 0.75, 1.0, 1.5, 2.0, 3.0, 4.0, and 5.0 ml. aliquots of the test extract. Add to each tube 5 ml. of basal medium lacking the particular amino acid to be determined, and sufficient distilled water to make a total volume of 10 ml. Prepare a similar series of standards containing the amino acid to be assayed, employing a pure solution of the appropriate amino acid in place of the test extract. Optimal concentrations are 15 γ of dl-valine or l-leucine per ml. or 20 γ of dl-isoleucine per ml. Plug the tubes with cotton and sterilize in an autoclave at 15 pounds pressure for 15 minutes. After cooling to room temperature, add one drop (0.03 ml.) of inoculum to each tube and incubate at 30° for 72 hours.

^{**} American Type Culture Collection, No. 8014.

Transfer the contents of each tube to a 125-ml. Erlenmeyer flask, using a constant volume of distilled water as a wash. Titrate the lactic acid produced with 0.05 N sodium hydroxide using bromthymol blue as the indicator.

Calculation. For each amino acid assayed, plot the titrations for the standard series in ml. of 0.1 N sodium hydroxide against γ of the standard used. From the appropriate curve, estimate the amount of each amino acid assayed per tube. Calculate the concentration per ml. of test extract. Determine the amino acid content of the test sample from the values obtained from not less than 5 of the tubes which do not vary by more than ± 15 per cent from the average. Synthetic dl-mixtures contain 50 per cent of the biologically active enantiomorph. If the racemic mixture was used as the standard, multiply the value obtained by one-half.

In Fig. 284 is shown a standard curve obtained with dl-valine, during the assay of a β -lactoglobulin preparation for that amino acid. The method of calculation is illustrated in the table below. Results are expressed as per cent of valine in the protein constituent of the material assayed.

MICROBIOLOGICAL ASSAY FOR VALINE IN A β -Lactoglobulin Preparation (N = 14.6 Per Cent)* (0.107 g. was hydrolyzed and diluted to 750 ml.)

Test Extract Added to Assay Tube	Titration After Incubation	dl-Valine Equivalent Evaluated from Standard Curves	dl-Valine per ml. of Test Extract
ml.	ml. 0.1 N NaOH	γ	γ
0	0	0	
0.25	0.7	5.1	20.4 (omit)
0.50	1.2	8.1	16 2\
0.75	1.8	12 2	16.3
1 0	2 . 2	14 7	14 7
1.5	3 3	22.0	14 7 Average
2.0	4.5	30 3	15.2 15.3
3.0	6.5	46 5	15.5
4 0	7.9	62 0	15.5
5.0	8.6	72.7	14.5

Calculation:

 $15.3 \times \frac{1}{2} \times 750 = 5.74$ mg. of l-valine per 100 mg. protein in sample.

There is some evidence that in addition to a proper balance of the essential amino acids, it may be necessary to supply certain peptide linkages in the dietary to insure satisfactory utilization of protein nitrogen (see p. 930). It has been demonstrated in rat assays that omission of a new factor, strepogenin, from a dietary including a hydrolysate containing all of the essential amino acids in satisfactory quantities was responsible for a poor biological response. This factor, believed to be a

^{*}The theoretical nitrogen content of β -lactoglobulin is 15.6 per cent. 0.107 g. contains 100 mg. of protein.

peptide, is a growth stimulant for *Lactobacillus casei* and *Streptococcus lactis*. A preliminary method of assay has appeared based upon the growth of the former microörganism.⁹⁹

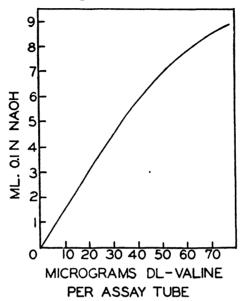

Fig. 284. Titration of lactic acid produced by *Lactobacillus arabinosus* grown at different levels of valine supplementation.

2. Use of Neurospora Mutants. In 1941 Beadle and Tatum¹⁰⁶ reported the production of biochemical mutants in the red bread mold Neurospora by irradiation with ultraviolet and x-rays. These mutants are unable to carry out certain specific chemical reactions which are normally possible to the unmutated or wild-type strain. For example, the untreated mold is able to synthesize all the components of protoplasm it needs (vitamins, amino acids, etc.) on a medium containing only sucrose, nitrate, inorganic salts, and biotin. Various mutant strains have been obtained which are unable to grow without the addition of certain specific vitamins or amino acids to the medium, i.e., the strain has lost the ability it one time possessed to synthesize that particular vitamin or amino acid. It is believed that this loss of specific biochemical power is due to the loss of a single gene, which would ordinarily control the particular reaction which no longer occurs in the mutant.

The implications of these remarkable findings are obviously wide-spread, not only in the field of genetics but also in many other ways, one of which is in the field of microbiological assay. The *Neurospora* mutants with specific nutritional defects can be used for microbiological assay of amino acids and other nutrients just as has been described for the use of

Sprince and Woolley: J. Exp. Med., 80, 213 (1944).
 Beadle and Tatum: Proc. Nat. Acad. Sc., 27, 499 (1941); Tatum and Beadle: ibid., 28, 234 (1942).

certain bacteria. For example, Horowitz and Beadle¹⁰¹ have described a cholineless strain of Neurospora, i.e., a mutant which cannot synthesize choline and is therefore unable to grow without the presence of added choline in the medium. These authors have described a method for the microbiological assay of choline by the use of this strain. The procedure is substantially identical in principle with that described on p. 976 for the microbiological assay of amino acids, except that growth response is followed by drying and weighing the mold mycelium. Comparison is made in terms of a standard curve obtained with known amounts of choline. Methods have also been described for the assay of certain amino acids (methionine, leucine, arginine) by the use of the proper Neurospora mutants, and in general this versatile phase of microbiological assay appears to be just beginning in so far as future application is concerned.

Another contribution of this work is to facilitate knowledge concerning gene action, and the reactions controlled by genes. If, as has been suggested, each step in a biochemical reaction is under the control of a single gene, studies of the various mutants should permit a better understanding of the intermediate stages in biochemical reactions. For example, by this method of approach the progressive reaction ornithine \rightarrow citrulline \rightarrow arginine, postulated by Krebs and Henseleit in connection with urea synthesis in mammalian liver (see p. 952) has been shown to occur in distinct gene-controlled steps in *Neurospora*. While this does not necessarily mean that the reaction occurs in this way, or even occurs at all, in higher cells, it at least indicates the possibility of it so doing. There is no doubt that further studies of this type will add significantly to our knowledge of the fundamental chemical processes of protoplasm.

III. EXPERIMENTS ON CARBOHYDRATE METABOLISM

- 1. Hyperglycemia Produced by Carbohydrate Ingestion. The average glucose content of normal blood is somewhat less than 0.1 per cent. This is increased (hyperglycemia) after the ingestion of carbohydrate food. The increase is noted more quickly after the ingestion of monosacchardes than after the ingestion of the more complex carbohydrates. After the ingestion of 100 g, of glucose the increase in the sugar of the blood sometimes occurs in three minutes.
 - a. Influence of Glucose: In the morning before breakfast, or at least three hours after breakfast, determine the normal sugar content of your blood by means of some accurate micro-method. (See Chapter 23.) Ingest 100 g. of glucose dissolved in 250 ml. of water, and again determine the blood sugar level at intervals of 5, 15, and 30 minutes, and one, two, and three hours. (Plot a curve similar to the one shown in Fig. 285.) The urine may also be examined for sugar at intervals of one hour after the sugar ingestion.

Repeat the experiment on another day using 250 g. of glucose and compare the results with those obtained after the ingestion of 100 g. Explain your findings. If desired, this experiment may be combined with the one on "Alimentary Glucosuria" (see p. 981).

b. Influence of Starch: Repeat the experiment as given above for glucose except that 170 g. of white bread or 100 g. of starch made into a paste¹⁰² are substituted for the 100 g. of glucose.

 ¹⁰¹ Horowitz and Beadle: J. Biol. Chem., 150, 325 (1943). See Chapter 35, under Choline.
 102 In making starch paste, rub up the dry starch in a mortar with cold water, pour the suspended starch granules into boiling water, and stir.

The experiment may be repeated as described above, using an increased amount of starch.

The various experiments may be conducted on patients suffering from diabetes mellitus if such are available and instructive data collected. The alimentary hyperglycemia will generally be slower in reaching its maximum and will be more prolonged than in the case of normal subjects. In some instances after the diabetic has ingested 100 g. of glucose the blood sugar does not reach its maximum until a period of two hours has clapsed. The blood sugar also returns to its former level more slowly than in the case of normal individuals.

2. Experiments on Alimentary Glucosuria. According to Folin and Berglund, the sugar of normal urine consists of a motley variety of carbohydrate products and carbohydrate derivatives including di- and polysaccharides. These are believed to arise from foreign unusable carbohydrate materials present in grains, vegetables, and fruits, and from decomposition products due to cooking, canning, and baking of food. The ingestion of pure glucose, fruetose, maltose, dextrin, or starch does not normally give rise to glucuresis, but the ingestion of impure

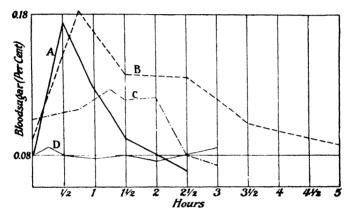

Fig. 285. Blood sugar as influenced by diet. A = glucose; B = starch; C = starch and fat; D = fat.

products or of an ordinary carbohydrate meal increases the sugar of the urine. So also may lactose and galactose.

Procedure: On arising at 7:00 A.M., the student should empty his bladder and discard the urine voided. He should then drink one glass of water but eat no food. At 8:00 A.M., the bladder is again emptied and the urine kept for analysis. The student then immediately drinks 200 g. of pure glucose dissolved in about 500 ml. of water. Urine specimens are collected again at 9:00, 10:00, and 11:00 A.M. Test each specimen for sugar by Benedict's qualitative reduction test. Determine sugar in each specimen according to the method of Folin and Svedberg (see Chapter 32).

Other students should go through the same procedure with the exception that for glucose there should be substituted 200 g. of cane sugar, 200 g. of commercial dextrin, 200 g. of pure dextrin-starch, 103 g. of pure lactose, a dozen graham crackers with water only, two baked apples, bread and butter, meat with water only, or a large dish of pure gelatin without added sugar.

This experiment may be made more complete by making determinations of blood sugar at short intervals as described in Exp. 1, p. 980. If desired,

¹⁰² Dextrin-starch mixture may be prepared by boiling 200 g. of starch in 900 ml. of water, cooling to 50° C., adding a little malt extract, and allowing to digest until completely liquefied.

data on glucosuria, hyperglycemia, and carbohydrate in feces (see below) may be collected from one experiment.

3. Effect of Exercise on the Composition of the Urine. After strenuous exercise the urine volume generally decreases, while the acidity and ammonia increase. The phosphate and lactic acid excretion increase and the chloride excretion decreases. The maximum effect usually is obtained in 20 minutes. Normal values should be restored in about an hour.

Procedure: The subject who has had no food for several hours is given 50 ml. of water every 15 minutes throughout the experiment, beginning for example at 12:00 noon. At 12:00 the bladder is emptied and urine specimens collected every 15 minutes thereafter. At 1:00 the subject engages in strenuous exercise for 2-3 minutes. Running up and down

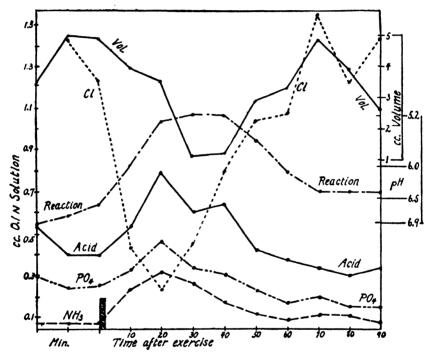

Fig. 286. Curves showing influence of exercise on composition of the urine. (Courtesy, Wilson, et al.: J. Biol. Chem., 65, 755 (1925).)

stairs for this period will suffice. In the urine specimens determine lactic acid, phosphate, total acidity, chloride, ammonia, and pH. (For methods, see Chapter 32.) Plot curves of amounts of these constituents per 10-minute specimen against time to show the effect of exercise on urine composition. The blood sugar may also be determined at intervals and the influence of the exercise noted. Curves from a typical experiment are shown in Fig. 286.

- The Effect of Insulin on the Blood Sugar Level. See the experiment described on p. 703.
- 5. Influence of Carbohydrate Deficiency. Carbohydrates occupy a very prominent place in the diet of man. That they are not essential dictary constituents, at least for the white rat, may be shown by the following experiment.

Demonstration on Carbohydrate Deficiency: Use young white rats as subjects feeding one rat Diet 1 and another rat Diet 2 as given in the following table:

CARBOHYDRATE DEFICIENCY DIET

	Diet 1 per cent	Diet 2 per cent
Casein		20
Butter fatLard		15 10
Starch or dextrin	0	55
Yeast, dried, ¹⁰⁴ gram per day	0.4	0.4

Both rats will grow normally in spite of the practical absence of carbohydrates in Diet 1. In the case of man, the withdrawal of carbohydrates is followed by ketosis (see p. 984). This ketosis is absent or much less pronounced in the case of the white rat.

IV. EXPERIMENTS ON FAT METABOLISM

- 1. Fat Utilization. This may be determined in a manner entirely analogous to that used in the determination of protein utilization (see p. 960). The fat may be determined by the Saxon method (see p. 409). It is claimed when moderate amounts of fat are fed that the fat of the feces is largely independent of the diet. Therefore, in order to secure accurate information regarding the utilization of food fat, it is said to be necessary to determine the fecal fat on a nonfat diet. There may possibly be a fat excretion from the intestine but much of the lipid of the feces is found in cellular structures (bacteria, epithelial cells, etc.). (See Chapter 21.)
- 2. Fat in Feces. A normal adult will digest and absorb at least 90 per cent of the fat in the diet when the amount ingested does not exceed 100 g. If the diet contains an excessive amount of fat, e.g., 300 g. per day, considerable appears in the feces. In pancreatic diseases and such conditions as are accompanied by a decrease in bile flow, the digestion and assimilation of fat is lessened.
- Experiments: (a) Ingest an ordinary mixed diet containing an average amount of fat per day, e.g., 75-100 g. Collect a stool and examine it microscopically as directed on p. 497. (b) Now ingest a diet containing an excessive quantity of fat, e.g., 300 g. per day. Separate the feces and subject a representative sample of the feces from the high fat diet to microscopical examination. (c) If it is desired, the fat may be extracted from some of the stool by applying the principle involved in the quantitative determination of fat in the Saxon method (see p. 409). Evaporate the ether extract and identify the fat in the residue by tests given in Chapter 3.
- 3. Influence of Fat (Fatty Acid) Deficiency. Although it has often been demonstrated that fats are not essential constituents of the diet from the energy standpoint, Burr and Burr have shown the essential nature of certain unsaturated fatty acids (see discussion on p. 922). The following experiment demonstrates the characteristics of a deficiency of essential fatty acids in the rat.
- Experiment: Two groups of rats, weaned at three weeks, are placed in individual cages and fed the following diet: purified casein¹⁰⁵ 24, sucrose 72.1, salt mixture (McCollum-Davis, see Appendix) 3.9. Supplementing this diet, 0.65 g. of dried ether-extracted yeast upon which is dried 2 drops of an ether extract containing the nonsaponifiable fraction of 70 mg. of cod

104 The yeast is fed separately 0.4 g. to each rat. It may be fed in the form of a powder or as tablets. The only carbohydrate present in Diet 1 is the very small amount in the dried yeast.

100 Reprecipitated curd casein is washed until free from chlorides, extracted repeatedly with alcohol, and finally extracted for one week with ether, and dried at 35°. For detailed directions see Burr and Burr: J. Biol. Chem., 82, 345 (1929).

liver oil, is fed daily. To each rat in one group 10 drops of lard are given daily. Water is supplied *ad lib*. and, if desired, the quantity consumed may be measured.

In about 70 to 90 days the symptoms of the deficiency will begin to appear in the fat-free group. The legs, especially the hind legs, become scaly and swollen, the tail becomes spotted and ridged and finally necrotic (Fig. 287), the hair on the back becomes filled with dandruff and tends to fall out, and degeneration of the kidneys sets in as may be observed from the bloody urine. The renal lesions are the immediate cause of death. In the females, ovulation becomes irregular and finally ceases.

The deficient animals eat the same amount of food but drink twice as much water as the controls. Before the deficient animals reach a moribund condition, their diet may be supplemented with a small amount of an oil or fatty food, to test the curative properties of the fatty acid molecules.

Fig. 287. Necrosis of the tail of a rat on a fatfree diet. (Courtesy, Burr and Burr: J. Biol. Chem., 82, 345 (1929).)

4. Ketosis. Ketosis may be induced in a normal person by the ingestion of a carbohydrate-free diet. The origin of ketosis is discussed on p. 925. The intensity of ketosis may be evaluated by determination of the excretion of ketone bodies in the urine (ketonuria). The following table shows the data obtained in an actual case of the withdrawal of carbohydrate food from the diet of a normal man (von Noorden).

Kernere	ACCOMPANYING	CARROHYDRATE	WETHER

Day	Diet	Excretion of Acctone Bodies Cal- culated as β-Hydroxybutyric Acid (Grams)
1	Protein, fat, and carbohydrate	None
2	Protein and fat	0.8
3	Protein and fat	1.9
4	Protein and fat	8.7
5	Protein and fat	20.0
6	Protein, fat, and carbohydrate	2.2

Experiment: Ingest an ordinary mixed diet for one day. Follow this by a period of two to four days in which no digestible carbohydrate is eaten. (A diet of meat, eggs, butter, agar-agar, and water has a very low digestible

carbohydrate value.) Collect the urine for each day of the experiment, examine it qualitatively for acetone bodies (see tests, Chapter 29). If present, determine the total acetone bodies quantitatively (for methods see Chapter 32). The blood may also be examined (see Chapter 23). Did the withdrawal of carbohydrate food cause a ketonuria?

ADEQUATE VS. OPTIMAL NUTRITION; THE DIETARY EFFICIENCY OF MILK

The foregoing experiments have demonstrated that certain factors must be present in a diet if it is to be deemed *adequate*. But such a diet, although it qualifies under all required nutritional standards, may be improved upon. We thus form what may be termed an *optimal* diet. To demonstrate the difference between an *adequate* and an *optimal* diet proceed as follows:

Place two white rats from the same litter, each weighing 35-45 g., in separate cages. Feed one rat an *adequate* diet (see below) and the other an *optimal* diet (see below).

Adequate Diet		Optimal Diet	
Whole wheat	82	Whole wheat	66
Whole milk (powder)	17	Whole milk (powder)	33
Sodium chloride	1	Sodium chloride	1

It will be noted that dry milk constitutes only one-sixth of the adequate diet whereas it makes up one-third of the optimal diet. Give the animals water ad lib. and weigh them at least twice a week. Continue the experiment for at least ten weeks, plotting the growth curve of each animal and keeping an accurate record of the food eaten (see Appendix for methods of recording data). If it is desired to investigate the relationship of these diets to reproduction, two rats of opposite sex may be used in each test and caged together.

The rat (or rats) receiving the *optimal* diet should grow more rapidly than the animal or animals receiving the *adequate* diet. If the experiment embraces the question of reproduction it will be found that the rats on the optimal diet have greater success in the rearing of young and that the offspring grow better during the nursing period than do the offspring of the rats ingesting the *adequate* diet.

In a comprehensive series of observations on these diets by Sherman and associates it has been found that the animals fed the optimal diet mature earlier and live longer. In common with other data secured from tests with albino rats these findings may be applied directly to the human dietary, and afford a very striking demonstration of the remarkable nutritive efficiency of milk.

Inorganic Metabolism

General. The elements that compose the human organism and their approximate relative amounts in the body are as follows:

	Per Cent	Approximate Amount in grams, in a 70-Kg. Man
Oxygen	65.0	45,500
Carbon	18.0	12,600
Hydrogen	10.0	7,000
Nitrogen	3.0	2,100
Calcium	1.5	1,050
Phosphorus	1.0	700
Potassium	0 35	245
Sulfur	0.25	175
Sodium	0 15	105
Chlorine .	0 15	105
Magnesium .	0 05	35
Iron	0 004	3
Manganese.	0 0003	0 2
Copper	0 0002	0.1
Iodine	0 00004	0.03

Various other elements are also present in traces; these are sometimes called as a group the "trace elements." In many instances their nutritional significance if any is obscure. In addition to copper, manganese, and iodine, which may be considered "trace elements" of known nutritional significance, this group includes the elements zinc. aluminum, fluorine, silicon, lithium, bromine, arsenic, lead, molybdenum, vanadium, and possibly others.

It is well recognized by now that the elements present in the animal body (and in nature in general) are not homogeneous in themselves but are mixtures of elements called *isotopes* which have identical chemical properties but differ in certain physical properties such as mass (atomic weight). Biological reactions do not distinguish between the isotopes of an element, but the artificial preparation and separation of isotopes, and their application to biological investigations and to therapeutic purposes, has become so important as to justify a brief consideration of this subject at this time.

ISOTOPES

Isotopes are defined as elements which possess identical chemical properties but differ in mass (atomic weight). Several isotopes may

therefore occupy the same position in the periodic table, or have the same atomic number, and can only be distinguished from one another by properties which depend upon atomic weight (or nuclear composition). In accordance with atomic theory, an atom consists of a central portion, the nucleus, and a system of surrounding (planetary or orbital) negatively charged electrons. The recognized units of the nucleus are the positively charged protons and the electrically neutral neutrons. Both of these nuclear components have approximately the same mass, which is about 1850 times that of the individual electrons which surround the nucleus. Thus the number of protons and neutrons in the nucleus of an atom to a large extent determines the atomic weight. The surrounding electrons differ from element to element (but not from isotope to isotope) and are largely responsible for the chemical properties (valence, etc.) of the element. The number of these electrons is equal to the number of positively charged protons in the nucleus, since the atom as a whole is electrically neutral, and this number is also the atomic number of the element.

Two isotopes of an element will therefore have the same electron configuration (and hence the same chemical properties); they will both have the same number of protons in the nucleus, since this must equal the number of surrounding electrons, but they will differ in the number of neutrons present in the nucleus, and therefore in relative mass or atomic weight. Thus the ordinary hydrogen atom contains one proton as a nucleus and one planetary electron, and has an atomic number of 1; deuterium (an isotope of hydrogen) has a nucleus containing one proton and one neutron, with one planetary electron. The atomic number is still 1, the chemical behavior is essentially unchanged, but the atomic weight is 2. It is customary to indicate an isotope by a superscript denoting its atomic weight, thus deuterium is H²; the various isotopes of oxygen are O¹⁵, O¹⁶ (the most abundant), O¹⁷, O¹⁸, and O¹⁹. Sometimes a subscript denoting the atomic number precedes the symbol of the element—e.g., sO¹⁶ for the common isotope of oxygen.

There are two general types of isotopes, stable and radioactive. Both types have been used in biological investigations. They require different investigative procedures for their utilization, and have different applicabilities. Each type will be considered separately. The accompanying table lists some of the characteristics of certain of the stable and radioactive isotopes of major biological interest. All of the stable isotopes which have found biological application are listed in the table. Only a few of the radioactive isotopes which have been utilized are included; as will be evident from the subsequent discussion in this chapter, radioactive varieties of practically all of the elements found in biological material are available and are coming into increasing use.

Radioactive Isotopes. Radioactive isotopes have been longest known, and were the first type used in biological investigations. Certain of these occur naturally—e.g., the radioactive isotope of lead, used by Von Hevesy for "tracer" studies on the absorption of lead by plants many years ago. The development of the cyclotron, whereby nonradioactive atoms may be

^{*} For a more complete table, including all the known isotopes, and giving types of radiation, energies, e.s. see the Appendix to Alexander's "Colloid Chemistry," vol. V, New York, Reinhold Publishing Corp., 1944.

bombarded by high-speed subatomic particles (protons, neutrons, deuterons, etc.) to produce artificially radioactive modifications of a number of elements (carbon, iron, phosphorus) stimulated interest in the use of radioactive isotopes and considerable work has been done with material obtained from this source. The application of radioactive isotopes to biological studies promises to become far greater with the availability of a great number of radioactive isotopes as the result of the development of controlled nuclear fission. The report of the Manhattan Project¹ regarding the availability of radioactive isotopes produced directly or indirectly by the uranium chain-reacting pile lists over 100

¹ Science, 103, 697 (1946).

radioactive isotopes of varying degrees of availability; more than 200 radioactive isotopes are now known. Many of these of course have little or no biological interest, but included in the list are isotopes for all of the common elements of biological importance, except for nitrogen and oxygen. The radioactive isotopes of these two elements have such a short half-life (see table, p. 989) as to make their preparation and use impractical at the present time. It is safe to predict that within the limits of their experimental availability and applicability, radioactive isotopes bid fair to play an increasingly important role in biological and medical investigations.

Radioactive isotopes usually are measured in terms of the radiation which they emit on decomposition to form other elements, with the accompanying emission of α - or β -particles, and sometimes of gamma rays; from a practical point of view, the β -ray emission is usually the most important. The radiation is measured by its effect on the ionization of a gas in an enclosed chamber exposed to the sample of material under test. An ordinary electroscope may be used, with a low sensitivity; most investigators use an apparatus called a Geiger-Müller counter. In this device, the radiation enters a special gas-filled counter tube which contains two electrodes, with a potential of about 1200 to 1400 volts across them. When an ionizing particle of radiation enters the tube, the ionization of the gas caused by the radiation produces a "surge" of electrons toward the anode, causing a momentary flow of current in an external circuit. This is immediately dissipated, to be produced again when another ionizing particle enters the tube. The separate current impulses can be suitably amplified and made to activate a counting device. Thus, theoretically, each ionizing particle can be counted; in practice, the counter is scaled to count a predetermined fraction of the total pulses. The activity of the material (and hence the isotope content) may therefore be expressed in counts per unit time (seconds or minutes), or in millicuries or microcuries (1 millicurie = 1000 microcuries = 3.7×10^7 counts per second). The National Bureau of Standards has suggested that a new unit be defined, the rutherford, whereby 1 rutherford (abbreviated rd.) equals a count of 10⁶ disintegrations per second. Thus a microrutherford would represent 1 disintegration per second.

Radioactive isotopes differ with regard to availability, half-life, and the type of radiation emitted. Availability now appears to be largely a matter of technical development. The type of radiation emitted (kind and intensity) influences the sensitivity and methods of measurement. The half-life of a radioactive element is the time required for one-half of the atoms to disintegrate. Isotopes with a very short or very long half-life are of less value than those with a half-life of the order of weeks or months. A short half-life means that too great a proportion of the original material will have lost its activity (and original chemical nature) during the time required for transport after preparation to the place of use, and for the manipulative details of an experiment. A very long half-life means that a high proportion of the isotope must be incorporated into a compound if accurate radioactivity measurements are to be made.

The uses of radioactive isotopes are discussed subsequently (p. 993).

The question is sometimes raised concerning the possible effects of the radiation on metabolic processes and cell function when radioactive isotopes are used for studies on living material. The sensitivity of radioactivity measurement is so great as ordinarily to permit a very high dilution of the isotope in "tracer" studies, and it is not believed that at such dilution the radiation could have any deleterious effect. It may be recalled in this connection that ordinary potassium as it is found in nature is weakly radioactive. Under some circumstances, it is the effect of the radiation which is actually desired; the use of radioactive isotopes in this connection is discussed on p. 995.

Stable Isotopes. Most of the common elements as ordinarily encountered consist of mixtures of stable isotopes. Thus ordinary oxygen consists of the three stable isotopes O¹⁶, O¹⁷, and O¹⁸, in the proportion respectively of 99.76, 0.04, and 0.20 per cent. Over 200 stable isotopes of the various elements have been recognized as existing, but only a very few have been obtained in concentrated form. To obtain the separate isotopes from a mixture, or fractions relatively enriched with respect to one isotope, advantage is taken of properties such as diffusion or reaction velocity which may vary with mass differences. Thus a water molecule containing O¹⁸ will be heavier than one containing O¹⁶, and the two types may be separated by controlled fractional distillation. By such methods or their equivalent, the stable isotopes H² (deuterium), C¹³, N¹⁵, O¹⁸, and S³⁴ have been made available for biological investigation. The first of these to become available in amount sufficient for investigative purposes was deuterium, first obtained by Washburn and Urey in 1932, by the fractional electrolysis of water. It was in fact the availability of deuterium which suggested to the imaginative genius of Schoenheimer and Rittenberg the possibility of its use in biological investigations, a concept which may be said to have initiated the present phase of application of isotopes to biological problems.

With the exception of deuterium, the amounts of stable isotopes available at the present time are somewhat limited, due largely to the cost of separation from the naturally occurring mixtures. Technical improvements in this respect may however be expected, and there is some indication that the uranium pile may be a future source of stable isotopes as well as of the radioactive variety.

The chief application of the stable isotopes in biological investigation is for the purpose of "labeling" or "tagging" a molecule or part of a molecule. The stable isotopes have the advantage over the radioactive type in that the time of preparation of the compound incorporating the isotope, or the duration of the experiment, are of no importance; there is no question concerning the possible effect of radiation on the experiment; and in some instances the isotope may be recovered at the end of the experiment and used again. Disadvantages relative to radioactive isotopes include the increased difficulty of measurement; the necessity for a higher concentration, since measurements of radioactivity are far more sensitive than measurements of mass; and the relatively few stable isotopes available.

With the exception of deuterium, the stable isotopes are measured

with an instrument called the mass spectrometer. The principle upon which this instrument operates is illustrated diagramatically in Fig. 288. The sample in the form of a gas, e.g. N₂, CO₂, is admitted to a highly evacuated chamber across which a stream of electrons is flowing. An electron colliding with a gas molecule causes it to become ionized, e.g.

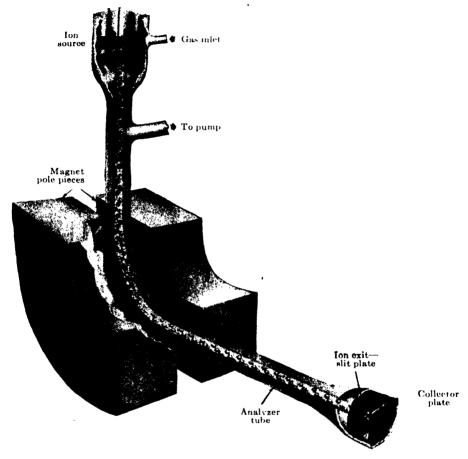

Fig. 288. The operation of the mass spectrometer tube is shown in this idealized view. The ion beam is projected into the tube and deflected by the magnetic field. The separation of the ions of different masses is indicated by the variance in the radius of curvature of the gray- and black-arrow beams in the area of the magnetic field. (Courtesy, Westinghouse Engineer.)

 $CO_2 \rightarrow CO_2^+$. The gas ions so formed are accelerated by suitable means to produce a stream of ions which passes along the tube shown and through a powerful magnetic field, so arranged as to deflect the ion from its initial path. On leaving the magnetic field, the ions pass to a collector plate and produce an ion current which is what is actually measured as an index of the number of ions striking the plate. Ions of different mass, e.g. $C^{12}O_2^+$ and $C^{13}O_2^+$, may be differentiated by either varying the strength of

the magnetic field, or more commonly this strength is held constant and the accelerating voltage is varied. Results are obtained in the form of a graph relating ion current to accelerating voltage. Isotopic ions differ on such a graph in their position along the voltage scale (which can be converted into mass, since a constant relation exists between these two quantities); the ratio of one isotope to another is given by the ratio of ion currents at the respective points on the mass (voltage) scale. It is this ratio of isotopes which is ordinarily desired—i.e., the relative abundance for example of C¹² over (¹³ in the sample as compared to their relative amounts in ordinary "nonisotopie" compounds.

The measurement of deuterium is a special case. It may of course be measured with the mass spectrometer, but equally satisfactory results can be obtained by converting the deuterium to the form of water (as by burning the sample in oxygen) and determining the specific gravity of the water so produced. There is a predictable relationship between the specific gravity of the water and its content of "heavy water," D₂O. A common method for determining specific gravity is the "falling drop" method, in which the time required for a drop of water to fall through a definite distance in a nonaqueous solvent is measured. This method is capable of high accuracy.

The isotope content of compounds labeled with the stable isotopes usually is expressed in terms of "atoms per cent" of isotope. For example, if a substance contains 12 hydrogen atoms, and one of these is replaced by deuterium, the isotopic content will be 1/12, or 8.3 atoms per cent. This is subject to some correction, since an ordinary "nonisotopic" compound contains a certain proportion of isotopes in accordance with their normal abundance. The excess of a given isotope over that normally present is referred to as "atoms per cent excess," a more satisfactory term when dealing with variations in the isotope content of compounds.

Use of Isotopes in Biological Investigations. A major use of isotopes (both stable and radioactive) in biological investigations at the present time is as a "label" or "tag" for a molecule or portion of a molecule, or for a particular ion species. The substance under investigation is prepared by suitable chemical means in such a way that the isotope becomes incorporated into the compound in significant excess over that normally present. For example, if oleic acid is reduced in the presence of a source of deuterium, isotopic stearic acid is obtained:

$$R \cdot CH = CH \cdot R + 2D \rightarrow R \cdot C - C \cdot R$$

$$\downarrow \qquad \qquad \downarrow \qquad \qquad \downarrow$$

$$D \quad D$$

If an organic cyanide is prepared from cyanide containing isotopic carbon, and this is then hydrolyzed, an organic acid containing isotopic carbon in the carboxyl group is obtained:

$$R \cdot C^*N + 2H_2O \rightarrow R \cdot C^*OOH + NH_3$$

where C* denotes the isotopic element. Various other reactions may be used. In general, only a small proportion of the final substance contains the isotope, but this is sufficient for most purposes. In the case of studies involving inorganic ions (e.g., Na, K, Fe, I), solutions of suitable salts containing the isotopic ion are used directly.

An important consideration enters here into the interpretation of results obtained with "labeled" organic molecules. If the isotopic element is in a labile position—i.e., if it can enter readily into exchange reactions with the solvent or with other elements in the molecule—interpretation is obscured. For example, an organic acid labeled with deuterium in the ionizable portion of the carboxyl group may exchange with the nonisotopic hydrogen of water present to render the labeling valueless as a means of identifying the compound:

$$R \cdot COOD + H_2O \rightleftharpoons R \cdot COOH + D_2O$$

Thus a stably bound isotope is of more value in this connection than a labile one, and due consideration must be given to this fact. It should be pointed out that some positions in organic molecules are stable in vitro but may become labile in vivo. Thus the α -amino nitrogen of an amino acid may be stable, but may become detached by metabolic processes so that the remainder of the molecule is no longer identifiable in terms of isotope content:

$$R \cdot CHN^*H_2 \cdot COOH \rightarrow R \cdot CO \cdot COOH + N^*H_3$$

Thus, although this type of labeling permits following the course of the nitrogen metabolism, it is valueless as a guide to what happens to the remainder of the molecule after deamination; for this purpose, the carbon chain should contain isotopic carbon, preferably in as many positions as possible, or stably bound deuterium may be present.

Valuable information is frequently obtained if the molecule is labeled in more than one position, preferably with different isotopes. In this way the fate of various portions of the molecule may be followed. Examples of this type of procedure have been given in connection with the discussion of intermediary metabolism in Chapter 33.

Alternately, the organism or animal may be forced to carry on its metabolic processes in an environment enriched with respect to a particular isotope. The extent to which the isotope is incorporated into the tissue compounds may then be established, under normal and experimental conditions, and some knowledge gained with respect to the effect of the experimental conditions on the normal metabolic processes.

In addition to their value in studies on metabolic processes, isotopes have important analytical uses as well. In the "isotope dilution" method of analysis of protein hydrolysates for amino acids, for example, a small amount of a particular amino acid, prepared to contain a known proportion of isotope, is added to the hydrolysate containing that particular amino acid in unknown amount. A portion of the amino acid in question is then isolated from the mixture (the exact amount is immaterial) and the isotope content determined. From the dilution of isotope relative

to that originally present, the amount of amino acid present in the mixture is readily obtained. Another use of this principle is in detecting the formation of intermediates in tissue metabolism which may be transitory or not adaptable to quantitative estimation. For example, if isotopic acetic acid is added to the diet of an animal and a small amount of acetic acid subsequently isolated from the animal's tissues, if acetic acid were not produced in metabolism or were simply metabolized as fed, the isotope content of the isolated compound should be the same as that administered. On the contrary, if the tissues produce nonisotopic acetic acid with which the isotopic acetic acid becomes mixed (diluted), the extent of this dilution should be a measure of the production of acetic acid by the animal body. This principle was utilized by Bloch and Rittenberg in their study on acetic acid production (see p. 926). A similar procedure has been used by others, and the method promises to be of value in studies on isolated tissues, enzyme systems, etc.

Uses of isotopes are not confined to those just presented; in fact, radioactive isotopes promise to be of value in many other ways important to biology and medicine. For example, radioactive phosphorus, P³², has proved useful in the treatment of certain types of lymph gland tumors. This type of cell is particularly sensitive to x-rays; apparently the localization of radioactive phosphorus in the cells, with its accompanying radiation, has a similar effect. Radioactive iodine in minute dosage may be detected in the thyroid gland shortly after its administration; as compared to the normal individual, the rate of uptake of the isotope is increased in hyperthyroidism and decreased in hypothyroidism. The distribution of radio-iodine in histological sections of the gland may also be established by the action of the radiation on a photographic plate ("radio-autograph"). Other radioactive elements (Na²⁴, K⁴², Fe⁵⁹, etc.) have been used for studies on the metabolism of these elements, circulatory time, life of the red cell, rate of exchange of ions between various body fluids, and for other purposes. It is perhaps not too much to say that many of our concepts of physiology and pathology may have to be revised in the light of future work of this kind, as past work involving the use of isotopes has brought about fundamental changes in concepts of intermediary metabolism.

COMPOSITION OF THE ANIMAL BODY

The elements which make up the animal body, and the relative amounts present, have been listed on p. 987. These elements are obtained from various sources. Carbon, hydrogen, and oxygen are supplied to the body by carbohydrates, fats, and proteins, and by water and the oxygen of the air; nitrogen, as well as a considerable proportion of phosphorus and sulfur, are supplied by proteins; the remaining elements are supplied by the mineral constituents of natural foodstuffs, by common salt, and to some extent by the minerals of drinking water.

About 90 per cent of the total oxygen of the animal body, and about 70 per cent of the total hydrogen, are present together in the form of water, which makes up roughly two-thirds of the total body weight. The remain-

ing oxygen and hydrogen, along with all the nitrogen, most of the carbon and sulfur, and some of the phosphorus, are found in the organic compounds of the body (carbohydrates, lipids, proteins, etc.). These compounds comprise about 90 per cent of the total solid matter of the animal body, the remaining 10 per cent (about 3.3 per cent of the total body weight) being largely inorganic. The inorganic elements essential for animal life include sodium, potassium, calcium, magnesium, phosphorus, iron, copper, chlorine, iodine, probably manganese and zinc, and possibly others.

The relative amounts of water, organic material, and inorganic elements ("ash") characteristic of the body as a whole do not necessarily represent

PROXIMATE CHEMICAL COMPOSITION OF AN ADULT HUMAN BODY

Adapted from the data of Mitchell, Hamilton, Steggerda, and Bean (J. Biol. Chem., 158, 625 (1945)). The subject was an adult male, aged 35, estimated to have been in reasonably good nutritional state at the time of death, which was due to an acute heart attack. The body was obtained from the Department of Anatomy of the University of Illinois College of Medicine, and had been preserved only by freezing until the dissection for analysis was begun about 6 weeks after death. Approved analytical methods were used.

[†] Somewhat enlarged. I Somewhat congested.

the composition of the individual tissues and organs of the body, where wide variation may be encountered, not only from tissue to tissue but for a particular tissue under varying normal and pathological conditions. These differences between the various parts of the animal body in this respect are illustrated by the data in the table on page 996.

The term "proximate" refers to an analysis in terms of fundamental components but not necessarily in terms of the elements themselves. Fresh tissues, or tissues from different animal species, may vary more or less from the values given in the table. The weight of the ash is slightly higher than the actual weight of mineral elements present, including as it must the carbon and oxygen of carbonates, the oxygen of phosphates and sulfates, etc.

The absence of carbohydrate from the table is to be noted. If the carbohydrate content is estimated by difference, it cannot account for more than a few per cent of the total body weight. This emphasizes the fact that in animal tissues as a whole, carbohydrate is present in limited amount, despite the high carbohydrate content of the animal diet, and in contrast to plant tissues where carbohydrate may make up the major portion of the solid matter present. Another factor which enters into the picture is that much of the carbohydrate in animal tissues readily undergoes post mortem changes, i.e. glycogen and glucose are converted to lactic acid, etc., so that a precise estimation of carbohydrate content requires special technical treatment.

WATER

Water is the most abundant compound in the animal body, making up approximately two-thirds of the total body weight, although the various tissues within the body may differ significantly in water content (see table, p. 996). Other organisms, e.g. the jelly-fish, may have a much higher proportion of water. Water furnishes what has been called "the aqueous milieu within which life processes occur." Water is more essential than food in the sense that an individual can survive much longer when deprived of food than when deprived of water. According to Thorpe, death usually results when about 20 per cent of the body water is lost. For an experiment illustrating the need for water in the diet, see p. 970.

Water possesses a number of physical and chemical properties which promote its physiological utility. The high solvent power of water permits the formation of a variety of true and colloidal solutions, within which reactions may occur at a much more rapid rate than if a solid phase were concerned. The high dielectric constant of water promotes ionization, thus facilitating reaction occurrence and velocity. Water itself enters into a great many of the reactions of biological material (hydrolysis, oxidation, reduction, etc.) and appears to catalyze other reactions in which it plays no apparent part. The lubricating action of water is important in connection with such physiological functions as swallowing and the role of the various internal fluids of the body (synovial, peritoneal, pleural, etc.).

Water is a good heat insulator, and at the same time appears to be of major importance in the control of heat loss from the animal body.

The heat required to convert 1 g. of water to water vapor at room temperature is approximately 0.6 Cal. Du Bois found in one instance that the amount of water lost by vaporization from the skin and lungs of a normal resting man under ordinary conditions of temperature and humidity was about 680 g. per day. The heat loss associated with this vaporization represented about one-quarter of the total daily heat loss. Other means of heat loss include radiation and conduction; as the environmental temperature rises toward that of the animal body (37°), these latter means become relatively ineffective and heat loss by vaporization of water becomes proportionately greater.

The significance of water in the animal body² has two general aspects: (1) The relation between water entering the body and that leaving it, i.e. the water balance, and (2) the distribution of water between the various water-containing fluids of the body.

Water Balance. The sources of body water include (1) the fluids of the diet, (2) the "solids" of the diet, which contain more or less water, and (3) the water produced by the oxidation of material within the tissues. The major channels of water excretion include (1) the lungs, (2) the skin, (3) the kidneys (urine), (4) the intestinal canal (feces), and (5), to a minor extent, the tears. The relative significance of these various factors may be illustrated by the following table.

Source			Excretion		
	ml.	Per Cent of Total		ml.	Per Cent of Total
Fluids of diet	1200 1000	48	Lungs	500 500	20 20
Oxidation within tissues	300	12	Urine	1400 100	56 4
Totals	2500	100	r	2500	100

WATER BALANCE OF A NORMAL INDIVIDUAL

Normally an individual is in "water equilibrium," i.e., water gain equals water loss with respect to all sources. A water intake in excess of the ability of the body to excrete water may be toxic ("water intoxication"); a water loss which exceeds water intake may lead to dehydration, and if sufficiently prolonged, to death.

Wide variation from the values given in the table is encountered under a variety of physiological and pathological conditions. Water intake by a normal person is largely a matter of individual choice or habit; it has been

² For a review, see Abbott: Am. J. Med. Sci., 211, 232 (1946). See also "The Relationship of Water to Certain Life Processes and More Especially to Nutrition" (Philip B. Hawk): Biochem. Bulletin, 3, 420 (1914); "Water as a Dietary Constituent" (Philip B. Hawk): Endocrinology and Metabolism (Vol. III), London and New York, Appleton, 1924.

amply demonstrated that copious water drinking produces no harm, even if taken with meals, and promotes digestion in the latter instance due to stimulation of glandular secretions. Water excretion through the skin as perspiration may be significantly increased at the expense of other channels, e.g. the urine, during severe exercise in a hot environment. Pathologically, the main channels of water loss, and the extent each may be involved, are as follows: by vomiting, up to 5 liters; overventilation, 1 to 2 liters; excessive perspiration, 10 to 15 liters; diarrhea, up to 5 liters. In diabetes insipidus, daily urine volumes of 30 liters or more have been observed, with a correspondingly large water intake.

Water excreted by the body through any channel except the lungs is invariably accompanied by electrolytes, chiefly sodium and chloride. The symptoms of excessive water loss (dehydration) are due to the loss of both water and electrolytes, and both water balance and electrolyte balance must be restored if the condition is to be alleviated.

Water excretion by the kidneys appears to be under the control of hormones from the posterior pituitary and the adrenal cortex. Absence or ineffectiveness of the "antidiuretic" principle of the posterior pituitary is believed to be the lesion in diabetes insipidus, although some balance with the anterior pituitary must be acting here, since the production of diabetes insipidus by experimental lesions of the posterior pituitary requires the presence of an intact anterior pituitary. The nerve fibers of the hypothalamic portion of the brain also appear to be of some importance in this connection. It is possible that, in the absence of the antidiuretic hormone, the tubular cells of the kidneys to a greater or lesser extent lose their ability to reabsorb the 99 per cent or more of the approximately 150 liters of glomerular filtrate produced in the kidney per day.

With regard to cortical hormones, of the pure principles thus far obtained (see Chapter 26), desoxycorticosterone is effective in maintaining normal water and electrolyte balance, as is the "amorphous fraction" of the cortical hormones. It is uncertain here whether the effect is primarily on the excretion of water or electrolytes, if indeed any distinction between these two can be made. This may also be true with respect to the pituitary principle. This serves to emphasize the fact that water excretion and electrolyte excretion are closely connected and should not be considered separately.

Distribution of Water in Body Fluids. The water of the body tissues and fluids is usually divided for consideration into two phases: (1) an extracellular phase, subdivided into (a) plasma (5 per cent of total body weight, or about 3 liters in a 70-kg. man, and (b) interstitial fluid, comprising about 15 per cent of the total body weight, or about 10 liters in an adult; and (2) an intracellular phase, making up about 50 per cent of the total body weight, or about 35 liters. Various methods, not all of which give the same result, have been used to establish this distribution of the body water and to follow variations in health and in disease. For example, a common basis for the determination of interstitial fluid volume is to determine the dilution of a known amount of injected material such as thiocyanate, sulfate, chloride, sucrose, etc., which is assumed to

distribute itself evenly throughout the extracellular water but not to penetrate the cells, at least under the experimental conditions. Suitable corrections for the amount present in the plasma, and the amount excreted, must of course be made. The use of radioactive isotopes, e.g. radio-sodium, radio-chlorine, is attracting attention in this connection and promises to be of considerable value.³

The factors determining the distribution of water between the various fluid "compartments" of the body are not known with certainty, but they appear to be largely osmotic and related to electrolyte concentration, possibly modified by differences in permeability of ions to various membranes. The role of the plasma proteins in the water equilibrium between the blood and tissues has been discussed in Chapter 22. The role of inorganic ions may be visualized by the following necessarily inexact illustration. If it is assumed for example that the interstitial fluid contains sodium chloride in isotonic concentration, the presence of approximately 9 g. of sodium chloride will permit the retention of 1 liter of water, since sodium chloride in 0.9 per cent solution is isotonic. Loss of sodium chloride will necessitate an equivalent loss of water, to keep the remaining fluid isotonic, and excess sodium chloride in the tissues will result in the presence of a larger volume of water for the same reason.

There appears to be an equilibrium between the various fluid compartments, to provide for the maintenance of a normal water content in the most essential phase. For example, the water content of the interstitial fluids may be decreased by 20 per cent or so without any detectable change in the water content of the plasma. Thus the water content of the plasma is not necessarily a reliable guide to general dehydration as some have assumed, at least in the early stages.

INORGANIC METABOLISM

The inorganic compounds of the body exercise a great diversity of vital functions in the animal economy. The calcium phosphate-carbonate complex that forms the basis of osseous tissue gives to the bones and teeth their rigidity and hardness. Because of their influence on such phenomena as permeability of cell membranes, hydrogen-ion and osmotic equilibria, solubility of proteins, etc., the inorganic salts dissolved in the body fluids affect the contraction of muscle, the irritability of the nervous system, enzyme activities, and the secretion of digestive juices, perspiration, and urine. Certain of the inorganic elements, e.g. phosphorus, sulfur, iron, etc., are combined in the molecules of biologically important compounds such as glutathione, lecithin, hemoglobin and other proteins, etc.

It has been demonstrated that inorganic elements must be available in the animal diet not only in adequate amount but also in proper balance with respect to one another. For example, a high intake of potassium salts results in increased elimination of sodium and chlorine, and in cases of vitamin D deficiency, too high or too low ratios of calcium to phosphorus in the diet lead to serious impairment of bone structure.

² See Winkler, Elkington, and Eisenman: Am. J. Physiol., 139, 239 (1943).

In the following pages are considered some of the metabolic aspects of inorganic elements and compounds. Quantitative methods for the determination of various inorganic elements in blood and urine have been described in Chapters 23 and 32; the occurrence and significance of these elements in the urine is discussed in Chapter 28.

SODIUM

This element is present to a considerable extent in the diet and in the body fluids of the animal organism, invariably in the form of the sodium ion, Na⁺, and in the diet at least, for the most part as sodium chloride. The sodium within the body fluids is sometimes said to exist in part as sodium chloride, but this concept is inexact, and is better replaced by the view that the sodium ion is a physiological entity whose function within certain limits is relatively independent of whatever anions (chloride, bicarbonate, lactate, phosphate, proteinate, etc.) are associated with it.

The adult human body contains about 100 g. of sodium, distributed almost entirely in the extracellular fluids (blood plasma, interstitial fluid) of the body. On the average, about 4 to 5 g. of sodium are ingested per day in the average diet, corresponding to about 10 g. of sodium chloride, which is the major form in which this element is ingested. Practically all of this ingested sodium is excreted by way of the urine. On diets low in sodium the urinary excretion falls to a very low level, so that the daily sodium requirement is considerably in excess of the amounts ordinarily ingested, and is commonly covered by the amount of sodium chloride (table salt) in the diet.

Carnivorous animals receive adequate salt from the animal tissues which constitute their food. The food of herbivorous animals is relatively low in sodium, and is high in potassium, the ingestion of which causes an increased urinary exerction of sodium. This loss of sodium induces a craving for this element, which in nature may be satisfied by such animals traveling long distances to "salt licks," while domestic cattle are furnished with "salt blocks." In the case of human subjects, the addition of salt to the diet makes it possible to eat with relish larger amounts of vegetable foods. Lactating cows not given a salt supplement yield milk of low sodium chloride content and may suffer otherwise. It has been shown in rat experiments that sodium deficiency unfavorably affects the appetite, the normal increase in weight, the storage of energy, and the synthesis of fat and protein. On a diet otherwise normal but of restricted sodium content (0.002 per cent), rats show retarded growth and disturbances of the eves and reproductive function, with death ultimately ensuing. Rats may have their sodium needs satisfied by diets containing as little as 0.1 per cent of sodium chloride.

It has been shown by the use of radioactive sodium that this element is absorbed exceedingly rapidly from the gastro-intestinal tract, some absorption apparently taking place even from the stomach, which is somewhat surprising in view of the relatively restricted absorptive capacities of this organ. Radioactive sodium (Na²⁴) has also been used as a means of

determining the volume of extracellular fluid in the animal body, on the assumption (which appears to be reasonably valid) that the sodium ion is distributed evenly, or in a predictable way, throughout the extracellular fluids of the organism and is virtually absent from the body cells.

The major functions of the sodium ion in the animal body appear to be in connection with osmotic pressure regulation and acid-base balance, although other possible functions such as a catalytic effect on enzyme activity, while as yet undiscovered, cannot be excluded. The role of sodium in osmotic pressure regulation and acid-base balance is best understood by a consideration of the electrolyte distribution of a typical body fluid (the blood plasma) as shown herewith.

APPROXIMATE ELECTROLYTE DISTRIBUTION OF NORMAL HUMAN BLOOD PLASMA

"Bases" = "Acids"

Ion: Na + K + Ca + Mg = Cl + HCO₃ + Pr + Others

Concentration:
$$154 + 5 + 5 + 3 = 106 + 28 + 17 + 17$$

(milliequivalents
per liter of $168 = 168$
plasma water)

The numerical values are to be considered as approximations only, subject to more or less wide variation under both normal and pathological conditions. As a matter of fact, the ionic concentration of an element in a biological fluid is somewhat difficult to define with exactness, since what is ordinarily measured is the total amount of element rather than that fraction which is ionized (see discussion of calcium, p. 1006). Nevertheless, the relationship shown above serves to bring out several fundamental facts.

In the first place, it must be true that the sum of all the cations present (Na, K, etc.) equals the sum of all the anions (Cl, HCO₃, etc.) This is evident only if concentrations are expressed in terms of milliequivalents rather than the more commonly used basis of milligrams, and this is one reason for such a choice, and for the increasing use of the former term in connection with such substances as sodium, chloride, bicarbonate, etc., in their relation to physiological processes. For example, if bicarbonate is replaced by chloride in plasma, this replacement is on the basis of ion for ion (i.e., equivalent for equivalent) rather than gram for gram. The equivalent concentration of a monovalent ion may be obtained by dividing the weight of ion present by the equivalent (combining) weight of the ion; for milliequivalents, both weights are expressed in milligrams. Thus if sodium is present to the extent of 354 mg. per 100 ml., or 3,540 mg. per liter, the milliequivalent concentration per liter is 3.540/23 = 154 milliequivalents (meq.) For a divalent ion such as Ca++, the equivalent weight is the combining weight divided by 2, since one Ca ion is equivalent to two monovalent anions.

From the data on electrolyte distribution, therefore, it can be seen that the sodium ion is the chief cation of blood plasma, and this is true also for

the other extracellular fluids of the body. Within the cells, sodium is present in relatively low concentration, being replaced largely by potassium and magnesium.

The division of the various ions of plasma into "bases" and "acids" deserves some clarification, since while this usage is rare in general chemistry it is quite common in physiology and medicine. The plasma (and the tissue fluids in general) are essentially neutral in reaction, and remain so under all conditions compatible with life. When an acid such as lactic acid enters into or is produced within a neutral buffered physiological fluid, to all intents and purposes the hydrogen ion of the acid disappears in the formation of water or other un-ionized molecule. The fluid still remains essentially neutral in reaction, and the only evidence that acid has been present is found in the increased amount of the acid anion-e.g., the lactate ion in this instance. This increased acid anion content is at the expense of such buffer anions as bicarbonate, phosphate, proteinate, etc., originally present. Thus the entrance of acid is reflected not by any marked change in pH, but by alteration in the relative amount and distribution of the various anions present. The anions therefore represent the "acid" portion of the electrolytes. An analogous situation prevails with respect to base, the entrance of which, within the framework of a neutral solution, will be evidenced almost entirely by an increase in cation (e.g., Na) content. Naturally, other factors enter into acid-base balance within the body, as is evident from the discussion in Chapter 24, but the concept of acid-base balance reflected in part by the kind and distribution of anions ("acids") and cations ("bases"), within an essentially neutral solution, is of considerable value in an understanding of all phases of this subject. From what has been said, it can be seen that sodium is the chief "base" of the plasma, and of the extracellular fluids in general.

Another aspect of sodium-ion concentration which is of importance is in connection with osmotic pressure regulation. The total osmotic pressure of a biological fluid such as the blood plasma is equal to the sum of the osmotic effectiveness of all the ions present. Thus the plasma corresponds osmotically to a solution 0.168 M (168 milliequivalents per liter) with respect to an electrolyte such as NaCl, which is assumed to be completely dissociated in solution to yield 2 ions, or to a solution of a nonelectrolyte which is approximately 0.34 M (2 \times 0.168). The osmolar concentration of plasma is therefore approximately 0.34. Note that of the total osmotically effective bases of plasma, sodium makes up approximately 92 per cent (154168). Thus changes in the osmotic pressure of plasma (and in general of the extracellular fluids of the body) are largely due to, and may be caused by, changes in the concentration of sodium present. It is true that under stress a loss of sodium may be compensated for to a small extent by an equivalent increase in potassium, but the ability of the organism to substitute bases in this manner is relatively restricted (in contrast to the wide variation in anion distribution which may occur) and any major loss of sodium from the body, as in Addison's disease, and prolonged diabetic ketosis, leads to a significant lowering of the osmotic pressure of the body fluids, and therefore water loss (dehydration). Restoration is not complete until both the lost base and the lost water are replaced.

The role of sodium in acid-base balance is secondary to its role in maintaining the total osmotic pressure of the body fluids. That portion of the body sodium equivalent to the bicarbonate present (i.e., about 28 milliequivalents per liter of plasma water, see p. 1002) represents most of the "available base" of the plasma which can be used for the neutralization of entering acids, and in conjunction with carbonic acid determines the pH of blood (see Chapter 24). It is more correct, however, to regard acid-base changes in terms of the anions present rather than in terms of sodium. Thus one may have an acidosis or alkalosis in terms of variation in plasma bicarbonate and CO₂ tension without significant changes in sodium content.

The sodium ion has an effect on irritable tissues such as muscle which does not appear to be related to osmotic forces, and which is counteracted by the presence of the calcium ion, in the proportion of about 1 to 2 calcium ions per 100 sodium ions. This is the basis for the use of such "physiologically balanced" solutions as Ringer's, Tyrode's, etc., rather than isotonic saline alone, in experiments involving the maintenance of function of isolated animal tissues or organs.

The excretion of sodium has been discussed on p. 900. On an ordinary diet urinary sodium amounts to about 4 to 5 g. per day, corresponding to 10 to 12 g. expressed as sodium chloride, but wide variations naturally can be expected. On a low-salt diet and in starvation, urinary sodium chloride excretion falls to very low levels.

CHLORINE

This element is found in biological material exclusively in the form of the chloride ion; the biological significance of postulated organic chlorine compounds, such as chlorolipids, has as yet to be conclusively demonstrated. In the diet chloride is found largely as sodium chloride, the daily intake approximating 6 to 7 g., representing about 10 g. of sodium chloride, but wide variation in this respect is encountered, depending as it does upon dietary habits. The adult human body contains approximately 100 g. of chloride, found largely in the extracellular fluids of the body, but present to some extent in red blood cells and to a lesser extent in the other cells of the tissues.

Although a close relationship exists between chloride and sodium in certain physiological processes, the chloride ion has a number of functions which are peculiar to it and which are essentially independent of sodium ion functions. Thus it is the chief anion of the gastric juice, being present there in approximately the same concentration as in the blood, at least before dilution or other modification of the gastric juice, and accompanied by the hydrogen ion in substantially equivalent amount, rather than by sodium as in the plasma and extracellular fluids of the body. The chloride of gastric juice is apparently derived ultimately from blood chloride (see Chapter 14), and is normally reabsorbed during later stages of digestion. Loss of gastric juice chloride by vomiting, or in pyloric or duodenal

obstruction, may lead to the development of an alkalosis due to bicarbonate excess, since the lost chloride is replaced in part at least by bicarbonate. It is interesting to note that on chloride-deficient diets there is no change in the output of chloride in the gastric juice, while chloride excretion by other channels, such as the urine and the perspiration, may be markedly decreased.

Another specific function of the chloride ion is in connection with the "chloride shift" in the blood during the carriage of carbon dioxide (see Chapter 24) whereby the bicarbonate content of the blood plasma is significantly increased by exchange with plasma chloride, which enters the red cells.

Chloride is likewise concerned in osmotic pressure regulation, making up about two-thirds of the total anions of blood plasma (see p. 1002) and occupying a similar position in the other extracellular fluids of the body. The role of chloride in this connection, however, is subject to somewhat greater variation than the role of sodium, since to a certain extent the organism can exchange chloride ions for other anions within the framework of a normal osmolar concentration of total anions. This ability to replace chloride ions by other ions is more restricted, however, than for the other major anion of the plasma, the bicarbonate ion, over half of which can be replaced, for example, by the lactate ion under certain conditions.

The chloride ion is an activator of salivary amylase, but this action is not specific for chloride and may be due in part to the effect of strong electrolytes in general on the solubilities of such proteins as globulins. Radioactive chloride (Cl³⁸) has been used for studies on the volume of the interstitial extracellular fluid of the body.

Chloride present in the diet in excess over that required by the body is excreted, chiefly by way of the kidneys. Excreted chloride usually is accompanied by excess sodium or potassium unless there exists a need for conserving base, in which case the ammonium ion accompanies the chloride ion to a variable extent. Factors controlling the excretion of chloride are similar to those concerned with the excretion of sodium and potassium. On a chloride-deficient diet, or in fasting, the chloride excretion may amount to but a trace.

POTASSIU M

This element, like sodium and chlorine, is also present in plant and animal tissues entirely as the potassium ion. The adult human body contains about 250 g. of potassium, present almost entirely in the cells rather than in the extracellular fluids as with sodium. While normal human blood plasma contains only about 5 meq. of potassium per liter of water, almost the entire cation content of red cells is made up of potassium (about 170 meq. per liter of cell water). Thus potassium is the major "base" of the body cells, and apparently subserves in the cells the same general functions relating to osmotic pressure regulation and acid-base balance that have already been described for sodium in the extracellular fluids of the body. This is not the only function of potassium, however; it has been

shown to aid in the enzymatic transfer of phosphate from ATP to pyruvic acid, for example (see p. 913); and the toxic effects of a significantly elevated plasma potassium level ("potassium poisoning") can hardly be ascribed to osmotic forces alone. The potassium ion has an effect on muscular irritability which, like that of sodium, tends to antagonize the effect of the calcium ion.

The abundance of potassium in plant foods and in meat precludes the danger of a deficiency of this element in a mixed diet. From 2 to 3 g. are commonly excreted in the urine per day on such a diet. Growth in rats may be retarded by reducing the daily potassium allowance below 15 mg. in the male and 8 mg. in the female: this difference may be due to differences in growth rate. Potassium requirement varies considerably in the different animal species. Prolonged consumption of a potassium-deficient diet may result in failure of the animal to respond to a correction of the deficiency. Potassium deficiency in man is associated with weakness and muscular paralysis, accompanied by a fall in the plasma potassium level; in animals hypertrophy of the heart and kidneys has been noted. In Addison's disease the excretion of potassium falls and plasma potassium rises, with the reverse changes in urinary and plasma sodium, indicating a function of the adrenal cortex in this connection. The administration of sodium chloride alone will sometimes alleviate the symptoms of the disease, apparently permitting the organism to restore the altered relation between sodium and potassium retention and excretion. It has been claimed that the symptoms associated with removal of the adrenal cortex may be reproduced experimentally by measures which increase the plasma potassium level to about twice the normal value.

CALCIUM

Calcium is an essential constituent of all living cells. Its mode of action is not clear but it appears to play a part in decreasing the permeability of cell membranes and the irritability of cells in general. Its effect on neuromuscular mechanisms is shown in higher animals by the development of hyperirritability and tetany as a result of a decline in the calcium content of the blood. Such a fall is observed in tetany following removal of the parathyroids, symptoms becoming noticeable when the calcium-ion concentration falls below 3 mg. per 100 ml. (total calcium below 7 mg.). Normal values are 9–11 mg. total or 4.25–5.25 mg. of ionized calcium. In fatal hyperparathyroidism, Ca⁺⁺ values of 7 mg. (total calcium 16 mg.) have been noted. McLean and Hastings find the calcium of plasma nearly all accounted for as calcium ions and calcium bound with protein, an equilibrium existing between the two forms. The parathyroids appear of prime importance in regulating the calcium content of the blood. The mechanism of this action is not clear.

Vitamin D improves the utilization of calcium for calcification and other purposes. There is almost overwhelming evidence that vitamin D promotes calcium absorption; there is also some evidence that it may act on the calcification process itself. The mechanism of vitamin D action is obscure. Any relation between vitamin D and parathyroid action is doubt-

ful. The action of vitamin D in calcium metabolism is discussed further in Chapter 35. Since calcium salts within the intestinal tract are more soluble at acid reaction than in neutral or alkaline solution, absorption of calcium is promoted by high gastric acidities, by acid-containing diets in general, and on diets containing lactose which lead to lactic acid fermentation in the intestines. Amino acid products of protein digestion may promote the absorption of calcium, possibly by the formation of soluble complexes. Other as yet unknown factors may also be concerned.

We are also much in the dark as to the nature of the calcification process as it occurs in bones and teeth. It appears to depend upon an adequate inorganic phosphate concentration of the blood plasma as well as upon the Ca⁺⁺ of the plasma, and these are maintained through a balance between absorption from the intestines and excretion by the intestines and the kidneys. One view is that we have a simple chemical or physicochemical equilibrium between blood and bone, the blood being commonly supersaturated with respect to calcium phosphate and carbonate, with cartilage possessing a certain selective action. Another view is that calcification involves an active chemical process in the bone cells, such as the liberation of inorganic phosphate from organic phosphates through the action of phosphatase. The subject of calcification is discussed further in Chapter 9.

Calcium Requirement. Sherman studied the daily calcium excretion in men and found the average output to be 0.45 g. This amount he therefore considered to be the minimum average requirement for adults, and suggested an optimum of 50 per cent more, or 0.68 g. of calcium per day. McCollum and Becker consider this to be rather a minimal than an optimal quantity. The recommendation of the National Research Council is 0.8 g. per day for adults. Sherman found 16 per cent of American dietaries to fall below the minimum of 0.45 g., showing the great need for the improvement of such dietaries with respect to calcium content. The growing child requires about twice as much calcium as the adult. Similarly increased amounts are needed by women during pregnancy and lactation. Otherwise a negative balance for calcium may result and the drain upon the calcium of the bones of the mother becomes excessive. Because of the large store of calcium in the bones the adult does not suffer so soon from calcium deprivation as the child. A lactating cow may lose as much as 20 per cent of its total supply of calcium without seriously interfering with milk production. In the growing child, however, any interference with the calcium supply leads to impaired calcification of the bones, as in rickets, as well as to slower growth of the body in general. It must be borne in mind that the child at birth is calcium-poor, i.e., the bones are incompletely calcified. The greater flexibility of the bones facilitates delivery, but the need of the newborn for calcium is necessarily more critical on this account.

In maintaining a proper calcium level in the diet, milk is of supreme importance. Every child should receive along with other foods a quart of milk (containing about 1.1 g. calcium) each day. Milk is recommended in supplying calcium, because of its high content of calcium, the available form in which this is present, and because milk has otherwise a high nutri-

tive value. Milk contains about 120 mg. of calcium per 100 g., cheese contains about 900 mg. Of other foods, eggs are useful, containing 70 mg. per cent, mainly in the yolk; as are also green vegetables, cabbage or lettuce supplying about 45 mg. per cent of calcium. Some green vegetables, such as spinach, while high in calcium are not so satisfactory, since much of their calcium exists as oxalate and is not readily utilized by the body. In certain foods, such as some cereals, the presence of phytic acid (inositol hexaphosphoric acid) impedes calcium and magnesium absorption, since this substance forms an insoluble compound with calcium and magnesium. This effect can be readily overcome by adding calcium carbonate to the diet, as for example by incorporation into bread. Bread has about 30 mg. per cent of calcium and meat on the average about 10. The utilization of calcium is improved by vitamin D, an adequate supply of which should therefore be insured.

The subject of calcium excretion has been discussed in Chapter 28. Most of the excreted calcium is found in the feces. This fecal calcium presumably represents unabsorbed dietary calcium. There is an intestinal secretion of calcium which may amount to 0.5 g. or more per day; most if not all of this appears to be reabsorbed. The many factors which influence the absorption and excretion of calcium have led some to doubt the validity of calcium balance studies as an index to calcium requirement unless these various factors can be subjected to rigorous control.

PHOSPHORUS

Since the greater part of the phosphorus of the body is associated with calcium in bone, the metabolism of these two elements is to a considerable extent parallel and follows that of the osseous tissues. Phosphorus, however, is abundant also in many of the softer tissues of the body and plays many important roles in life processes. Through the intermediary formation of lecithins it is concerned with fat metabolism. Through the formation of hexosephosphates, of adenylic acid, and of creatine phosphate, it plays a primary role in the carbohydrate metabolism of animals as well as in fermentation processes. Phosphates play a role in the neutrality regulation of the organism (see p. 750). They are concerned with the absorption of sugars from the intestine and the reabsorption of glucose in the kidney tubules. Phosphorus is a constituent of the phospholipids present in all tissues and which are especially abundant in nervous tissues. It is present in nucleoproteins of the chromatin material of cells and in phosphoproteins such as casein. Apparently most of the phosphorus, as well as of the fat of milk, arise from the legithin of the blood of the lactating animal.

Many studies of phosphorus metabolism have been made using radioactive phosphorus; this isotope also has some use in the treatment of disease (see p. 995). The important conclusions regarding phosphorus in its relation to bone and teeth formation which have resulted from the use of radioactive phosphorus have been presented in Chapter 9. For a further discussion of phosphorus in its relation to calcium metabolism and vitamin D, see Chapter 35.

Phosphorus Requirement. Sherman found the minimum phosphorus requirement for the normal adult to be on the average about 0.88 g. per day. For optimal nutrition the requirement has been placed at about 1.3 g. per day. For growing children the average requirement is about 1.3 g. per day. A somewhat greater amount is needed by women during the period of pregnancy and lactation and in the postlactation period to make up for losses which have occurred from the body and particularly from the bones. Four per cent of American dietaries were found to fall below the minimum phosphorus requirement, the danger of deficiency being less than in the case of calcium, and yet a matter of some concern. The phosphorus content of the diet is most readily maintained at a proper level through the liberal use of milk, a quart of milk a day containing 0.88 g. of phosphorus being recommended for children. In addition to milk (93 mg. of phosphorus per 100 g.) good sources of phosphorus are meat (average 150 mg. per cent), eggs (180 mg.), cheese (680 mg.), nuts (400 mg.), whole cereals (as whole wheat, 420 mg.), while white flour and polished rice are much lower in phosphorus (about 90 mg.). The form of phosphorus in the diet is of little practical importance since in any case, as the result of the digestive processes, the phosphorus is absorbed in inorganic form. Too high a ratio of calcium to phosphorus in the diet, however, is unfavorable to phosphorus absorption. A diet high in beryllium or strontium also hinders phosphorus absorption and gives rise to a form of rickets.

MAGNESIUM

Magnesium is an indispensable constituent of all living cells. The daily requirement for magnesium has been estimated to be about 0.43 g. for adults. Magnesium is present in such amount in plant foods and in meat that there is little possibility of the diet being inadequate with regard to this element.

About 71 per cent of the magnesium of the body is present in the bones. In muscle magnesium exceeds calcium in amount. In blood, where the reverse is true the magnesium content is very constant. This is true also of the body as a whole, the concentration of magnesium remaining constant at about 0.045 per cent during growth, whereas calcium and phosphorus tend to increase in percentage. Excessive intake of magnesium gives rise to an increased excretion of calcium in the urine, and vice versa.

Like calcium, magnesium depresses nervous irritability, but to a greater extent. A level of magnesium in the blood of 20 mg. per cent produces anesthesia, apparently by action on the central nervous system. Injections of calcium salts have a wakening effect; the reason is not known, but it is probably not through ion antagonism. Magnesium ions are necessary for the action of many enzyme systems, particularly those concerned in carbohydrate metabolism in muscle and other tissues. The mode of action of the magnesium ion in these instances is not known. Magnesium ions inhibit the activity of adenosinetriphosphatase, the enzyme which splits phosphate from ATP. It has been suggested that this may be related to magnesium anesthesia.

Diets extremely low in magnesium (1.8 parts per million) have been fed to young rats by Kruse, Orent, and McCollum. Serum magnesium drops to 0.5 mg. per cent. There is marked vasodilation and hyperexcitability, leading to tetany and death. There is a rise of cholesterol of the blood and a corresponding decrease in free fatty acids, perhaps representing a disturbed metabolism of fat. There is also a marked decalcification of the skeleton. The grass-tetany of cattle is associated with a low magnesium content of the blood.

Intestinal absorption of magnesium salts does not present a nutritional problem because of the relative solubility of the magnesium salts and their abundance in the diet. The excretion of magnesium has been discussed in Chapter 28. The action of magnesium sulfate in the duodenum in bringing about emptying of the gallbladder is employed in clinical diagnosis and therapy.

IRON

Iron exists in the body chiefly in the heme portion of the hemoglobin of the red blood cells. It is also found, however, as an indispensable constituent of various oxidation-reduction enzymes essential for the life of cells in general. Among the heme-containing enzymes are catalase, peroxidase, the cytochromes and cytochrome oxidase, and probably others. The action of these enzymes is inhibited by cyanide, which apparently combines with the iron. Iron is also found in the liver in the form of a compound called ferritin. Ferritin is an iron-containing protein, the protein portion of which has a molecular weight of about 500,000, and the iron is considered to be present in the form of colloidal Fe(OH)₃ interspaced in the crystal lattice of the protein. The significance of ferritin in nutrition remains to be elucidated.

Young animals (of all species so far studied) placed on a pure milk diet at the time of weaning develop a severe anemia. Addition of purified iron salts alone to the diet does not cure the condition, but does so if supplemented with very small amounts of copper salts. It is well established that the animal organism cannot convert the iron of the diet into hemoglobin unless very small amounts of copper are also present. There are a few instances in the literature where this has also been demonstrated in the case of human nutritional anemia. In the majority of human nutritional anemias, however, a copper deficiency does not exist and the anemia is due simply to iron deficiency. These nutritional anemias are not to be confused with the anemia of folic acid deficiency (see Chapter 35) or with pernicious anemia or other anemias due to increased blood destruction or disturbances of the blood-forming organs.

Iron Requirement. The recommended daily allowance of iron as given by the National Research Council is 12 mg. per day for adults (15 mg. per day in pregnancy), and 6 to 15 mg. per day for children, depending upon age. Stearns and Stinger claim that for infants 0.5 mg. per kg. body weight per day is necessary to insure retention of iron.

⁴ Granick: J. Biol. Chem., 146, 151 (1942); Michaelis, Coryell, and Granick: J. Biol. Chem., 148, 463 (1943).

The form of the iron in the diet must also be considered. Anemia due to iron deficiency is not uncommon in women and pre-school children. Hence general adequacy of this element in the diet cannot be assumed. Infants are born with an iron reserve in their livers which is later used for hemoglobin formation to supplement the low iron content of their milk diet. If continued beyond the normal lactation period such a diet leads to the development of a nutritional anemia. Children ordinarily require supplementary iron-containing foods by the time they are one year old. There is some evidence that the administration of iron to normal children and young adults, or increasing the iron intake above the usual levels by other means, will consistently produce a slight but significant (about 10 per cent) increase in the blood hemoglobin content.

Milk contains about 0.24 mg. of iron per 100 g. This small amount of iron appears to exist in a readily assimilable form. Most foods appear to contain two forms of iron; heme-iron which is not utilizable and non-heme forms which are available. The two forms can be distinguished by the fact that the latter types react with bipyridine. The iron need not be in organic combination. Metallic iron or any of the ordinary iron salts may be used to supply iron. It is possible that under certain conditions ferrous compounds are somewhat better utilized than ferric compounds; at least, this is a general belief among physicians. Eggs contain 3 mg. of iron per 100 g. of food, all of the iron being available. Lean muscle meats contain about the same amount, 50 per cent of which is available. Beef liver or heart contain about 8 mg. per cent of iron, about 60 per cent of which is available. Spinach contains about 3.6 mg. of iron but like the iron of blood, alfalfa, and oysters this appears to be less than 25 per cent available. The minimum amount of iron which must be added to milk for maximum hemoglobin regeneration is said to be 0.0007 per cent.

The absorption and excretion of iron have been the object of much study. Relatively little is known about the mechanism of iron absorption, but it is known for example that the action of copper in promoting iron utilization is not related to iron absorption. There is some indication that the absorption of iron may be influenced by the state of the body iron stores. Studies with radioactive iron have shown that iron may be absorbed quite rapidly, appearing in the red blood cells in maximal concentration in about 24 hours.

Very little iron is ever excreted. Only a fraction of a mg. per day is found in the urine, with more in the feces, but this latter probably represents for the most part unabsorbed iron of the diet. Iron split off from the hemoglobin of the red cells after their destruction appears to be retained within the body and used over again. The chief need for iron appears to arise in infants on a milk diet, or after blood loss as by hemorrhage or during menstruation.

COPPER

Although copper has long been known as a constituent of such compounds as the hemocyanin of the blood of certain lower organisms, the first demonstration that copper played a vital part in the animal organism was in connection with the conversion of dietary iron to hemoglobin, as described on p. 1010. Since that time, copper has been shown to be an essential component of certain enzymes such as tyrosinase and ascorbic acid oxidase, and a copper-containing protein (hemocuprein) has been isolated from animal blood. Animals placed on a copper-deficient diet soon lose weight and die, nor is the death due to the concomitant anemia, since an equally intense anemia due to simple iron deficiency may be maintained for a long time. Thus copper is an essential element in the animal body, but the precise role still remains obscure. Some studies have demonstrated that copper is associated with the activity of certain oxidation-reduction enzymes in tissues. The mode of action of copper on hemoglobin formation is not known.

The amounts of copper required per day are extremely small; balance studies indicate the copper requirement of man to be about 2 mg. per day. The adult human body contains about 100 mg. of copper. Copper appears generally to be present in the ordinary mixed diet in adequate amounts, so that the possibility of a copper deficiency is limited. Perhaps because of this fact, there have been relatively few demonstrations of copper deficiency in man.

IODINE

The adult human body contains about 25 mg, of iodine, about 15 mg, of which is in the thyroid. The iodine requirement is about 0.05 mg. per day. It is needed for the production of thyroxine and a deficiency leads to the condition of simple goiter. Ocean water is relatively rich in iodine. as is also the dust formed in the atmosphere from the drying of the salt spray, which dust is carried inland by the winds, where the rains dissolve it and carry it into the soil which thus becomes enriched with iodine. Where the distances from the sea are greater or mountain barriers intervene, this does not occur, while at the same time iodine is being leached out of the soil, which thus becomes low in iodine. In such regions, including the Great Lakes region and the Alpine countries of Europe, the vegetable foods grown in the iodine-poor soil are poor in iodine, as is also the drinking water, and goiter is prevalent. In Japan goiter is very rare, in part because of the use in the diet of seaweed which is very high in iodine. Sea foods such as fish and ovsters are rich in iodine. Good sources are also vegetables from sea coast districts. Fair amounts are also found in the fat of milk. In goiter regions, however, such foods should not be depended upon but should be supplemented with potassium iodide. A few drops of 10 per cent iodide solution given every two weeks would cover the requirement, since some storage of ingested iodine occurs. The most satisfactory method for insuring an adequate intake of iodine without danger of overdosage is to use table salt to which has been added one part per 100,000 of iodine as sodium iodide. Such salt is widely sold. Care must be taken in the administration of iodine to persons with hyperactive thyroids. Studies with radioactive iodine indicate that this element is rapidly taken up from the blood by the thyroid gland, with significant differences in this respect between normal, hyperthyroid, and hypothyroid individuals (see also p. 995). Iodides also appear to be selectively concentrated and excreted by the salivary glands in man.

Variations in the iodine content of the blood show a relation to thyroid disease, but the results obtained are somewhat irregular. About 85 per cent of the serum iodine is bound to proteins. The normal range of serum iodine content is from 5 to 12 micrograms per 100 ml. A thyroid hyperplasia has been produced in rabbits by feeding cabbage. Various synthetic compounds are known, such as thiouracil (see p. 190) which exert a specific effect on the thyroid gland and have proved useful in the treatment of thyroid disease.

SULFUR

Strictly speaking the metabolism of sulfur does not come under the head of inorganic metabolism, since only an insignificant part of the sulfur ingested is in inorganic form, by far the greatest proportion being combined in protein molecules as the amino acids cystine and methionine. Proteins of foods vary in sulfur content from 0.4 to 1.6 per cent with an average of about 1 per cent. The sulfur-containing amino acids and their metabolism are discussed in Chapter 33.

The end product of sulfur metabolism is sulfuric acid which is either immediately neutralized and excreted as inorganic sulfate in the urine or may be first conjugated with phenol, glucuronic acid, or indoxyl. On the average, about 1.0 g. of sulfur is excreted daily in the urine.

Certain sulfur compounds have important biological interest, e.g., thiocyanate in saliva and other fluids, taurocholic acid in bile, thioneine of the blood corpuscles, and glutathione present in all cells and concerned with oxidation processes. These substances are discussed elsewhere in this book, as are also the properties and metabolism of the sulfur-containing amino acids and the various forms of urinary sulfur.

MANGANESE

There is considerable evidence that manganese in small amounts is a dietary essential. Rats placed on a manganese-deficient diet show a retardation of growth and reproductive failure in both male and female. The arginase activity of the liver of the manganese-deficient rat is lower than normal; in ritro addition of manganese ions restores the enzymatic activity. Other isolated enzyme systems are known to be activated by manganese ions in small amount. In the case of the growing chick, a manganese deficiency is associated with the development of perosis (bone malformation). Studies with radioactive manganese indicate that the chief channel of excretion is through the liver into the bile. It has been suggested that the diet of children should contain from 0.2 to 0.3 mg. of manganese per kg. of body weight.

OTHER ELEMENTS

Fluorine. Fluorine is found widely distributed in animal and plant tissues, in very small concentration. When added to the diet in small amount, it is excreted in proportion to the intake. Individuals on a normal

diet containing no added fluorine excrete about 0.3 to 0.5 mg. per day; this presumably represents the amount ordinarily present in the diet. In certain parts of the world the soil contains sufficient soluble fluoride so that the drinking water, and food grown on the soil, contain enhanced amounts of fluorine relative to other localities. Individuals living in such communities are prone to develop "mottled enamel" (dental fluorosis), an unsightly condition of the teeth. At the same time, the incidence of dental caries in these communities is in general much lower than elsewhere. For example, in one town where the fluorine content of the drinking water averaged 1.5 parts per million (p.p.m.), i.e. 1.5 mg. per liter, the incidence of dental caries was only about 50 per cent of that in another town whose drinking water contained 0.25 p.p.m. of fluorine. These and other facts have stimulated interest in the possible role of fluorine in the prevention of dental caries. According to some, there is increasing evidence that an inverse relationship exists between the fluorine content of drinking water and the incidence of dental caries; others deny that there is any proved connection between the two, and point out the experimental difficulties involved; for example, although an experimental dental caries can be produced in the rat, it is recognized to be quite different from human dental caries. The concentration of fluorine in water claimed to be effective in the prevention of caries. approximately 1 p.p.m., is said to be below the level which will cause dental fluorosis. A fluorine level of 6 p.p.m. apparently has no harmful effects on the bones. The fluoride ion in significant concentration (0.01 M) is an enzymatic poison for tissues, and fluoride salts are used commercially as ingredients of animal poisons.

Cobalt. Cobalt is present in plant and animal tissues in small amount, but there is no conclusive evidence that it is an essential element in animal nutrition. Certain diseases of cattle and sheep have been attributed to a cobalt deficiency, and respond to cobalt therapy. In the case of sheep disease the cobalt is effective orally but not when injected, suggesting that the action may be on bacteria in the gastrointestinal tract rather than on the tissues themselves. The administration of cobalt salts to rats and rabbits produces a marked polycythemia; the reason is not known. Studies with radioactive cobalt indicate that absorption and elimination take place rapidly, with the kidney the main channel of excretion.

Zinc. There is some evidence that zinc may be an essential element in normal nutrition. Rats on a diet low in zinc show a marked delay in intestinal absorption and a retarded growth rate. Zinc is a constituent of highly purified carbonic anhydrase, the enzyme important in the formation and decomposition of carbonic acid (see pp. 318 and 615). The zinc content of carbonic anhydrase is about 0.2 to 0.3 per cent, i.e., approximately equivalent to the iron content of hemoglobin. Zinc is also a constituent of crystalline (but not amorphous) insulin. Whether or not zinc plays any significant role in connection with the action of insulin or carbonic anhydrase is not known, nor has any specific function been ascribed to zinc in animal nutrition.

Various other elements found in traces in biological material are of uncertain significance. Aluminum has a wide distribution in animals and plants but is not known to be essential, nor does any aluminum added to food during cooking in aluminum utensils have any demonstrable effect on nutrition. However, it has been demonstrated that female albino rats fed biscuits made with a tartrate baking powder gave evidence of a distinct nutritional advantage over rats from the same litter which were fed biscuits made with an alum baking powder. This advantage was apparent from the standpoint of reproduction as well as from that of growth.

Boron is essential for plants but apparently has no significance in animal nutrition. The position of arsenic as a "trace element" is debatable. Silicon is found in plant and animal tissues but its function is unknown. Bromine has no normal or pathological significance aside from its known pharmacological effects. Selenium may be taken up by plants and thus become transferred to animals where it may have a toxic effect.

Acid-forming and Base-forming Foods, Certain foods, such as vegetables and fruits, on burning, outside or inside the body, leave an ash or residue in which the basic elements (sodium, potassium, calcium, and magnesium) predominate, whereas cereals, meat, and fish foods leave an ash in which the acid-forming elements (chlorine, phosphorus, and sulfur) predominate. Such foods are spoken of as base-forming and acid-forming foods, respectively, and will influence the acid-base balance of the body and the acidity of the urine. Sulfur, while present in foods chiefly in neutral form in the sulfurized amino acids, is oxidized in the body to yield sulfuric acid and is hence an acid-forming element. High protein foods are hence generally acid-forming. On the other hand, the citrus fruits contain citric acid and acid potassium citrate, the citrate radicals of which are completely oxidized in the body to carbonic acid, leaving behind potassium which is one of the bases of the body (see p. 1002). Hence many "acid" fruits are base-forming. Grape juice is much less effective than orange juice in reducing urine acidity because the tartaric acid it contains is not completely oxidized but is eliminated to a certain extent in the urine as such. Prunes and cranberries contain benzoic and quinic acids, the latter being oxidizable to form benzoic acid, which is then excreted in the urine chiefly in the form of hippuric acid (a conjugate of benzoic acid and glycine) which increases the acidity of the urine. With the exception of foods containing incompletely oxidizable organic acids, the acid-forming or base-forming value of foods may be calculated by obtaining the differences between the equivalents of normal acid, calculated from the content of sulfur, chlorine, and phosphorus (considering phosphoric acid as divalent) and of normal alkali calculated from the content of sodium, potassium, calcium, and magnesium. A table of the acid- or base-forming value of various foods will be found in Appendix IV.

Through the use of considerable amounts of potatoes or other vegetables or of fruits such as oranges, it is possible to markedly lower the

^{*} Hawk, et al. Unpublished. For abstract see "Researches and Writings," Philip B. Hawk and Collaborators. Published privately, 1942.

acidity of the urine or even to make it alkaline. Naturally reduction in the amount of acid-forming foods has a similar tendency. Increase of urinary acidity above the usual levels is less readily brought about. Reduction in the acidity of the urine by increasing the solubility of uric acid therein may reduce a tendency to formation of uric acid calculi in the urinary bladder. A certain balance between acid-forming and base-forming foods may be otherwise desirable, since too much acid-forming food might under certain circumstances be a drain upon the fixed base of the body. Fortunately, however, the body has ordinarily a marked ability to protect itself from excess acid formation, through ammonia production and in other ways. It is not clear, therefore, that a harmful effect is produced by a preponderance of acid-forming foods provided mineral, vitamin, and other dietary requirements are met.

EXPERIMENTS ON INORGANIC METABOLISM

- 1. "Salt-free" Diet. The effect of a salt-deficient diet upon the metabolic processes is reflected in the composition of the urine as shown by the following experiment
- Procedure: Ingest an ordinary mixed diet containing an ample salt content for a period of two days. Follow this period by the ingestion of a diet which has had its salt content reduced to a very low value. Sugar and olive oil or nonsalted butter may supply the bulk of the calorific part of the diet and dialyzed egg white or casein or commercial protein preparations, e.g., plasmon, gluten, or glidine may supply the protein. Ingest such a diet for three days. (This is an "acid-forming" diet, p. 1015.) Collect the urine and analyze for chloride, titratable acidity, ammonia, and total nitrogen. Compare the data from the normal days with those obtained when the "salt-free" diet was ingested.
- 2. Salt-rich Diet. On an ordinary mixed diet a normal adult will daily excrete 10-15 g. of chloride, expressed as sodium chloride, in the urine. On a salt-free diet this excretion decreases, whereas if the diet contains an excessive quantity of sodium chloride this excess will be promptly excreted in the urine. Normal feces contain very little sodium chloride even after excessive sodium chloride ingestion (see Exp. 3, below).
- Experiment: Ingest an ordinary mixed diet for two days. On each of the following two days take a similar diet plus a weighed amount (e.g., 10 g.) of sodium chloride. Collect the urine for the four days in 24-hr. samples, preserve and analyze for sodium chloride (for methods see p. 893). What proportion of the added chloride was recovered?
- 3. Inorganic Elements in the Feces. The salts of sodium and potassium are almost completely absorbed from the intestine. Hence the alkali metals and chlorides are excreted mainly in the urine and are found only in very small amounts in the feces even when large amounts are ingested. With calcium, magnesium, iron, and phosphate, conditions are different. Ordinarily about 90 per cent of ingested calcium and over half of the magnesium are eliminated by way of the feces. From 20 to 30 per cent of the phosphorus ingested is usually found in the feces.
- Experiments: (a) Ingest for a period of three days an ordinary mixed diet without added salt and containing no milk. Separate the feces for the period (see p. 959) and retain a portion of the well-mixed feces for analysis.
 - (b) Proceed as above with the exception that there is added to the mixed diet 10 g. of common salt and a quart of milk (containing about 1.1 g. of Ca, 0.1 g. of Mg, 1.4 g. of chloride expressed as sodium chloride, and 1.0 g. P). Mix the feces well and reserve part for analysis.
 - Ash 10 g. samples of the feces from the above diets. Dissolve with the aid of a little dilute nitric acid, filter, and make up to 100 ml. Determine in aliquot portions of this solution: (1) Chlorides. (2) Calcium and mag-

nesium. (3) Phosphorus. (For details of analytical methods see Chapter 32.) Calculate the percentages of the added Ca, Mg, P, and Cl which are recovered from the feces.

For a more detailed study of chloride excretion combine this experiment and Exp. 2, above.

- 4. "Alkaline Tide." For a time after a meal the normal acid reaction of the urine may be changed to neutral or alkaline. This has been explained as due to the production of a temporary alkalosis because of the secretion of the acid gastric juice. The presence of an alkaline tide has been used as an indication of the secretion of hydrochloric acid in the stomach in cases where it was desirable to avoid passing the stomach tube. The urinary ammonia excretion may also serve a similar purpose.
- Experiment: Ingest an ordinary mixed diet. Urinate just before dinner and note the reaction of the urine to litmus. If acid, determine the hydrogenion concentration by the method given on p. 812. (If alkaline, discard the urine and make the test on another day.) After eating a heavy dinner (meats) collect the urine at intervals of a half-hour and take the reaction to litmus and determine the hydrogen-ion concentration as before. Did your urine change in reaction after the meal and if so how long a period elapsed between the meal and the occurrence of the maximum change in reaction?
- 5. Hydrogen-ion Concentration of the Urine as Influenced by the Ingestion of Acid-forming and Base-forming Foods. It has been demonstrated that vegetables and fruits, on burning, leave an ash in which the basic elements (sodium, potassium, calcium, and magnesium) predominate, whereas cereals, meats, and fish foods leave an ash in which the acid-forming elements (chlorine, sulfur, and phosphorus) predominate.

The acid- or base-forming potentialities of various foods are given in the Appendix. Potatoes, oranges, raisins, apples, bananas, and cantaloups are important base-forming foods. Among the most important acid-forming foods are found rice. whole-wheat bread, oatmeal, meats, and eggs. Certain fruits, e.g., cranberries,

REACTION OF URINE AS INFLUENCED BY DIETS

		sal rts•	1	2	3	4	.5	6

^{*}Tabulated from data reported by Blatherwick (Arch. Int. Med., 14, 409 (1914)). Experiments all made on the same subject (B).

*Basal diet No. 1 contained 100 g. of Graham crackers, 25 g. of butter, 400 ml. of whole milk ingested at each of the three daily meals. One apple and one soft-boiled egg added at supper. In diet No. 2 whole-wheat crackers were substituted for the Graham crackers.

*This day was preceded by NaHCO₂ ingestion for three days and by rice ingestion for four days.

*This diet followed immediately after the diet of prunes (see 5).

prunes, and plums, yield a basic ash but are acid-forming foods. For further discussion see p. 1015.

On a mixed diet the hydrogen-ion concentration of the urine has been found to average about pH 6.0. Base-forming foods decrease the acidity and the ammonia content of the urine, while acid-forming foods have the reverse effect.

Experiment: Ingest a uniform diet consisting of milk, crackers, butter, peanut butter, and water in desired quantities for a period of three days. Follow this by a period of six days during the first three of which considerable quantities of acid-forming foods (see Appendix) are added to the diet. During the second half of the period (days four to six) add an abundance of base-forming foods to the diet. Distilled water should be used for drinking purposes and a uniform volume should be ingested daily. Collect the urine in 24-hour periods, preserve, and analyze for hydrogen-ion concentration, titratable acidity, and ammonia (for methods see Chapter 32). Compare your results with those tabulated in the table on p. 1017.

6. Hydrogen-ion Concentration of the Urine as Influenced by Alkali Ingestion. The ingestion of certain organic salts of the alkalis, e.g., sodium citrate and sodium bicarbonate, causes an increase in the pH of the urine. The ingestion of acids (either organic or inorganic) or acid salts, e.g., sodium dihydrogen phosphate, decreases the pH of the urine. The alkalis are much more effective in

Influence of Ingested Sodium Bicarbonate on Hydrogen-ion Concentration of Urine

Experiment	Sodium	pH before	Time of	Collection	of Specim	en of Urin	ne and pH
Number	Bicarbonate, Grams	Bicarbonate Ingestion	11.00 A.M.	12.00 Noon	1.00 P.M.	2.00 P.M.	3.00 P.M.
1 2 3 4 5	4 8 12 8 8	7.40 5.40 5.30 7.40 5.85 6.70	8.30 8.50 8.70 8.50	7 48 8 30 8 70 8 70	7 48 6.50 8 70 8.50 8 70 8.50	7.40 6.50 8.70 8.50 8.70	5 85 7 40 8 70 8 50 8 30 8 50

producing changes in reaction than are the acids. The influence of ingested alkali (sodium bicarbonate) is shown in the foregoing table containing data submitted by Henderson and Palmer.

Blatherwick reports a decrease in ammonia nitrogen output from 0.256 g. to 0.072 g., and accompanying decreased acidity under the influence of bicarbonate ingestion (25 g. in two days).

Experiments: Influence of Alkali: Ingest a uniform diet consisting of milk, crackers, butter, peanut butter, and distilled water for a period of two days. During the next two days take the same diet and ingest 24 g. of sodium bicarbonate between meals (12 in A.M. and 12 in P.M.). Collect the urine in 24-hr. periods and analyze it for titratable acidity, hydrogen-ion concentration, and ammonia. Compare your results with those shown in table above.

If desired, the bicarbonate may be given in one dose of 8 to 12 g. and the urine collected in hourly specimens for the next five hours and each specimen analyzed. Data from such experiments are shown in table above.

7. Influence of Calcium Deficiency. A demonstration of the harmful effect following the elimination of calcium from the diet may readily be made if the diets listed below be fed to young white rats.

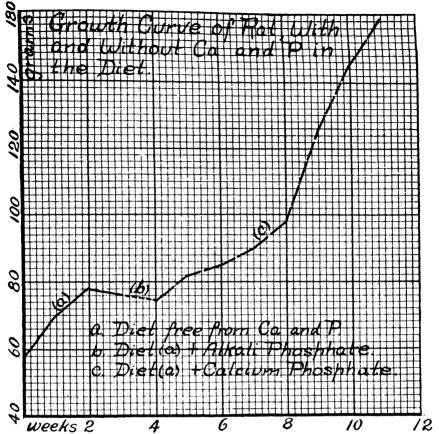

Fig. 289. Growth curve of rat with and without calcium and phosphorus in the diet. (Unpublished data from the senior author's laboratory.)

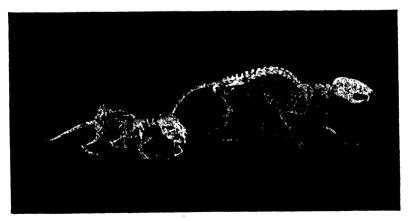

Fig. 290. Skeletons of twin albino rats showing influence of calcium deficiency. (Courtesy, Sherman and MacLeod: J. Biol. Chem., 64, 429 (1925).)

Procedure: Place two young white rats (40-60 g.) in separate cages and feed the diets given in the following table. Make frequent body-weight determinations. The rat receiving Diet 2 will show normal growth. The rat receiving Diet 1 will fail to show normal gains in weight. This diet is deficient in calcium. See Figs. 289 and 290.

	Diet 1 (Per Cent)	Dict 2 (Per Cent)
Beef liver (steamed and dried)	20.0	20.0
Casein	10.0	10.0
NaCl	1.0	1.0
KCl	1.0	1.0
CaCO ₃	0.0	1.5
Dextrin or starch	65.0	63 5
Butter fat	3.0	3.0

8. Influence of Ultraviolet Light on Inorganic Metabolism. Ultraviolet radiation has calcium-depositing properties. See discussion under Vitamin D, Chapter 35.

Procedure: Place three young white rats (litter mates) weighing 50-60 g., in individual cages, and supply ad lib. a rachitogenic diet such as described in Chapter 35. Keep the rats in a dark or dimly lit room, but subject one to an hour's exposure to direct sunlight at about noon each day, and expose another to one minute's irradiation at a distance of two feet from an ultraviolet lamp. After four weeks examine the leg bones roentgenographically or by the line test (see Chapter 35), and perform bone ash analyses on the dried, fat-free bones.

9 Influence of Iron and Copper Deficiency. The anemia caused by the ingestion of milk as the sole article of diet may be cured by the addition of an iron (and

copper) supplement.

Procedure: Place three young white rats (litter mates) on a milk diet and perform hemoglobin determinations weekly on blood obtained by clipping off the tips of the tails. After the hemoglobin has dropped to half its original value, feed one rat a daily supplement of 0.25 mg. of Fe (as ferric chloride) and another rat 0.25 mg. of Fe (as ferric chloride) and 0.05 mg. of Cu (as copper sulfate). Continue the third animal on the original milk diet without Fe or Cu supplement. Continue weekly determinations and compare the condition of the three animals, noting especially the color of the tails, ears, and eyes.

Vitamins and Deficiency Diseases¹

In 1881 Lunin, a pupil of Bunge, recognized that a diet consisting only of purified protein, carbohydrate, fat, and minerals would not sustain life. When such diets were supplemented with certain natural foods, notably milk, normal growth and well-being of the experimental animals were restored. These findings were in accord with earlier demonstrations of the curative value of citrus fruit juices in scurvy, a disease contracted by sailors, soldiers, prisoners, and others who subsisted on limited fare. They also coincided with observations by the Dutch physician Eijkmann in 1897 that beriberi or polyneuritis, a disease resulting from the prolonged consumption of polished rice, could be cured by supplementing the diet with rice polishings or extracts thereof. These and similar studies suggesting the presence of indispensable substances in natural foods were brought to a head by Hopkins (1912) who called them "accessory food factors." The work of Osborne and Mendel and of McCollum (1913) established beyond doubt the presence of these factors in milk. Funk (1912) introduced the term "vitamine" in the belief that he had isolated one of these factors and established that it possessed the properties of an amine. The final "e" has since been dropped inasmuch as these substances as a class are not related to amines.

A vitamin is a potent organic compound, occurring in minute proportions in natural foods, which must be available to the animal organism in the diet or from other sources in order that a specific metabolic function or reaction may proceed normally. The "other sources" referred to in this definition may, for example, be ultraviolet irradiation of precursors in the skin or bacterial synthesis in the intestinal tract. Unlike amino acids, vitamins do not enter into the tissue structure. Vitamins are exogenous, hormones endogenous. Compounds which may be vitamins for some species may be synthesized by others and hence behave, in effect, as hormones. Certain of the vitamins need not be consumed as such in the diet, because the body has the capacity of synthesizing them from precursors or provitamins, such as the carotenoids ("provitamins A") and ergosterol or 7-dehydrocholesterol ("provitamins D"). In the latter instance, the nondietary source of activation consists in artificial or solar ultraviolet radiation of specific frequencies.

With the rapid advancement of our knowledge of the chemical constitution of the vitamins, it is not surprising that structurally related chemical derivatives, both natural and synthetic, should be discovered which exhibit typical physiological activity, though perhaps in varying degree.

¹ The rapid strides being made in this field require that special attention be paid to the date of publication of material on this subject. Important books and review articles on the general subject of vitamins are cited in the Bibliography at the end of this chapter.

To these, the term vitamers has been applied. Naturally occurring vitamin D is believed to exist in various chemical forms; and what was previously regarded as vitamin A in plant sources is now known to consist of various carotenoids, principally β -carotene, which function as precursors of the vitamin. Hence a distinction should be made between vitamin activity, which indicates certain specific biological properties, and the term vitamin itself, which refers to a definite chemical entity, of which there may be several exhibiting similar biological activity.

Some vitamins are characterized by species specificity; i.e., they are required by certain species of animals and not by others. For example, vitamin C is necessary in the diet of man, guinea pigs, and monkeys, but dogs, rats, and other species are able to synthesize this vitamin which for these species may thus be regarded as a hormone. To a certain extent the physiological requirement for vitamins of various species of animals may be met by bacterial synthesis of the vitamins in the rumen or intestinal tract. This process, however, does not signify that these species are independent of an external supply of the nutrients in question.

The vitamins are recognized biologically by their absence rather than by their presence; that is, the characteristic symptoms of each vitamin deficiency must first be produced before the effect of the vitamin in question can be demonstrated. In addition to (and probably secondary to) their role in the prevention of specific deficiency diseases, each of the vitamins participates to a greater or less degree in the promotion of growth. Our knowledge of the physiological modus operandi of the known vitamins is not far advanced. It is known, however, that most of the vitamins participate in enzymic reactions of a highly complex nature. Vitamins may be precursors of enzymes, such as thiamine is of cocarboxylase or niacin of coenzymes I and II; or they may be substrates such as vitamin A is of rhodopsin.

The condition induced by the absence of a single vitamin from the diet is called an avitaminosis, e.g., "avitaminosis B_1 "; if the deficiency is multiple, the term polyavitaminosis is applied. Many observations, particularly on the effect of deficiency or dosage of one vitamin on the storage or excretion of another, suggest the need for balanced proportions of certain dietary essentials. Until more complete data are available on the specific mechanism of the action of individual vitamins, however, it will be difficult to establish the existence of such interrelationships.

The number of substances now recognized as vitamins has grown considerably since the "vitamin theory" of deficiency diseases was promulgated. Each one of the original vitamins has been discovered to be multiple in character, "water-soluble vitamin B" having expanded to a family of at least 10 distinct components, some of which have active derivatives or structural analogs. The present list of vitamins cannot be regarded as complete, but it is probable that from the standpoint of human nutrition all the major vitamins have been identified. The table on p. 1024 summarizes the common names of the vitamins, and their principle vitamers—i.e., structurally related compounds possessing qualitatively similar activity. Some question has been raised as to the propriety

1024 PRACTICAL PHYSIOLOGICAL CHEMISTRY

SUMMARY OF PRINCIPAL COMPOUNDS WHICH POSSESS VITAMIN ACTIVITY

V	itamin	Principal	Vitamers

of including choline or inositol among vitamins since such compounds are present in the foods in more than trace quantities. Nevertheless, they do not form a material part of body tissue and functionally they conform to the definition of vitamins stated above.

Early in the development of our knowledge of vitamins, only biological methods were available for measuring the quantities present in foods. These procedures were based upon determining the minimal dosage required to cure or prevent symptoms of deficiency in experimental animals receiving diets complete in all respects except for the vitamin under assay. A major improvement in bioassay technic was the introduction of standard preparations which permitted comparison of the biological response of the "unknown" in terms of the known, thus reducing the so-called "inter-laboratory variation."

Concurrent with the advances in isolation and identification of the vitamins, chemical and physical analytical procedures have been evolved for determining the content of almost every vitamin. More recently, microbiological procedures have been developed (particularly for the vitamins of the B group) based on the propagation of various bacteria, yeasts, or molds in special media in which one of these vitamins is the limiting factor.

The conditions employed in the nonbiological assay procedures, especially in the preliminary extraction or hydrolysis of the samples, are of course not necessarily equivalent to the conditions to which such foods may be subjected in the gastrointestinal tract. Therefore a distinction must be kept in mind between vitamin content as determined by analysis and vitamin potency as measured by feeding tests. The latter is an index of nutritional activity or physiological availability, whereas the former indicates the total quantity of the vitamin present (or determinable). Correlation of animal assays of foods with nonbiological assays suggests that the full content of vitamins is usually, but not always, biologically active under the experimental conditions employed; but the assessment of vitamins in foods in terms of their physiological availability for man is a field of investigation of which only the surface has been scratched.

It is thus important when using present-day tables of the distribution of vitamins in foods, such as that presented in Appendix III, to bear in mind that most of these data are based on assays for total vitamin content rather than for available vitamin content in the physiological sense. In tables, spinach, e.g., whose "vitamin A" is due to the activity of carotenes, or butterfat, whose "vitamin A" is due to a mixture of carotenes and preformed vitamin A, are usually presumed to have been evaluated biologically; and whenever possible the interpretation of nonbiological assays is made in the light of existing animal assay data.

In using tables of food composition it must be recognized that consistency is the exception rather than the rule. Such factors as soil, climate, season, varietal differences, and period of harvesting which affect plant foods; or composition of the feed, age at slaughter, and duration of lactation which affect animal foods; as well as storage, transportation, processing, "refining," and culinary losses, account for a several-fold range of

RECOMMENDED DIETARY ALLOWANCES (Continued from p. 1027.)

FURTHER RECOMMENDATIONS:

Pat. There is available little information concerning the human requirement for fat. Fat allowances must be based at present more on food habite than on physiological requirements. While a requirement for certain unsaturated fatty acids (the linoleic and arachidonic acids of natural ats) has been amply demonstrated with experimental animals, the human need for these futty acids is not known. In spite of the paucity of information on this subject there are several factors which make it desirable that fat be included in the diet to the extent of at least 20 to 25 per cent of the total calories and that the fat intake include "essential" unsaturated fatty acids to the extent of at least 1 per cent of the total calories. At higher levels of caloric expenditure, e.g., for a very active person consuming 4500 calories and for children and adolescent persons, it is desirable that 30 to 35 per cent of the total calories be derived from fat. Since foodstuffs such as meat, milk, cheese, and nuts may be expected to contribute "invisible" at to the extent of from one-half to two-thirds of the total amounts of fat implied by the above proportions of the total calories, it is satisfactory to use separated or "visible" fats such as butter, margarine, lard, and shortenings only to the extent of one-third to one-half of the amounts indicated.

Copper. The requirement for copper for adults is about 1 to 2 mg. daily. Infants and children require approximately 0.05 mg. for each kilogram Iodine. The requirement for iodine is small, probably about 0.002 to 0.004 mg, daily for each kilogram of body weight, or a total of 0.15 to of body weight. The requirement for copper is approximately one-tenth that for iron. A good diet normally will supply sufficient copper.

Phosphorus. Available evidence indicates that the phosphorus allowances should be at least equal to those for calcium in the diets of children and of women during the latter part of pregnancy and during lactation. In the case of other adults the phosphorus allowances should be approximately 1.5 times those for calcium. In general it is safe to assume that if the calcium and protein needs are met through common foods, the phosphorus 0.30 mg. daily for the adult. This need is met by the regular use of iodized salt; its use is especially important in adolescence and pregnancy. requirement also will be covered, because the common foods richest in calcium and protein are also the best sources of phosphorus.

Vitamin K. The requirement for vitamin K usually is satisfied by any good diet. Special consideration must be given to newborn infants. Physicians commonly give vitamin K either to the mother before delivery or to the infant immediately after birth.

heavy work or in hot climates 20 to 30 g. daily may be consumed with meals and in drinking water. Even then, most persons do not need more sait than usually occurs in prepared foods. It has been shown that after acclimatization persons produce sweat that contains only about 0.5 g. to persons who sweat profusely. The average normal intake of salt is 10 to 15 g. daily, an amount which meets the salt requirements for a water intake up to 4 liters daily. When sweating is excessive, one additional gram of salt should be consumed for each liter of water in excess of 4 liters daily. With Salt. The needs for salt and for water are closely interrelated. A liberal allowance of sodium chloride for the adult is 5 g. daily, except for some

the liter in contrast with a content of 2 to 3 g. for sweat of the unacclimatized person. Consequently after acclimatization, need for increase of salt beyond that of ordinary food disappears.

Water. A suitable allowance of water for adults is 2.5 litters daily in most instances. An ordinary standard for diverse persons is 1 ml. for each calorie of food. Most of this quantity is contained in prepared foods. At work or in hot weather, requirements may reach 5 to 13 liters daily. Water

* Tentative goal toward which to aim in planning practical dietaries; can be met by a good diet with a variety of natural foods. Such a diet will should be allowed ad libitum, since sensations of thirst usually serve as adequate guides to intake except for infants and sick persons. also provide other minerals and vitamins, the requirements for which are less well known.

The allowance depends on the relative amounts of vitamin A and carotene. The allowances of the table are based on the premise that approximately two-thirds of the vitamin A value of the average diet in this country is contributed by carotene and that carotene has half or less than half ■ We gratefully acknowledge the courtesy of the National Research Council in granting permission to reproduce this table. the value of vitamin A.

◆ For adults (except pregnant and lactating women) on diets supplying 2,000 calories or less, such as reducing diets, the allowances of thiamine, riboffavin, and niacin may be 1 mg., 1.5 mg., and 10 mg., respectively. The fact that figures are given for different calorie levels for thiamine, riboflavin, and niacin does not imply that we can estimate the requirement of these factors within 500 calories, but they are added merely for simplicity of calculation. Other members of the B complex also are required, though no values can be given. Foods supplying adequate thiamine, riboflavin, and niarin will tend to supply sufficient of the remaining B vitamins.

• For persons who have no opportunity for exposure to clear sunshine and for elderly persons, the ingestion of small amounts of vitamin D may *There is evidence that the male adult needs little or no iron. The requirement will be provided if the diet is satisfactory in other respects.

7 During the latter part of pregnancy the allowance should increase approximately 20 per cent over the preceding level. The value of 2500 be desirable. Other adults probably have little need for vitamin D.

calories represents the allowance for pregnant, sedentary women.

* Allowances for children are based on the needs for the middle year in each group (as 2, 5, 8, etc.) and are for moderate activity and for average weight at the middle year of the age group.

* Needs of infants increase from month to month with size and activity. The amounts given are for approximately 6 to 8 months. The distary requirements for some of the nutrients such as protein and calcium are less if derived largely from human milk. variation in the vitamin content of natural foods. Hence the values given in tables must be regarded as indicative of expected orders of magnitude rather than absolute vitamin contents. The tables reproduced in Appendix III embrace data collected from many sources.

MINIMUM DAILY REQUIREMENTS OF VITAMINS AND MINERALS ACCORDING TO REGULATIONS UNDER SECTION 403 (j) FEDERAL FOOD, DRUG AND COSMETIC ACT,

older		0.75						10	

Under the provisions of the Food, Drug and Cosmetic Act, the Federal Security Agency has established standards of minimum daily requirement for certain of the major vitamins (and minerals) to serve as a basis for proper labeling of foods intended for special dietary uses. These values are presented in the table above as a guide to the interpretation of such labeling but are not to be confused with the table of recommended daily allowances prepared by the Food and Nutrition Board of the National Research Council reproduced in its latest (1945) revision on p. 1027. The latter is intended to furnish a "tentative goal toward which to aim in planning practical dietaries" and provides for variations in requirements due to sex, age, activity, and the physiological demands of pregnancy and lactation. Individual needs may deviate significantly from these allowances owing to differences in body weight, glandular activity, gastrointestinal disturbances, and many other "conditioning factors" (Jolliffe).

The term "major vitamins" is sometimes applied to thiamine, riboflavin, niacin, ascorbic acid, and vitamins A and D, for which fairly reliable knowledge exists as to human requirements; it is generally believed that if diets are devised to supply adequate amounts of these vitamins, sufficient quantities of all other vitamins (somewhat presumptuously called "minor") will be present. This view is questionable and merely reflects current ignorance as to the essentiality and quantitative requirements for such vitamins which, it is hoped, future research will correct.

¹⁰ For pregnant or lactating women, the minimum daily requirements of both calcium and phosphorus are increased to 1.5 g., and iron to 15 mg.

Whether a given food, as prepared for consumption, is a poor, fair, good, or excellent source of the vitamins or of other dietary essentials, must be judged by the size of the usual portion and the frequency with which it is consumed. The Council on Foods of the American Medical Association^{10a} tentatively adopted the following standards for determining the significance of a source of a dietary essential:

- 1. In general, when one-tenth of the day's requirement for an average man is furnished in a portion which can be easily eaten in one day, the food may be regarded as a "fair" source.
- 2. When one-tenth of the day's requirement is contributed by an amount of the food which at the same time furnishes not more than 200 calories, the food may be classed as a "good" source.
- 3. When one-tenth of the day's requirement is furnished by a food which appears in the diet practically every day, and in which the portion contributing one-tenth of the essential furnishes not more than 100 calories, the food may be classed as "excellent."
- 4. When a food is not one which can be easily eaten in amounts to furnish one-tenth of the day's requirement, or is one eaten infrequently, or both, and the amount required for one-tenth of the day's allowance of the essential furnishes more than 200 calories, the food is a negligible or poor source.

VITAMIN A

Physiological and Clinical Aspects of Vitamin A. Vitamin A was first recognized by the failure of rats to grow on diets lacking in natural

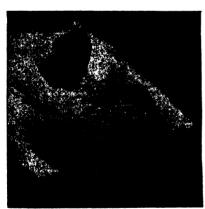

Fig. 291. Showing ophthalmia in two stages of severity. (*Left*) Incrustation caused complete closing of eye. (*Right*) Depilated and hemorrhagic area surrounding eye.

fats and oils. At about the time of cessation of growth the eyes become hemorrhagic, keratinized, and later infected. This condition, known as xerophthalmia, is associated specifically with deficiency of vitamin A, hence the name antiophthalmic (or antixerophthalmic) vitamin (Fig. 291). Interruption of growth (Fig. 292) and lowered resistance to bacterial infection are secondary results of a specific disturbance in the metabolism of epithelial membranes resulting from vitamin A deficiency. This is

deduced from the fact that keratinization is observed in the sublingual and submaxillary glands, and in the respiratory, alimentary, and genitourinary tracts, as well as in the cornea and conjunctiva. Similar involvement of the oral and pharyngeal mucosa is responsible, at least in part, for the diminution of food consumption and consequent loss in weight.

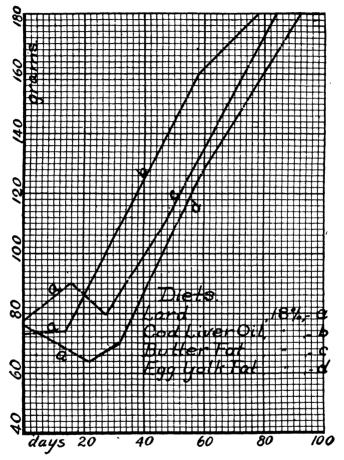

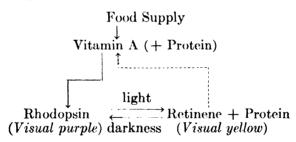

Fig. 292. Vitamin A and growth. The diet containing lard was deficient in vitamin A, while cod liver oil, butter fat, and egg yolk fat are rich in this substance. (Courtesy, Osborne and Mendel: J. Biol. Chem., 16, 434 (1913); 17, 405 (1914).)

The formation of urinary and renal calculi observed after vitamin A depletion is probably also a sequel to the metaplastic changes in the epithelial membranes. Sinus and ear infections, colds, and other affections of the respiratory tract have been attributed to similar causes. A form of dryness of the skin (xerosis) and a follicular hyperkeratosis (phrynoderma) are among the symptoms of avitaminosis A found in man as well as in animals. Suggestions have been made to name vitamin A the "anti-

infective vitamin"¹¹ or the "antikeratinic vitamin"¹² but these have not been generally adopted, the former, at least, because of its exaggerated implications. Inanition accompanying severe vitamin A depletion may contribute in no small degree to the lowered resistance to bacterial invasion. The primary specific effect of lack of vitamin A, however, is the "substitution of stratified keratinizing epithelium for normal epithelium in various parts of the respiratory tract, alimentary tract, eyes and paraocular glands, and the genito-urinary tract" (Wolbach).

There is evidence that lack of vitamin A may produce nervous conditions due to degenerative changes in the myelin sheath. The value of liver and a vitamin-rich diet in the treatment of pernicious anemia may be due partly to the influence of vitamin A on the nervous system, as well as to the blood-regenerating properties of such a diet. Since the lack of vitamin A interferes with the process of ovulation, an adequate proportion of this vitamin is necessary in the diet for normal fertility. It has been demonstrated that a liberal allowance of this vitamin is conducive to longevity.

In addition to its role in the maintenance of normal epithelium of the eye and paraocular glands, vitamin A plays a functional role in vision. Visual purple or rhodopsin, a conjugated carotenoid protein contained in the retinal rods, is reversibly bleached upon stimulation by light, with the formation of vitamin A. In the process of regenerating visual purple, some of the vitamin A is lost, necessitating continuous replenishment of the supply. This process may be illustrated schematically as follows:

A similar and even more rapid cycle occurs in the retinal cones. In vitamin A deficiency rhodopsin formation is diminished, resulting in a lowering of visual acuity, i.e., the ability to see in subdued light. This condition is known as nyctalopia¹³ or night-blindness and is the earliest sign of vitamin A deficiency in man, though it may result from other causes. Dark adaptation is the term applied to the adjustment of the visual threshold to darkness after exposure of the eyes to light. Accurate quantitative measurement of the visual threshold—i.e., the light intensity required to elicit a visual sensation, can be made by photometric instruments which measure the rate of restoration of visual acuity following stimulation by a light source of standard intensity.^{13a} Evidence of lack of vitamin A has

¹¹ Green and Mellanby: Brit. Med. J., 2, 691 (1928).

¹² Vedder: Porto Rico J. Pub. Health and Trop. Med., 5, 283 (1930).

¹³ The term "hemeralopia" (literally day-blindness) has been applied improperly to this condition.

¹²⁸ Clinical instruments are the Bio-Photometer (manufactured by the Frober-Faybor

been demonstrated in our own country by the prevalence of impaired dark adaptation among both adults and children.

Severe outbreaks of vitamin A deficiency in humans are not common and such instances as have been reported were of limited geographic distribution. The incidence of ophthalmia is relatively high for example in China, Labrador, and India. An acute epidemic among Danish children during World War I was attributed to the substitution of margarine for butter which was largely exported. The fortification of margarine with vitamin A is now a common practice in most countries where it is sold.

Twenty to 25 units of vitamin A per kg. of body weight suffice to maintain a normal visual threshold in most species studied. This amount will also maintain the normal estrus cycle in the rat although storage in the liver does not occur until approximately four times this level is reached. Liberal allowances of vitamin A, among other factors, tend toward optimum, as distinguished from adequate, nutrition (see p. 985). In experiments on the rat, Sherman and his associates have shown that by feeding several times the dose of vitamin A sufficient to prevent deficiency symptoms, the reproductive period of females as well as the longevity of both sexes could be prolonged.

The recommended daily allowances of vitamin A for various sex and age groups are incorporated in the table on p. 1027. These values are based on a consensus obtained under the sponsorship of the National Research Council. An outline of the clinical symptoms of vitamin A deficiency is given in the American Medical Association syllabus on p. 1186.

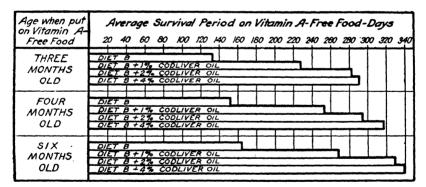

Fig. 293. Effects of moderate and of increasingly intensive feeding of vitamin A upon the storage of this vitamin in the body at different ages. (Courtesy, Sherman and Cammack: J. Biol. Chem., 68, 69 (1926).)

Storage of Vitamin A. When young animals, previously fed a diet containing vitamin A, are deprived of this vitamin, they continue to grow for a period dependent upon the amount of vitamin A which they have stored. The storage capacity for this vitamin is relatively greater in young animals, i.e., at the age of most rapid growth. This relation is illustrated in Figs. 293 and 294, which show the duration of life of rats on a vitamin

A-free diet following the feeding of a diet¹⁴ supplemented with codliver oil. The vitamin is stored principally in ester form in the liver although substantial amounts are retained by the lungs and kidneys. Since vitamin A is required by the adult for reproduction and lactation and aids in the maintenance of resistance to bacterial invasion, the capacity of the body to store this vitamin is a wise provision of nature.

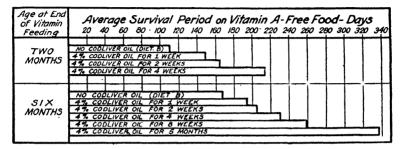

Fig. 294. Effects of intensive feeding of vitamin A for different lengths of time upon the bodily store of this vitamin at different ages. (Courtesy, Sherman and Cammack: J. Biol. Chem., 68, 69 (1926).)

Distribution of Vitamin A. 15 Preformed vitamin A occurs only in lipids of animal origin, whereas carotenoid precursors occur in the vegetable kingdom where they are synthesized. Some animal fats, like butterfat, may contain both carotenes and vitamin A in variable proportions, depending on the animals' ration and the extent of conversion of the former into the latter. The chief natural foods of vitamin A value are butterfat (hence milk, cream, cheese, etc.), egg yolk, liver, and pigmented and leafy vegetables (e.g., carrots, tomatoes, pimientos, spinach, lettuce, alfalfa). Vegetable oils as a class are deficient in vitamin A although red palm oil may contain as much as 0.2 per cent of carotenes. The liver oils of certain species of fish including the shark (notably the soupfin species), swordfish, halibut, mackerel, etc., are extremely high in vitamin A, some oils being several hundred times as rich as codliver oil, which is one of the earliest known and most abundant sources of both vitamins A and D. There are great variations within species due to accumulation of the vitamin with age, variations in sex and reproductive cycle, marine nutrition and temperature, etc. Natural fish liver oils are refined or concentrated and blended to standard potencies for therapeutic use or food

Certain unicellular marine organisms are able to synthesize vitamin A. These provide food for marine plankton, which are consumed by caplin and other small fish, which in turn are consumed by the cod. The vitamin is also present to a smaller extent in the visceral and body oils of the cod, salmon, and of certain other fish.

¹⁴ The "Diet B" referred to in these illustrations consisted of one-third dried whole milk, two-thirds whole wheat, and table salt to the extent of 2 per cent of the wheat.

14 For vitamin A values of foods, see Appendix III.

^{*} Butler: Commercial Fisheries Rev., April 1946, p. 13.

In products of the plant world vitamin A activity, being due to carotenoids, is closely associated with pigmentation; the green outer leaves of lettuce are richer than the white center leaves, green tips of asparagus are richer than "bleached" tips, sweet potatoes are richer than white potatoes, yellow corn than white, palm oil (red) than coconut oil. The milk of cows on green pasturage is higher in vitamin A than is the milk of stall-fed animals. There is no direct quantitative relationship between the color of butter or of cod liver oil and their vitamin A potency, however, since in animal fats such activity is due principally to the colorless preformed vitamin. (It should also be mentioned that commercial butter is often artificially colored.) The yellow pigment carotene, when prepared under conditions which preclude its oxidation, possesses the physiological activity of vitamin A into which it is converted in the animal body. Hence

carotene, or rather carotenes, since this compound exists in several isomeric forms, are the precursors or provitamins of vitamin A. In addition to the carotenes, other naturally occurring carotenoids which possess vitamin A activity in animals are cryptoxanthin of yellow corn and paprika, myxoxanthin and aphanin of algae.

The synthesis of provitamins A in plants has been shown to be accelerated by light radiations especially of short wavelength, although the ultimate amount of vitamin formed is not increased. Apart from the above method there is no evidence that the animal body can produce vitamin A de novo, except in the case of the pigeon. ¹⁶ Although synthesis of carotenes seems to parallel chlorophyll formation, the latter pigment does not possess vitamin activity.

The rate of intestinal absorption of vitamin A and its precursors varies in different species of animals and is influenced by the nature and content of fat in the diet. Excessive quantities of mineral oil inhibit absorption. The efficiency of converting carotenoids into vitamin A likewise varies with the particular compound as well as with the species; in general, rodents are most efficient, pigs and cattle less, and cats least, while the relative capacity of the human infant or adult in this respect remains to be determined.

Chemistry of Vitamin A. β -Carotene has been shown by Kuhn and Karrer to have the following structural formula:

When this molecule is oxidized at the central double bond, two molecules of vitamin A are formed:

Vitamin A

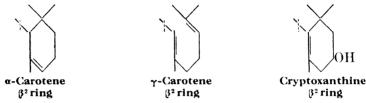

Hunter and Williams¹⁷ claim to have effected this conversion by oxidation with hydrogen peroxide to give vitamin A aldehyde, and subsequent reduction to the alcohol. β-Carotene may be rewritten (after Ruzicka)

¹⁶ Kon and Drummond: Biochem. J., 21, 632 (1927).

¹⁷ Hunter and Williams: J. Chem. Soc., 554 (1945); Hunter: Nature, 158, 257 (1946).

$$\beta^1$$
 β^2

It will be noted that the molecule is symmetrical and contains two β -ionone rings, designated β^1 and β^2 respectively. The α and γ isomers differ in respect to the configuration of only one of these rings, the molecular formula of all of these isomers being $C_{40}H_{56}$. In place of the β^2 ring indicated above for β -carotene, other carotenoids contain the following groups:

These compounds possess half, or less than half, the vitamin A activity of β -carotene.

At least one intact β -ionone ring is essential for such activity, since isomers or derivatives in which the only change is in both rings, are inactive. Examples are:

The vitamin Λ activity of certain important natural carotenoids relative to β -carotene is approximately as follows:

β -Carotene	100
α-Carotene	50
γ-Carotene	30
Cryptoxanthine	55
Neo-β-carotene	38
Lycopene	0
Xanthophyll	0

 β -Carotene is approximately twice as potent biologically as its naturally occurring isomers; it was believed that fission of the carotenoid molecules occurs at the central double bond yielding two molecules of vitamin A; there is substantial evidence, however, that asymmetrical breakdown to the active β -ionone fragment of the molecule can also occur.

Since factors of absorption and efficiency of conversion affect the biological activity of carotenoids, the estimation of vitamin A potency of plant foods from the relative content and activity of the individual pigments is not always reliable.

It has been found that the "crude carotene" of many plant foods (i.e., the pigment in the petroleum ether extract which absorbs light at 420 m μ) has a vitamin A activity of about 1 USP unit per microgram.

The carotenoids can exist in a large number of stereoisomeric forms due to cis-trans configuration about the conjugated bonds. Not all of the theoretically possible isomers exist, however, because of steric interference; for example, β -carotene has 20 stable isomers. These are differentiated by the heights and wavelengths of the maxima in the visible and ultraviolet absorption spectra and by chromatographic separation. About half of the isomers of β -carotene have been found in nature. The available evidence indicates differences to exist in their provitamin A activity. Vitamin A has two stereochemically available double bonds and thus has four possible isomers. Their existence in nature is demonstrated by the discovery of a new form of the vitamin in fish liver oils differing from vitamin A₁ in the cis-trans configuration at the double bond nearest the hydroxyl group. To this isomer has been given the name neo-vitamin A. ²⁰ (See Fig 296.)

 β -Carotene has been adopted as the International Standard of vitamin A activity, the unit being the activity of 0.6 γ of the pure, crystalline compound. The crystals are deep red (melting point 183° C.), but in solution are intensely yellow. β -Carotene is very susceptible to oxidation, losing color in the process.

While the synthesis of vitamin A has been reported²¹ it has not been achieved on a commercially practicable scale. The vitamin has been isolated from high-potency fish liver oils, and various esters as well as the free alcohol have been crystallized (see Fig. 295).

Vitamin A alcohol forms pale, yellow crystals melting at $63-64^{\circ}$ when deposited from ethyl formate solution or at 7-8° when methyl alcohol is the solvent. It forms esters, but is not precipitated by digitonin, thus providing a means of separation from cholesterol which like vise occurs in the nonsaponifiable fraction of animal fats. The vitamin is distillable in vacuo, thus forming the basis for the commercially important process of concentration from fish liver oils; viz., Hickman's method of molecular distillation. Vitamin A forms colored compounds with certain condensing agents, one of which, antimony trichloride, produces an evanescent blue color of sufficient intensity to afford a measure of its concentration. This color absorbs light maximally at 620 m μ , in contrast with the more stable

¹⁹ Douel, Sumner, Johnston, Polgár, and Zechmeister: Arch. Biochem., 6, 157 (1945).

²⁰ Robeson and Baxter: Nature, 155, 300 (1945).

²¹ Kuhn and Morris: Ber., 70B, 853 (1937). The synthesis of "vitamin A acid" and the corresponding ketone from β -ionone has been reported (Arens and van Dorp: Nature, 157, 190 (1946). The former has a biological potency one-tenth that of vitamin A, when given orally, but its sodium salt in aqueous solution is half as potent as the vitamin.

Fig. 295. Crystalline vitamin A alcohol (high melting). (Courtesy, Distillation Products, Inc., Rochester, N. Y.)

Fig. 296. Crystalline neo-vitamin A. (Courtesy, Distillation Products, Inc., Rochester, N. Y.)

greenish-blue color produced with carotene which shows an absorption maximum at 590 m μ . For the analysis of foods or animal tissue containing both factors, the SbCl₃ reaction necessitates either correction for the differences in rate of color development and fading or, preferably, preliminary separation of the carotenes from preformed vitamin A.

Vitamin A shows an absorption band in the ultraviolet with a maximum at 328 m μ . This fact forms the basis of the spectrophotometric method of estimating the (preformed) vitamin A content of fish liver oils.

In the absence of air, vitamin A is quite stable at high temperatures, but when oxygen is present it is readily destroyed. Aeration of codliver oil for 12 hours at 100° oxidizes the vitamin A, but leaves the antirachitic potency unimpaired. Vitamin A appears to be less resistant to oxidation when removed from its natural environment, probably because of the presence of protective antioxidants such as tocopherols, phospholipids, and possibly other agents. Certain phenolic substances, like hydroquinone, are very effective in delaying rancidity and the coincident loss of vitamin A in oils. Light exerts a destructive influence upon vitamin A; hence the practice of dispensing fish liver oils in dark glass bottles and of conducting analytical operations in amber or red glass apparatus. Ultraviolet radiation destroys vitamin A.

DETERMINATION OF VITAMIN A

In estimating vitamin Λ in natural products the distinction between vitamin content and vitamin activity must be carefully drawn. Vitamin A activity is derived principally from the physiologically available amounts of preformed vitamin A, which may be present as free alcohol or as esters, and of the carotenoids, which vary in their individual potencies. Furthermore, activity is influenced by the physical state of the particular source of the vitamin and by the nature and content of fat in the diet. When the chemist speaks of the content of vitamin A he refers only to the chemical entity and not to its biological precursors; he seeks to achieve specificity in analytical procedures, whereas the nutritionist is concerned with the net biological activity. Hence the bioassay continues to play an important function, especially in the evaluation of foods whose vitamin activity is of multiple origin, despite the improvement in physical and chemical methods of assay. In products whose vitamin A activity is derived from less complex sources, such as the crystalline alcohol or its esters, high potency fish liver oils or β -carotene preparations, it is only necessary to establish correlation between values for vitamin content obtained by physical or chemical methods and the bioassay values to justify the use of the nonbiological procedures. Because of the small size of sample available, the analysis of blood and tissues for vitamin A is limited to the nonbiological methods.

CHEMICAL METHODS

Colorimetric Methods for Preformed Vitamin A and Provitamin A. The carotenes are determined colorimetrically preferably after isolation by saponification and extraction or by adsorption and elution pro-

cedures. Prediction of biological potency from the content of carotenoids is complicated by their individual differences in activity and absorbability. Chromatographic separation of the carotenoids and their identification and estimation from spectrophotometric absorption data afford a more accurate but involved basis for estimating the vitamin A activity of plant carotenoids.

Various color reactions have been proposed for the estimation of preformed vitamin A, especially in liver oils. ²² The most widely used reaction is that of Carr and Price. ²³ When a solution of antimony trichloride in chloroform is added to a dilute solution of a vitamin A-bearing oil, a blue color appears which soon reaches a maximum intensity and then rapidly fades or changes to reddish-brown, or other colors, varying with the individual oils. Under carefully controlled conditions the blue color persists long enough to make accurate readings possible. Glycerol 1,3-dichlorohydrin activated by distillation over antimony trichloride has been proposed as a colorimetric reagent for vitamin A, greater color stability being claimed for the reaction product. ²⁴

Carr-Price Test: Into a dry test tube introduce 0.2 ml. of a 20 per cent (weight in volume) solution of codiliver oil in chloroform. 26 Add rapidly, so that the solutions mix, 2 ml. of a saturated solution of antimony trichloride in chloroform. Observe the color changes.

Determination of Provitamin A (Carotene); Adapted from the Method of the Association of Official Agricultural Chemists.²⁶ Principle. Carotene is determined colorimetrically in petroleum benzin solution. Xanthophyll is removed by extraction with 90 per cent methyl alcohol, and Iycopene, when present, by adsorption on activated magnesium carbonate.²⁷

Procedure: Preparation of Extract: Saponify a sample containing 1-5 g. of solids by refluxing on a boiling water bath with 75 ml. of a freshly prepared, saturated solution of potassium hydroxide in alcohol. Cool, add 100 ml. of petroleum benzin, and shake. Decant the benzin-alcohol mixture into a 500-ml. separatory funnel. Reëxtract the residue 5 more times with 25-ml. portions of petroleum benzin. Discard the residue.

Gently pour 100 ml. of water through the alcohol-benzin solution. Draw off the alkaline-alcohol-water solution and reëxtract the latter three times by shaking not too vigorously with 30-ml. portions of petroleum benzin using two other separatory funnels. Combine all the petroleum benzin extracts and wash with 100-ml. portions of water until the last washing gives no color with phenolphthalein.

Remove xanthophyll from the petroleum benzin solution by extraction with 25-ml. portions of 90 per cent methanol (90 ml. of methanol + 10 ml. of water), until the methanol washings are colorless.

²² These have been reviewed by Fisher and Bailey: J. Assoc. Official Agr. Chem., 13, 352 (1930) and by Bacharach and Smith: Analyst, 59, 70 (1934).

²² Carr and Price: Biochem. J., 20, 497 (1926).

²⁴ Sobel and Werbin: J. Biol. Chem., 159, 681 (1945); Ind. Eng. Chem., Anal. Ed., 18, 570 (1946).

²⁸ The chloroform should be washed two or three times with its own volume of water, dried over anhydrous Na₂SO₄, decanted and distilled, rejecting the first 10 per cent of the distillate. During these processes the chloroform should be protected from light.

²⁶ "Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists," 6th ed., p. 600, 1945.

²⁷ Fraps, Kemmerer, and Greenberg: J. Assoc. Official Agr. Chem., 23, 422 (1940).

Wash the petroleum benzin solution containing the carotene twice with 50 ml. of water to remove the methanol, filter through anhydrous sodium sulfate, and adjust to volume to obtain a convenient concentration for measurement of the carotene.

Colorimetric Measurement: Determine the absorption of the solution with a photoelectric colorimeter using a 440-my filter. Calibrate the instrument with freshly prepared standard solutions of purified²⁸ β-carotene in petroleum benzin.

Comment. This procedure measures crude carotene, a mixture of carotenoids in which β -carotene usually predominates. These may be fractionated by adsorption on a magnesium oxide column followed by spectrophotometric²⁹ analysis of the isolated bands. If lycopene is present (as in tomatoes), together with the xanthophyll it may be removed from the petroleum benzin extract by adsorption on activated magnesium carbonate,²⁷ thereby eliminating the methanol washings.

Determination of Preformed Vitamin A. Colorimetric Method of Oser, Melnick, and Pader.³⁰ Principle. The blue color produced by vitamin A in the presence of antimony trichloride in chloroform solution is measured photometrically. An internal standard is included to compensate for the effect of inhibitors or accelerators on the color development.

Procedure: Preparation of the Unsaponifiable Fraction: Perform all operations in amber glassware. Into an Erlenmeyer flask transfer a weighed sample, containing preferably at least 50 USP units of vitamin A. The sample may be weighed by difference from a weighing bottle furnished with a rod and stopper. Saponify by refluxing on a boiling water bath for 0.5 hr. with freshly prepared 0.5 N alcoholic potassium hydroxide, using 15 ml. for each gram of sample solids. Cool, and transfer to a separatory funnel, adding an equal volume of water as a wash. Extract four times with 75 ml. of freshly redistilled ether, and discard the aqueous phase. Wash the combined ether extracts once with 50 ml. of water, once with 25 ml. of 0.5 N aqueous potassium hydroxide, and then with 50-ml, portions of water till the last washing gives no color with phenolphthalein. Dry the ether extract with anhydrous sodium sulfate and evaporate to dryness on a water bath, removing the last few milliliters at room temperature with a stream of nitrogen. Dissolve the residue immediately in sufficient purified³¹ chloroform to produce a concentration of from 5 to 15 USP units of vitamin A per ml. A turbid chloroform solution may be clarified with anhydrous sodium sulfate.

Colorimetric Procedure: A direct-reading photoelectric colorimeter with a 620-my filter is used for the measurements. Set the instrument at 100 per cent transmittance with a solution containing 1 ml. of chloroform and 9 ml. of antimony trichloride reagent. To another tube add 1 ml. of the test solution and 9 ml. of chloroform, and read (A). To a tube containing 1 ml. of chloroform extract of the sample, add 9 ml. of antimony trichloride reagent rapidly from a blow-out pipet and measure the maximal blue color as indicated by the full swing of the galvanometer usually attained within

²⁸ β -carotene may be purified as follows: Dissolve 100 mg. of β -carotene in 2 ml. of chloroform, and reprecipitate with 20 ml. of methanol. Filter, wash with a few drops of methanol, and dry in a vacuum desiccator.

²⁹ Fraps and Kemmerer: Ind. Eng. Chem., Anal. Ed., 13, 806 (1941).

³⁰ Oser, Melnick, and Pader: Ind. Eng. Chem., Anal. Ed., 15, 724 (1943).

³¹ Wash reagent grade chloroform three times with an equal volume of water and dry over anhydrous sodium sulfate. Redistil on the day used.

²² A 25 per cent solution of antimony trichloride in dry chloroform. Filter if solution is turbid.

4 seconds (B). To another tube containing a 1 ml. aliquot of the test solution, with a micropipet add 0.1 ml. of a vitamin A standard 33 containing 10 USP units (or 3 microgm.) of vitamin A followed by 9 ml. of the antimony trichloride reagent. Measure the maximal color (C).

Calculations. Convert galvanometer readings, G, expressed in percent transmittance, to photometric densities, P.D., as follows:

$$P.D. = 2 - \log G$$

Then,

 $\frac{\mathrm{B}-\mathrm{A}}{1.01\mathrm{C}-\mathrm{B}}$ × 10 USP units (or 3 microgm.) × dilution factor

= USP units (or microgm.) of vitamin A per gram of sample.

If a vitamin A ester should be employed as the standard, results should be corrected to the basis of vitamin A alcohol.

Comment. The colorimetric method is more specific than the spectrophotometric method described below.³⁴ In the analysis of new products that have been fortified with vitamin A, however, the analysis of an unfortified blank, if available, is advised in order to ascertain the specificity of the procedure.

Spectrophotometric Method.³⁵ Since vitamin A (preformed) is characterized by selective absorption in the ultraviolet, the intensity of this band, whose maximum is at 328 m μ (Fig. 297) serves as a measure of vitamin A content. Inasmuch as this region of the spectrum is beyond the visible range, spectrophotometric equipment is necessary. Adaptations of this method have been particularly useful in the testing of fish liver oils where the vitamin A activity is due entirely to the vitamin per se. Greater accuracy is obtainable by the removal of interfering substances present in the saponifiable fraction, particularly in oils containing less than 15,000 units of vitamin A per gram. (For the preparation of unsaponifiable extracts, see p. 1046.)

The method involves the comparison of the intensity of ultraviolet radiation (of wavelength 328 m μ) transmitted through the test solution containing vitamin A, with that incidental upon it, in practice that transmitted by the solvent alone. Results are expressed in terms of the extinction coefficient derived as follows:

$$E_{1 \text{ cm.}}^{1 \%} = \frac{1}{\text{cd}} \log_{10} \frac{I}{T}$$

in which $E_{1 \text{ cm.}}^{1\%}$ is the extinction coefficient, c is the concentration (in per cent), d the thickness of the cell (in cm.), and I and T the intensity of the

²⁵ A solution of the distilled vitamin A esters or of crystalline vitamin A acetate may be employed as the standard; the results are expressed in terms of vitamin A alcohol.

Oser, Melnick, Pader, Roth, and Oser: Ind. Eng. Chem., Anal. Ed., 17, 559 (1945). For treatments of this subject, see Chapter 23; also Morton: "The Application of Absorption Spectra to the Study of Vitamins, Hormones and Coenzymes," Hilger, London, 2d ed., 1942; and Chapter IV in Wokes: "Applied Biochemistry," Baltimore, Wm. Wood and Co., (The Williams & Wilkins Co.), 1937.

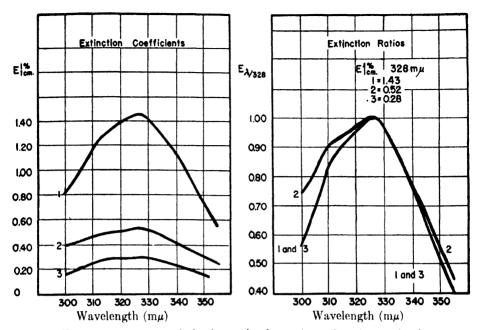

Fig. 297. Advantage of plotting extinction ratios rather than extinction coefficients in presenting ultraviolet absorption curves of vitamin A solutions.

- 3. Dilution of (1) 1:5 with ethyl laurate.

"incidental" and transmitted light, respectively. For a discussion of the derivation of this equation see p. 465.

The conversion of the extinction coefficient (or "E value," as it has been abbreviated) to vitamin A units is effected by multiplying by a conversion factor derived from observed ratios of biological potency to E value in fish liver oils. Such conversion factors have been found to vary over a wide range in different laboratories, due to differences in the oils themselves, as well as to the errors inherent in both the biological and instrumental methods employed. The conversion factor 1600, adopted by the British Pharmacopoeia, is based also in part on the postulated stoichiometric relationship of vitamin A to \$\beta\$-carotene. It has been suggested by Gridgeman in a privately published critical review that this factor be abandoned in favor of 1740. However, since the accumulated experience of most American investigators, based on bioassays of fish liver oils using the USP Reference Cod Liver Oil as the standard, has shown the conversion factor for most fish liver oil sources of vitamin A to be close to 2000, the latter has been generally adopted as a "commercial standard conversion factor."36 The factor 2000 has been found to yield close estimates of biological potency in distilled natural vitamin A esters, although there is lack of agreement in the literature as to the potencies of synthetic

* Oser: Oil, Paint, Drug Rep., 139, 4 (1941).

vitamin A derivatives when compared on a molecular basis. The E value of the best preparation of pure vitamin A alcohol has been found to be 1750; the vitamin A activity of 3,500,000 units per gram, calculated from the factor 2000, (without correction for the lower molecular weight of the alcohol compared to the esters naturally present in fish liver oils), approximates closely the reported biological estimates.

To be valid as a basis for estimating vitamin A content, the absorption curve from which the extinction coefficient at 328 m μ is taken should be characteristic of the vitamin A absorption curve. Irrelevant absorption due to oxidation products of the vitamin or to other inactive substances may be evidenced by distortion of the vitamin A curve. This is more readily recognized when the curve is plotted without regard to concentration of the vitamin; i.e., on the assumption that the extinction coefficient at the maximum (328 m μ) is equal to unity. The value at any other wavelength thus becomes an extinction ratio; i.e., the ratio of the extinction coefficient at that wavelength to that at the maximum (Fig. 297). In the evaluation of vitamin A in fish liver oils the practice has been adopted of regarding estimates as questionable when the extinction ratio at 300 m μ (E_{300/328}) exceeds 0.73 and that at 350 m μ exceeds 0.65.

Determination of Preformed Vitamin A. Spectrophotometric Method. Principle. Vitamin A may be determined by measurement of the extinction coefficient of the characteristic absorption band in the ultraviolet region of the spectrum, whose maximum is generally considered to be at 328 m μ . In nonpolar solvents 325 m μ is more nearly correct although practically the difference is not significant.

Procedure: Preparation of the Unsaponifiable Fraction: Perform all operations in amber glassware. Into an Erlenmeyer flask weigh, by difference, a sample of the oil containing at least 250 USP units of vitamin A. Saponify by refluxing on a boiling water bath for 0.5 hour with 15 ml. of freshly prepared 0.5 N alcoholic potassium hydroxide. Cool and transfer to a separatory funnel, adding an equal volume of water as a wash. Extract four times with 75 ml. of freshly redistilled ether, and discard the aqueous phase. Wash the combined ether extracts once with 50 ml. of water, once with 25 ml. of 0.5 N agueous potassium hydroxide, and then with 50-ml. portions of water till the last washing gives no color with phenolphthalein. Dry the ether extract with anhydrous sodium sulfate and evaporate to dryness on a water bath, removing the last few milliliters at room temperature with a stream of nitrogen. Dissolve the residue immediately in sufficient isopropanol ("99 per cent") to give a final concentration of from 5 to 15 USP units of vitamin A per ml. This range of concentration is optimal for use with a 1-cm, absorption cell.

Spectrophotometric Measurement: By means of a Beckman quartz spectrophotometer or instrument of similar sensitivity, measure the extinction of monochromatic (328 my) light by the solution and by the blank solvent.

Calculation. Calculate the extinction coefficient, $E_{1 \text{ cm.}}^{1\%}$ using the, formula

$$E_{1 \text{ cm.}}^{1\%} = \frac{1}{d \times c} \log_{10} \frac{I}{T}$$

[&]quot; By the War Food Administration.

in which d is the length of the light path through the solution, c is the concentration of the sample in grams per 100 ml. of solution, and $\frac{\mathrm{I}}{\mathrm{T}}$ is the reciprocal of the fraction of the "incident" light which is transmitted by the solution. When the instrument is set at 100 per cent transmittance with the pure solvent, the expression $\log_{10} \frac{\mathrm{I}}{\mathrm{T}}$ is the photometric density. Multiply

 $E_{1\,\mathrm{cm.}}^{1\,\%}$ by the standard conversion factor 2000 to obtain the vitamin A potency of the sample expressed in USP units per gram or by 600 to convert to micrograms of vitamin A.

Comment. This method is applicable chiefly to fish liver oils where the vitamin is present in comparatively high concentrations. Though a more accurate value is obtained by conducting the determination on the unsaponifiable fraction, oils of higher potency may often be assayed with little error by dissolving them directly in isopropanol. An index of the reliability of the spectrophotometric estimate may be obtained by comparing the absorption curve of the test solution with that of pure vitamin A alcohol. For this purpose, the ratios of the extinction coefficients at 300 and 350 m μ to that at 328 m μ are particularly valuable. In the analysis of fish liver oils a spectrophotometric estimate for vitamin A may be questioned if the extinction ratios $E_{300/328}$ and $E_{350/328}$ are greater than 0.73 and 0.65 respectively. For the analysis of foods that have been enriched with vitamin A, a blank test of an unfortified sample or of a sample in which the vitamin A has been destroyed by selective ultraviolet irradiation is advised.

Determination of Vitamin A and Carotene in Blood Serum. Colorimetric Method of Dann and Evelyn. ³⁹ Principle. Vitamin A and carotene are extracted from serum with ethyl ether after saponification with alcoholic potassium hydroxide. Carotene is determined colorimetrically in the extract by photometric measurement of the light absorption of a chloroform solution at 440 m μ , and preformed vitamin A, by measurement of the light absorption at 620 m μ of the blue color produced by reaction of the vitamin with antimony trichloride.

Procedure: To 10 ml. of serum in a small flask add an equal volume of 95 per cent ethyl alcohol and 2 ml. of a 60 per cent aqueous solution of potassium hydroxide. Boil for three minutes. Pour the mixture into 10 ml. of water in a separatory funnel, and wash the flask with two 15-ml. portions of water, followed by two 25-ml. portions of ether, adding the washings to the separatory funnel. Shake the funnel vigorously for one minute, then allow the phases to separate. Discard the aqueous (lower) layer. Wash the ether phase by shaking vigorously with 10 ml. of water, then twice gently with 25 ml. of water. Filter the ether solution through a layer of anhydrous sodium sulfate on a sintered glass filter. Wash the residue with 20 ml. of ether, combining the wash with the filtrate. With the aid of a stream of nitrogen, evaporate the ether solution to dryness on a hot water bath. Take up the residue in 10 ml. of chloroform in the absorption cell of a photoelectric colorimeter.

²⁸ Little: Ind. Eng. Chem., Anal. Ed., 16, 288 (1944).

³⁰ Dann and Evelyn: Biochem J., 32, 1008 (1938).

Measure the light absorption of the solution at 440 my setting the instrument at 100 per cent transmittance with pure chloroform. Calibrate the instrument by measuring the absorption of standard solutions of C.P. β -carotene in chloroform containing 0.2, 0.4, 0.6, 0.9, 1.2, 1.5, 1.8, 2.1, 2.5, and 3.0 γ per ml. Plot photometric densities against concentrations of carotene. From the graph, determine the concentration of carotenoids per ml. in the chloroform extract of the unknown and multiply this value by 100 to obtain the concentration per 100 ml. of serum.

Place the cell in a hot water bath and evaporate off the chloroform with the aid of a stream of nitrogen. The latter provides an inert atmosphere and prevents oxidation of vitamin A. Take up the residue in 1.7 ml. of chloroform. Place the cell in the photoelectric colorimeter equipped with a 620 my filter, set at 100 per cent transmittance with 10 ml. of a solution containing 1.7 ml. of chloroform and 8.3 ml. of antimony trichloride reagent (see p. 1043). Rapidly add 8.3 ml. of antimony trichloride reagent to the unknown and determine the maximal extinction. Calibrate the instrument by conducting the test on pure solutions of vitamin A in chloroform containing 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 6.0, 8.0, and 10.0 γ per 1.7 ml.

Calculation. Plot photometric density against concentration of vitamin A per 1.7 ml. Determine the concentration in the chloroform extract of the unknown, and multiply this value by 10 to obtain the concentration of apparent vitamin A per 100 ml. of serum. This value must be corrected for the interference of carotenoids which react with antimony trichloride to produce a blue pigment. The color produced by 1 γ of preformed vitamin A is approximately equal to that of 20 γ of β -carotene. Determine the true concentration of vitamin A by means of the formula

$$A - \frac{C}{20} = \gamma$$
 of vitamin A per 100 ml. of serum

where A is the concentration of apparent vitamin A and C that of carotene both expressed per 100 ml. of serum.

Interpretation. The normal vitamin A level for blood serum is 15 to 60 γ (approximately 50 to 200 USP units) per 100 ml. The principal carotenoids in blood serum are carotene and xanthophyll, which are present in a relatively fixed proportion. Under these conditions, measurement of total carotenoids, which is necessary for the determination of total vitamin A activity, would be a good practical index of carotene content. Chromatographic analysis, however, has demonstrated that the true carotene content varies from 10 to 50 per cent of the total carotenoid. The normal total carotenoid range in blood serum is 100 to 300 γ expressed as β -carotene.

BIOLOGICAL METHODS

Since none of the chemical or physical methods for estimating vitamin A activity is sufficiently specific for all compounds possessing vitamin A

⁴⁰ Crystalline vitamin A acetate is a convenient standard since it is more stable than the free alcohol. The ester contains 82.7 per cent vitamin A. On a molar basis the acetate and the free alcohol have equal chromogenic properties with antimony trichloride.

¹¹ Clausen and McCoord: J. Pediatrics, 13, 635 (1938).

⁴² Wohl: "Dietotherapy, Clinical Application of Modern Nutrition," p. 225, Philadelphia, W. B. Saunders Co., 1945.

activity, the biological assay remains fundamentally the most reliable means for determining vitamin A potency and is the basis against which the more precise nonbiological procedures must be evaluated. Many of the limitations of bioassays are removed when they are planned to measure not only the response of animals to dosage of the test material but to known dosage of some standard of reference. By balancing the distribution of test animals among assay and control groups with respect to strain, litter origin, sex, age, body weight, and standardizing the environmental factors, diet, feeding, and dosing conditions, etc., it is possible to reduce the error of biological assay to a minimum. The assay can be set up according to a statistical design to permit control of these variables, and also to provide a measure of the limits of precision of the estimate and the extent to which individual factors such as sex, litter, etc., contribute to the total variance. An essential feature of bioassays in which responses are quantitatively graded to dosage is that the slope of the response curve (when dosage is plotted logarithmically) must be reasonably parallel to that of the reference curve. Otherwise the standard and unknown preparations are likely to be qualitatively different; e.g., the unknown may be contaminated with a substance that is toxic or inhibits absorption. The effect of departure from parallelism may be measured in an assay designed to permit statistical analysis of variance.

The curative method for assaying vitamin A is based on depleting young rats of their reserves of this vitamin and determining the relative growth responses of groups of these animals receiving daily supplements of the test material or of the standard preparations of vitamin A. The basal diet fed throughout the depletion and assay periods is of course complete with respect to all nutrients required by the rat, except vitamin A. A serious error may be caused by failure to include in the basal vitamin A-free diet a sufficient amount of vitamin E (tocopherol), since the responses of the animals may be influenced by differences in the vitamin E content of the assay and reference materials.

The U.S. Pharmacopoeia^{42a} method for vitamin A is a "rat-curative" assay and is most generally employed for the evaluation of food and pharmaceutical products. As officially described, however, it is a minimal potency assay (i.e., it provides for one assay and one reference group), and therefore permits only the statement that the assay material contains "less than" or "not less than" the unitage of vitamin corresponding to the administered dosage level. The method may be adapted to quantitative estimation of actual potency by feeding two or more dosage levels of the assay material and a similar number of dosage levels of the standard of reference (USP Reference Cod Liver Oil, which may be supplanted by a crystalline vitamin A acetate standard). The dosage interval—i.e., the ratio of each dose to the next lower dose—is constant in both assay and reference groups. The resulting data may be computed according to the analysis of variance, as illustrated by the example in Appendix VIII, ⁴² to give an estimate of potency, the standard error of this estimate,

⁴²⁸ XIIIth Revision, in press, 1946.

⁴⁹ For comprehensive treatments and examples of the statistical design and interpretation

and, most important of all, an objective indication of whether the assay is a valid basis for such estimation.

Biological methods have been described for vitamin A based on prevention rather than cure of the deficiency in rats, on keratinization of vaginal epithelium (which occurs at about the twenty-third day of depletion in young rats), and on the colorimetric determination of the vitamin A stored in the livers after controlled feeding periods. 44 These procedures, however, are either less adaptable than the curative rat growth method to quantitative study or are too recent to have achieved widespread

The U.S. Pharmacopoeia biological assays for vitamins A and D are given in full on pp. 1161 to 1167.

THE "VITAMIN B COMPLEX"

Since the vitamin concept was first postulated, the initial group of three vitamins has expanded to more than 20 by virtue of the discovery of the multiple nature of previously known vitamins or the recognition, from biological experiments, that as yet unknown nutrients must exist. Most outstanding in this regard has been the branching out of the vitamin B complex, a group of water-soluble factors usually associated in nature with thiamine (the original vitamin B), rich sources being liver, yeasts and brans. The possibility that the "antiberiberi vitamine" of Funk (also known as the antineuritic factor or water-soluble B) might be a complex was suggested by the work of Emmett and Luros⁴⁵ on the basis of differences in susceptibility to heat destruction. Smith and Hendrick 46 showed that autoclaved yeast, in which the antineuritic vitamin was destroyed. still possessed supplementary value for rats receiving adequate amounts of vitamin B from oats or in the form of a vitamin B picrate. Goldberger, 47 in 1926, recognized that rats required not only the antineuritic vitamin ("B sensu stricto") but also another factor which he called P-P (pellagrapreventive). In 1927 the Accessory Factors Committee of the British Medical Research Council recommended the symbols B₁ and B₂ for the heat-labile (antineuritic) and the heat-stable components, respectively. (For a time vitamin B₂ was called G in the United States.) The erroneous belief that the latter was identical with the pellagra-preventive factor was corrected when distinction was drawn between human pellagra and canine blacktongue, on the one hand, and so-called rat pellagra on the other. Between the time that Jansen and Donath, 48 in 1927, isolated the crystal-

of biological assays, see the papers of C. I. Bliss, R. A. Fisher, J. H. Gaddum, et al., cited in the review by Bliss and Cattell: Ann. Rev. Physiol., 5, 479 (1943). ribose group attached to an isoalloxazine ring, caused them to adopt the common name riboflavin for vitamin B₂.

Evidence for the existence of additional growth and antidermatitis factors for rats, pigeons, and chicks prompted the continued search for new vitamins in the B group, which in the years since 1927 has culminated in the identification and synthesis of at least nine additional vitamins. From the standpoint of human nutrition, one of the most significant is nicotinic acid (now called niacin), which was identified by Elvehjem, Madden, Strong, and Woolley,⁵¹ in 1937, as the canine blacktongue factor. This compound had been known for many years and had actually been isolated from rice polishings by Funk⁵² in his efforts to isolate "vitamine B." The therapeutic trial of nicotinic acid in human pellagra was rewarded with prompt and dramatic success.

The recognized components of the vitamin B complex and a few of the still unidentified factors are listed in the table on page 1051.

Clinical experience with beriberi or pellagra has emphasized that these diseases are often associated with deficiencies of other nutrients than thiamine or niacin alone. Therapeutic administration of individual crystalline vitamins often reveals the presence of underlying deficiencies which respond to supplementary dosage with other pure vitamins of the B group or with rich sources of the vitamin B complex such as yeast or liver. In this connection it is significant that the relative proportions of the various members of the vitamin B group as found in natural sources, both plant and animal, are quite variable; for example, seeds and legumes are relatively higher in thiamine than in riboflavin whereas in milk and leafy vegetables the reverse is true. Moreover, processing by heat, exposure to light, or other destructive influences effect still further variations in the quantitative relationship of the B vitamins.

Bacteria present in the mammalian intestinal tract are capable of synthesizing various vitamins of the B group, noteworthy among them being biotin, folic acid, and pantothenic acid. Factors which influence such bacterial growth—e.g., nutrients in the diet of the host or bacteriostatic medication (like the sulfonamides)—may depress intestinal synthesis sufficiently to induce secondary deficiencies.

The use of microbiological assay procedures has aided materially in the elucidation of the factors in the vitamin B complex. Examples of such assays are given under Riboflavin, Pantothenic Acid, Niacin, Vitamin B₆, and Pteroylglutamic Acid. In principle, these methods are identical with the procedures for amino acid assay described in Chapter 33 and illustrated on page 976. A table outlining the conditions for extraction, hydrolysis, and optimal concentration for microbiological vitamin assays by selected methods is given on p. 1052.

BIOLOGICAL ASSAY FOR VITAMINS OF THE B COMPLEX

With certain reservations, deficiencies in the vitamins of the B group can be produced experimentally in rats or chicks, thus permitting bio-

52 Funk: J. Physiol., 43, 395 (1911); 46, 173 (1913).

⁴¹ Elvehjem, Madden, Strong, and Woolley: J. Am. Chem. Soc., 59, 1767 (1937).

assays to be performed by the conventional graded dose-response technique in which the criterion of response is usually growth. The availability in pure form of at least 10 components of the vitamin B complex has made it possible to feed highly purified basal diets deficient only in a single vitamin; viz., the one under assay. While the rat has numerous advantages as a test animal, it is not suitable for all vitamin assays because in some instances it is able to synthesize the vitamin systemically (e.g., niacin), or because synthesis by intestinal flora may interfere with the experimental production of the deficiency (e.g., biotin, pantothenic acid, or pteroylglutamic (folic) acid). The rat can be adapted for use in bioassays of the latter group of vitamins, however, by administering doses of intestinal bacteriostatics such as certain of the sulfa drugs.

Animal assays for thiamine and riboflavin (see pp. 1069 and 1084) developed along standardized lines have received wide acceptance. It seems desirable to describe one general method of bioassay for the remaining members of the vitamin B group which is typical of those that have been applied successfully to the assay of riboflavin, vitamin B₆, pantothenic acid, biotin, and pteroylglutamic (folic) acid.

Principle. Weanling rats are maintained upon a diet adequate in all respects except for the lack of the one vitamin under assay. When growth ceases, or other deficiency symptoms are noted, the animals are divided into groups, some (reference groups) receiving graded doses of the pure vitamin solution, while others (assay groups) receive similarly graded doses of the test material. Comparison of the average growth responses serves as the basis for quantitative evaluation of the test material.

Procedure: Weanling rats, 21 to 24 days of age, are placed in individual cages with raised screened floors to minimize coprophagy which, because of intestinal synthesis or impaired absorption, can seriously interfere with the development of the deficiency condition. Clean water and the following basal diet (see p. 1070) are offered ad libitum:

Extracted ("vitamin-free") casein	18
Sucrose	68
Hydrogenated vegetable oil	9
Codliver oil	1
Salt mixture	4

For assays of biotin, pantothenic acid, or pteroylglutamic (folic) acid, 1 per cent of sulfasuxidine, or 0.5 to 1 per cent of sulfaguanidine, should be substituted for equivalent amounts of sucrose. For the first two weeks, this basal diet is fed without supplementation in order to facilitate depletion. Thereafter each rat receives, in addition, a daily supplement of the vitamin mixture described below, 53 from which the single vitamin under assay has been omitted.

¹² Vitamin Mixture.

Thiamine 40 γ ; riboflavin 80 γ ; niacin 500 γ ; pyridoxine hydrochloride 40 γ ; calcium pantothenate 250 γ ; biotin 0.2 γ ; p-aminobenzoic acid 250 γ ; pteroylglutamic acid 10 γ ; choline chloride 5 mg.; inositol 2 mg.; and menadione 50 γ .

Prepared as follows:

Solution A: Thiamine, riboflavin, pyridoxine, inositol, niacin, and choline made up in 20 per cent ethyl alcohol in such concentration that the daily dose is contained in 0.75 ml. Adjust to pH 3.5. Store in refrigerator until used.

The supplementary doses of vitamins may be measured into porcelain or glass cups (Syracuse watch glasses are suitable) from which they are avidly and completely consumed; a better method, however, is to administer the doses directly into the posterior oral cavity or esophagus by means of a syringe with a blunt-edged needle (No. 18 gauge).

Animals are observed daily and weighed semiweekly. When growth has ceased for a period of at least four days, or characteristic symptoms of the B complex deficiencies under investigation appear (dermatitis, denudation, edema, "bloody whiskers," "spectacled eyes," etc.), the supplemental feeding of the standard and test materials is begun. Observations are continued for a period of at least four weeks.

Discussion. The need for certain of these factors—e.g., choline, inositol, and niacin—by the rat under normal conditions may be questioned. Nevertheless, in bioassay work most investigators prefer to include all vitamins of the B group in synthetic rations as a precautionary measure.

In the older assays of vitamins in the B complex, it was customary to furnish the basal vitamins in the form of a natural source from which the vitamin under test had been removed by extraction, chemical treatment, autoclaving, etc. With the availability of synthetic vitamins, and particularly now pteroylglutamic acid, it is probable that the addition of natural sources of the B complex (treated or untreated) or of liver preparations as a source of "unknown" factors added "for good measure," may be dispensed with in these basal rations.

The approximate ranges of feeding levels for certain of these vitamins which result in good linear or logarithmic dose-response curves in the rat are:

Thiamine	2	to 10 γ
Riboflavin	2	to 10 γ
Pyridoxine	1	to 20 γ
Calcium pantothenate	10	to 100 γ
Biotin	1	to 10 γ
Pteroylglutamic (folic) acid	0.25	to 2.5 γ

Interpretation. Characteristic syndromes of various vitamin B complex deficiencies in the rat have been reported as follows:

THIAMINE. Loss of weight; emaciation; hunched posture; tendency to walk on toes or in circles; palsy; paralysis; convulsions, especially on stimulation (such as spinning by tail).

RIBOFLAVIN. Loss of weight; dermatitis; keratitis; cataract.

Pyridoxine. Impaired growth; muscular weakness; convulsive (epileptoid) seizures; acrodynia (exudative dermatitis and edema of extremities, ears, and nose).

Pantothenic Acid. Inhibition of growth; achromotrichia; necrosis and

Solution B: Calcium pantothenate and p-aminobenzoic acid made in 20 per cent ethyl alcohol in such concentration that the daily dose is contained in 0.25 ml. Keep neutral. Store in refrigerator until used.

At time of feeding mix in proportion of 7.5 parts of solution A and 2.5 parts of solution B and feed 1.0 ml. per rat daily.

If desired, this vitamin supplement may be incorporated into the basal ration in an amount to furnish these daily doses in 5 g. of diet.

hemorrhage of the adrenals; "bloody" (porphyrin-stained) fur and whiskers; hypochromic anemia; leukopenia.

BIOTIN. Retarded growth; denudation; exfoliative pruritic dermatitis; elevation and rounding of lumbosacral region of spine; tendency to step off top of digits.

P-AMINOBENZOIC ACID. Impaired growth and lactation (?); achromotrichia (?).

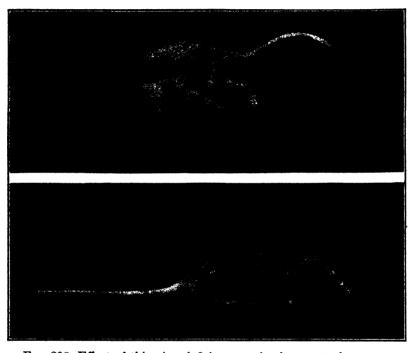

Fig. 298. Effect of thiamine deficiency and subsequent change to an adequate diet. The spastic paralysis shown in the upper figure was cured (below) about 24 hours after addition of thiamine. (Courtesy, The Bureau of Home Economics, U.S. Department of Agriculture.*)

PTEROYLGLUTAMIC (FOLIC) ACID. Impaired growth; achromotrichia; "bloody" (porphyrin-stained) whiskers; leukopenia; agranulocytopenia (sulfa-induced).

CHOLINE. Fatty liver; hemorrhagic necrosis of the kidneys; hemorrhage into eyeballs and other organs; cirrhosis of the liver.

INOSITOL. Fatty liver; "spectacled" eyes; failure of lactation and growth.

THIAMINE

The term "deficiency disease" was first applied to a condition known as beriberi, which was common in southeastern Asia and the islands of the Pacific Ocean. The similarity in pathology between this disease and poly-

^{*}Smith and Munsell: U.S. Dept. Agr. Circ. No. 84, 1929.

neuritis observed in fowls restricted to a diet of polished rice, both of which could be cured by feeding the "silverskin" (i.e., pericarp and germ) of the grain, prompted Eijkman, in the Dutch East Indies, to investigate the subject from the nutritional standpoint. Eijkman produced beriberi in fowls on a diet of polished rice and prevented the syndrome by dietary means. His classic studies, reported in 1896–1897, paved the way for a host of other investigations which culminated in the formulation of a vitamin hypothesis. Besides those Oriental countries where polished rice is the main article of diet, other places in which beriberi has been observed are prisons or asylums, localities where the diet is apt to be restricted or faulty, and in war-stricken countries.

After numerous attempts to isolate the vitamin by methods involving silver or lead precipitation, crystallization of a picrate, adsorption, etc., the vitamin was finally crystallized from rice polishings by Jansen and Donath in 1926, in the very laboratories in which the original studies were conducted by Eijkman who was able, after 30 years, to confirm the antineuritic activity of the crystalline vitamin hydrochloride. A decade later the structure and synthesis of the vitamin were announced by R. R. Williams and his co-workers.

Clinical cases of thiamine deficiency in the Western Hemisphere are rare today. Subclinical cases of deficiency are probably more prevalent, arising from a limited intake of the vitamin or from increased requirements such as are observed in pregnancy or lactation. The neuritis observed in cases of chronic alcoholism has been claimed to result from diminished intake of food as well as insufficient thiamine to metabolize the alcohol consumed.

Physiological and Clinical Aspects of Thiamine.⁵⁴ Thiamine is essential for the growth and metabolism of all animals as well as of many plants and microörganisms. Deficiencies are characterized by a variety of symptoms and clinically are often complicated by the effects of lack of other nutrients.

In thiamine deficiency (avitaminosis B₁) a form of peripheral neuritis is manifested, affecting both the sensory and motor nerves. During the early stages, neuralgia and cramps of the calf muscles are common; as the condition advances the thigh muscles become weak and toe- and foot-drop develop along with hypesthesia. The acute disease, beriberi, may be of the dry type, in which cachexia, numbness, and paralysis are the primary symptoms, or of the wet type, associated with marked ("pitting") edema and paresthesia of the extremities. In animals, the symptoms are loss of muscular coördination, spastic movements, retraction of the head (opisthotonos), and paralysis. (See Fig. 298.) Recovery from the symptoms of polyneuritis is very rapid when thiamine is administered, especially by injection.

Debility and progressive decline in weight are observed early in vitamin B₁ deficiency as a result of anorexia (loss of appetite), which is one of the

[&]quot;Cowgill: "The Physiology of Vitamin B₁," in "The Vitamins," Chicago, Am. Med. Assoc., 1939. Vedder: "The Pathology of Beriberi," *ibid.* Strauss: "The Therapeutic Use of Vitamin B₁ in Polyneuritis and Cardiovascular Conditions," *ibid.*

most striking symptoms of this deficiency disease. The loss of appetite, which is the main cause of growth failure, has been attributed to a general systemic disturbance rather than to diminished secretory functions of the digestive glands or to reduced gastric motility, although diminished motor function of the gastrointestinal tract is observed clinically in thiamine deficiency.

The rapid restoration of appetite following thiamine supplementation of avitaminotic subjects has been mistakenly regarded as indicating a specific appetite-stimulating function of the vitamin. The anorexia of thiamine deficiency, however, is more probably explained by the impaired carbohydrate metabolism of cellular tissue in general. Attempts to explain the loss of appetite on the basis of lowered secretory or motor function or diminished basal metabolic rate have not succeeded.

In polyneuritis pathological changes in the tissues and organs of the body include cardiovascular and neural disturbances, atrophy of the endocrine glands and other vital organs, but hypertrophy of the adrenals. Prolonged deficiency results in cardiac failure and death. An outline of the clinical symptoms of thiamine deficiency is given in the American Medical Association syllabus on p. 1186.

Degeneration of the myelin sheaths of peripheral nerves and also of the ganglion cells of the brain and spinal cord is produced in experimental polyneuritis, but since similar findings are observed in starvation, even when the supply of thiamine is adequate, it is preferable to regard the primary neurological effect of the avitaminosis as a functional defect concerned with the physiology of the neurons.⁵⁵ The rapid recovery from neurological symptoms which follows thiamine therapy supports this view.

In the animal organism, thiamine plays an important role in the metabolism of carbohydrates. In 1937 Lohmann and Schuster⁵⁶ isolated from yeast a crystalline coenzyme, cocarboxylase, the pyrophosphate ester of thiamine. When this compound is bound to a specific protein from yeast and a magnesium ion, an enzyme is formed which catalyzes the decomposition of pyruvic acid to acetaldehyde and carbon dioxide. Unphosphorylated thiamine has no cocarboxylase activity, although it can stimulate the action of cocarboxylase in alkali-washed yeast preparations. The pyrimidine portion of the vitamin with an intact amino group has similar properties. Substitution of the magnesium by other divalent ions results in somewhat diminished biological activity of the enzyme.

In animal tissues, in contrast to yeast, a cocarboxylase catalyzes the conversion of pyruvic acid to oxalacetic acid which is oxidized further, resulting in the final conversion of a molecule of pyruvate to carbon dioxide and water or to acetic acid and carbon dioxide.

The fundamental role of thiamine in the metabolism of carbohydrates and proteins is indicated by the following observations. A deficiency of thiamine in pigeons results in an increase in the glycogen content of liver and heart muscle. The synthesis of fats from carbohydrate (on a fat-free

⁵⁵ Wolbach: J. Am. Med. Assoc., 168, 7 (1937).

⁵⁶ Lohmann and Schuster: Naturwissenschaften, 25, 26 (1937).

diet) in pigeons and rats requires thiamine. Supplementation with thiamine of a diet consisting only of glucose doubles the survival period of rats; similar supplementation of a diet of casein prolongs life by 67 per cent.

Free thiamine is phosphorylated in vivo to cocarboxylase (or diphosphothiamine) by liver and kidney tissue and to some extent by muscle and brain. Diphosphothiamine may be involved in the synthesis of acetylcholine and in the control of its hydrolysis in vivo. The activity of choline esterase of serum is strongly inhibited by cocarboxylase.

Diphosphothiamine is the prosthetic group of several enzymes. A diphosphothiamine enzyme is present in gonococcus which catalyzes the aerobic oxidation of pyruvic acid to acetic acid and carbon dioxide. Other pyruvic oxidases have been noted in *Bacterium delbrückii* and *Streptococcus hemolyticus*.

Three separate enzymes extracted from washed pig heart catalyze the following reactions: the decarboxylation of α -ketoglutarate to succinosemialdehyde, the decarboxylation of pyruvate accelerated by acetaldehyde, and condensation of two aldehydes to acetoin. These three enzyme reactions are anaerobic and phosphate is not involved in any of them.

The average American diet has been estimated to contain 1.3 mg. of thiamine per day. Prior to bread and flour enrichment, the value was 0.8 mg. Moderate thiamine deficiency may be the root of many ill-defined nutritional disturbances, especially when anorexia is a symptom. Such cases respond readily to the therapeutic test; i.e., supplementation of the diet. The thiamine requirement is a function of sex, body weight, muscular activity, and other conditions. Diet, especially the intake of non-fat calories, is an important factor. The recommended daily allowances of thiamine are shown in the table on p. 1027. The remarkable tolerance for thiamine is indicated by the fact that 500 mg. have been taken daily for a month by normal people, without any objective symptoms. It is of interest in this connection that peripheral neuritis in chronic alcoholism has been attacked therapeutically on the hypothesis that the condition is due partly to a disturbance of the vitamin B₁:non-fat calorie ratio.

It has been shown that lactating rats require an additional quota of antineuritic vitamin, in the absence of which the mother will neglect or destroy the litter. The vitamin may be supplied directly to the young, or indirectly through the mother's milk.^{56a}

Thiamine and its compounds are the only naturally occurring substances having vitamin B₁ activity for the higher species. Certain synthetic analogs have less biological potency; e.g., the compound having a methyl group in the 6-, rather than in the 2- position in the pyrimidine nucleus; the 2-ethyl, instead of the 2-methyl, compound is active for *Phycomyces*; thiamine disulfide, a possible intermediate in the metabolism of thiamine, obtainable by mild oxidation of the vitamin, has full activity.

Thiamine may be inactivated both in vitro and in vivo by an enzyme,

¹⁸⁸ Sure: J. Biol. Chem., 76, 685 (1928); Sure and Walker: J. Biol. Chem., 91, 69 (1931); Macy, Outhouse, Graham, and Long: J. Biol. Chem., 73, 189 (1927).

thiaminase, present in certain fish and shellfish (see p. 1184). The vitamin is hydrolyzed to 2-methyl-6-amino-5-hydroxymethyl pyrimidine and 4-methyl-5-hydroxyethylthiazole.

A pyridine analog of vitamin B₁, pyrithiamine, exerts strong antivitamin activity, probably by competing with the vitamin in certain enzyme systems. The effect of pyrithiamine is neutralized by the administration of an excess of thiamine. For further discussion see Chapter 36.

Storage and Synthesis of Thiamine. The available evidence seems to indicate little capacity on the part of the animal body to store thiamine. It occurs both free and phosphorylated, somewhat higher concentrations being present in the heart, liver, and kidneys, than in muscles and brain. It is possible to increase the thiamine content of the tissues by dietary means; however, their storage capacity is so limited that even under these circumstances only a few weeks' reserve can be maintained. It is thus important that the daily diet include an adequate supply of thiamine.

Whereas certain microörganisms can synthesize the vitamin, others require an external source; some utilize the thiazole and pyrimidine portions—e.g., *Phycomyces blakesleanus*—whereas others can synthesize one moiety and combine it with the other obtained from an external source. Thiamine is synthesized by all higher plants, though to only a limited extent in the dark.

The vitamin may be classed as a plant hormone for, though it is essential for embryonic cell division in the roots, it is synthesized by other plant organs. An external supply of thiamine to the root has been found to protect against root-shock during transplanting and to be beneficial for growth and development. Higher plants secrete thiamine from the roots, thereby providing the nutrient for soil microbes.

Though all animals require thiamine, sheep and cattle do not need an external supply, since the vitamin is synthesized in sufficient amount by bacteria in the rumen. Though thiamine is known to be synthesized by intestinal flora in rats and humans, the nutritional importance of this contribution is not known. Difficulties encountered in the production of experimental thiamine deficiency in humans subsisting on a diet low in thiamine have been attributed to the intestinal synthesis.

Thiamine and cocarboxylase have the same biological activity for higher animals. Thiamine can be phosphorylated by live yeast, by dried yeast, or by a phosphatase obtainable in the presence of hexosediphosphate, adenosine triphosphate, and a specific protein. The vitamin may also be phosphorylated by certain bacteria. Liver and kidney and, to some extent, muscle and brain, can perform the same function.

Distribution of Thiamine.⁵⁷ This vitamin is essentially of plant origin. There is no proof of its synsthesis by the animal body proper although it is synthesized to some extent by bacteria in the intestinal tract. Its presence in such products as milk, eggs, and liver depends on the dietary supply of the animal. Of the various meats used for human consumption, pork muscle is the richest in thiamine. The ability to synthesize thiamine

⁵⁷ For thiamine values in foods, see Appendix III.

is possessed by plants and by lower forms of life; e.g., bacteria, molds, and yeasts. The latter are a potent natural source of this factor, as well as of other components of the vitamin B complex.

Thiamine is widely distributed in the plant world, seeds, leaves, roots, stems, and fruits being recognized sources. In cereal grains as a class, thiamine is found in highest *concentration* in the germ or embryo, less in the bran, and least in the endosperm. The amount of thiamine in a milled grain such as flour depends on the proportion of each part of the grain present. Leaves and grasses (e.g., spinach, alfalfa, timothy hay, etc.) are rich sources of thiamine as are also beans, nuts, fruits, milk, and egg yolk.

Vitamin B₁ may occur in natural materials as free thiamine, as a protein complex, as a pyrophosphoric acid complex (cocarboxylase), and as a phosphorus-protein complex. In milk, the vitamin is present both as free thiamine and as the vitamin-protein complex. In brain and liver, it is found as cocarboxylase and as its protein complex. In wheat, thiamine occurs in the free form. In blood, it is present as the pyrophosphate in the cells and as free vitamin in the serum. Thiamine is excreted in the free form in the urine.

Chemistry of Thiamine. The efforts of many investigators to isolate pure crystalline thiamine from natural sources culminated in the work of Jansen and Donath (*loc. cit.*). They adsorbed an acid extract of rice polishings on clay, eluted with Ba(OH)₂, and alternately precipitated (first with silver nitrate then with phosphotungstic or silicotungstic acid) and decomposed with acid, finally obtaining a platinic chloride precipitate from which a crystalline thiamine hydrochloride was prepared. The procedure yielded about 1 part of the vitamin from 3,000,000 parts of rice polishings.

Analysis of the crystalline vitamin led to attempts by Williams and his co-workers to effect its synthesis which was successfully achieved in 1936⁵⁸ and has now reached the stage of large-scale commercial production. Thiamine has the structural formula indicated in the accompanying scheme employed for its synthesis.

Williams: J. Am. Chem. Soc., 58, 1063 (1936); Cline, Williams and Finkelstein: J. Am. Chem. Soc., 59, 1052 (1937); Williams: Ind. Eng. Chem., 29, 980 (1937). The synthesis of thiamine was also accomplished, at about the same time, by Todd and Bergel (J. Chem. Soc., p. 364 (1937)) and by Andersag and Westphal (Ber., 70, 2035 (1937)).

Thiamine hydrochloride (C₁₂H₁₇N₄SOCl, mol. wt. 300.5)

Thiamine hydrochloride is a white crystalline solid. The crystals are stable at 100° C. for 24 hours but decompose when heated to the melting point of 249° C. The compound is hygroscopic and dissolves in water to form an acid solution which is optically inactive. One gram dissolves in 1 ml. of water, in 18 ml. of glycerol, in 100 ml. of 95 per cent alcohol, or in 315 ml. of absolute alcohol. It is insoluble in ether, acetone, chloroform, and benzene. The vitamin has a characteristic yeasty odor and taste.

Thiamine is a basic substance forming insoluble compounds with picric, phosphotungstic, and tannic acids, and with salts of the noble metals. It is adsorbed from acid or neutral solution by fuller's earth, silica gel, or norit, and may be eluted by alkalinization or treatment with quinine.

As the pH increases beyond neutrality, thiamine becomes unstable, especially at elevated temperatures. Heating at 100° C, in acid or neutral solution for one hour has little destructive effect but at higher temperatures gradual destruction takes place. However, at pH 3.5 or less the vitamin may be autoclaved at 120° C, with little loss. Oxidation is not the primary factor in this decomposition. Dried yeast, when heated in an autoclave for several hours at 120°, loses its thiamine activity but retains practically all of its riboflavin, this difference in thermolability being one of the earliest methods applied to the differentiation of the vitamin B complex.

The thiamine in foods is stable at cooking temperatures, though a considerable fraction is extracted and often discarded in the cooking water. In neutral or alkaline solution, thiamine exhibits spectrophotometric absorption maxima at 235 and at 267 m μ . Below pH 5.5 there is a single band at 246 m μ .

The principal ester of thiamine is the pyrophosphate, known as cocarboxylase or diphosphothiamine.

Thiamine Pyrophosphate (Cocarboxylase)

This compound differs from the free base in that it functions as a coenzyme in the decarboxylation of pyruvic acid. It is a white, crystalline compound melting at 242-244° C., and resembles thiamine itself in its susceptibility to mild oxidation and sulfite-cleavage.

Thiamine and its pyrophosphate are destroyed when treated with sul-

fite or nitrite due to cleavage of the two-ring structure of the molecule. This reaction is employed in the preparation of vitamin B complex supplements (e.g., liver) free from thiamine, for use in biological assays. Both thiamine and cocarboxylase, when treated with mild oxidizing agents like potassium ferricyanide in alkaline medium, are converted to thiochrome, a blue fluorescent compound: likewise

both react with diazotized p-aminoacetophenone to produce red dyes. The reaction products obtainable from the free vitamin may be distinguished from those derived from the pyrophosphate by extraction of the former with organic solvents in which the latter are insoluble. The thiochrome or diazotization reactions serve as the basis for analytical determination of the vitamin (see above).

Determination of Thiamine. 1. Introduction. Reliable chemical methods for the determination of thiamine are based on (a) measurement of the fluorescent compound, thiochrome, obtained by mild oxidation, and (b) the more specific but less sensitive diazotization reaction of Prebluda and McCollum. Colorimetric assays of various extracts and concentrates have been found to correlate well with bioassay results, whereas thiochrome values are somewhat low.59 Thiochrome values have also been found to be low when compared with the results obtained in yeast fermentation studies and in rat-curative tests. 60

For the chemical tests, the thiamine must first be extracted quantitatively from foods and biological materials by boiling with dilute acids. The vitamin is then freed from its natural complexes by the action of enzyme preparations containing phosphatases. This step, by hydrolyzing carbohydrates, also facilitates extraction. In order to accomplish complete extraction from materials rich in protein, digestion with proteolytic enzymes like pepsin is also employed. The extract of the free vitamin is then purified by passage of the solution through a column of zeolite, a synthetic adsorbent which removes thiamine and allows the passage of many undesirable materials. Thus, reducing agents, heavy metals, and other compounds which interfere with the thiochrome and colorimetric reactions are discarded in the filtrate. The vitamin is then eluted from the zeolite column in a relatively pure form with an acidified solution of potassium chloride.

In the thiochrome procedure the vitamin is oxidized by an alkaline solution of potassium ferricyanide to thiochrome. This compound is extracted with isobutanol in which its fluorescence is determined photo-

⁵⁰ Brown, Hartsler, Peacock, and Emmett: Ind. Eng. Chem., Anal. Ed., 15, 494 (1948). 60 Hennessy, Wapner, and Truhlar: Ind. Eng. Chem., Anal. Ed., 16, 476 (1944).

metrically. In order to correct for the presence of other fluorescent compounds which may be present in the final extract, a blank test is conducted in which the ferricyanide is omitted. Since the conversion to thiochrome is not quantitative and other oxidation products which do not fluoresce may be formed, care must be exercised to standardize the oxidation procedure and to employ a fixed amount of ferricyanide. Though thiamine pyrophosphate (cocarboxylase) also yields a blue fluorescent compound on oxidation with ferricyanide, the product is not extractable by butanol.

The thiochrome method assumes that the blank fluorescence is independent of the treatment with ferricyanide, which may account for low values by this procedure. This assumption is invalid when N¹-methylnicotinamide is present. 6¹.6² This compound fluoresces in the thiamine blank, but not when it is treated with ferricyanide. N¹-Methylnicotinamide is a metabolite of niacin which, like thiamine, is adsorbed by and eluted from zeolite. It is partly responsible for erroneous results obtained in the assay of urine by the thiochrome method.

In the colorimetric procedure, the eluate from the zeolite is first added to a solution of phenol in alcohol to increase the sensitivity of the test. The solution is then made alkaline and diazotized p-aminoacetophenone is added. The mixture is allowed to stand while the red dye develops. The latter is then extracted selectively by xylene which leaves behind in the aqueous phase dyes produced by the coupling of the reagent with phenol, phosphorylated thiamine (if present), acid-base indicators, and other interfering compounds. Results obtained by the colorimetric procedure agree well with those obtained by biological assay.

Since many microörganisms require an external supply of thiamine for growth, microbiological methods may be employed for the determination of this vitamin. Caution should be exercised in the choice of microörganisms, however, since some can utilize portions of the thiamine molecule, or degradation products of the vitamin which are not biologically active for higher organisms. Successful microbiological assays have been conducted employing Lactobacillus fermentum 36, the growth of which, under the conditions of the test, is not stimulated by the pyrimidine or thiazole portions of the thiamine molecule, either alone or together. Results obtained by yeast fermentation methods are erroneous if the pyrimidine portion is present, since it stimulates yeast fermentation. Correction for this interference may be made by conducting a test on a sulfite-treated sample in which the thiamine is inactivated. ^{63,64}

Cocarboxylase may be determined specifically and directly by measurement of the carbon dioxide produced by the decarboxylation of pyruvic acid by yeast cells previously washed free of cocarboxylase. 66

Human thiamine deficiency, both clinical and subclinical, may be diagnosed by several biochemical procedures. These involve measurement of

the concentration of thiamine, cocarboxylase or pyruvic acid in the blood or urine. Since the levels of these compounds may fluctuate widely depending on the dietary intake for several days immediately preceding the test, a more reliable diagnosis is made when the response to a test dose of the vitamin is measured. A simple and reliable diagnostic test 66,67 involves colorimetric measurement (see p. 1066) of the urinary excretion of thiamine in the 4-hour period following intramuscular injection of 0.35 mg. of the vitamin per square meter of body surface, 12 hours after the last meal. Normal individuals excrete more and deficient subjects less than 50 γ of thiamine during the 4-hour period.

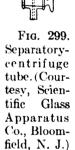

2. Modification of the Fluorometric Method of Hennessy and Cerecedo. 68 Principle. The thiochrome method for the determination of

thiamine involves extraction of the vitamin, dephosphorylation, purification by adsorption-elution, and oxidation. The fluorescent thiochrome is extracted with isobutanol and determined fluorometrically. For a general discussion of fluorometry see Chapter 23.

Procedure: Preparation of Sample: Extract a sample containing not more than 2 g. of solids by refluxing for 0.5 hour with 75 ml. of 0.1 N sulfuric acid. Cool to 40° C. If the material is rich in protein, add 0.5 g. of pepsin and incubate overnight at 37° C. Bring to 100° G. and then cool. Add 10 ml. of 1.8 M sodium acetate and adjust the pH to 4.5 if necessary. Add 0.5 g. of takadiastase and incubate overnight at 37° C., or 3 hours at 45-50° C. Cool. Dilute to 100 ml. with distilled water, and filter.

Pass an aliquot of the filtrate containing approximately 3–5 γ of thiamine through a base exchange tube⁵⁰ containing a column of activated zeolite.⁷⁰ Wash the column twice with 20-ml. portions of distilled water. Elute the vitamin with 25 ml. of 25 per cent potassium chloride in 0.1 N hydrochloric acid. Mix the eluate.

Pass a standard solution containing 5 γ of thiamine in acidulated water (pH 4.5) through a separate column, and elute as above.

Fluorometric Procedure: Pipet a 5-ml. aliquot of the eluate into each of two 30-ml. separatory funnels. Specially prepared separatory centrifuge tubes, (see Fig. 299) are particularly valuable for this purpose. To one, the test (T), add 3 ml. of potassium ferricyanide solution. Add 16.5 ml. of isobutanol to both, then 3 ml. of 15 per cent sodium hydroxide to the other, the

⁶⁶ Hochberg and Melnick: J. Biol. Chem., 156, 53 (1944).

⁶⁷ Melnick and Field: J. Nutrition, 24, 131 (1942).

⁶⁶ Hennessy and Cercedo: J. Am. Chem. Soc., 61, 179 (1939); Hennessy: Ind. Eng. Chem., Anal. Ed., 13, 216 (1941).

^{*}The base exchange tube contains a reservoir at the upper end having a capacity of approximately 30 ml., followed by a tube of 5 to 6 mm. internal diameter approximately 14 cm. long. At the lower end is a capillary of such diameter that when the tube is charged, the rate of flow will be approximately 1 ml. per minute.

⁷⁶ Approximately 50 mesh Decalso. Activate the zeolite by stirring with four 10-volume portions of 3 per cent acetic acid for 10 minutes each. Between the second and third acid wash, treat for 15 minutes with 5 volumes of 25 per cent potassium chloride solution. Wash the zeolite with water till free of chloride, then with alcohol, and ether. Dry in air and store in a sealed bottle. Place a pledget of glass wool over the upper end of the capillary, and pour a water suspension of 2 g. of the activated zeolite into the tube.

⁷¹ Dissolve 30 mg. of potassium ferricyanide in 100 ml. of 15 per cent sodium hydroxide.

blank (B). Shake the funnels for 1.5 minutes, centrifuge, and discard the aqueous phases. Clarify the isobutanol layers by shaking with approximately 1 g. of anhydrous sodium sulfate, transfer to cuvettes, and read in a fluorometer equipped with appropriate filters. ¹² Use an aqueous solution of quinine sulfate containing 0.2 γ per ml. in 0.1 N sulfuric acid to check the setting of the instrument.

Calculation. Calculate the thiamine content of the sample employing the formula:

$$\frac{T_u - B_u}{T_b - B_b} \times \frac{1}{5} \times \frac{25}{A} \times \frac{100}{G} = \gamma$$
 of thiamine per g. of sample

T_u equals the galvanometer reading obtained with the isobutanol extract of the unknown treated with ferricyanide; T_s is the corresponding value obtained with the standard; B_u and B_s are the galvanometer readings obtained in the blank tests conducted on the unknown and standard respectively; A is the volume of the unknown solution passed through the column; and G is the weight of sample taken for analysis.

3. Colorimetric Method of Hochberg, Melnick, and Oser. ⁷³ Principle. The red pigment formed in the reaction between thiamine and diazotized p-aminoacetophenone is measured in a photoelectric colorimeter. The method involves the preparation of a clear extract of the free vitamin, adsorption on and elution from a zeolite column, reaction with diazotized p-aminoacetophenone, extraction of the red pigment with xylene, and comparison with a standard similarly treated. The method is applicable to the determination of thiamine in urine. Here the extraction and enzymic hydrolysis are omitted, and the urine samples, after adjustment of the pH to 4.5, are passed directly through the zeolite column.

The use of large samples for analysis makes the colorimetric method sufficiently sensitive for the determination of thiamine in most products. However, it is not recommended for use in the assay of materials rich in protein but low in thiamine. Because large samples are taken for analysis, high concentrations of adsorbable amino acids are released which interfere with the retention of thiamine on the zeolite column.

Procedure: Preparation of the Extract: Weigh out a sample containing at least 20 γ of thiamine. A Reflux for 30 minutes with 150 ml. of 0.05 N sulfuric acid, cool to 50° C., and add 10 ml. of 1.8 M sodium acetate solution. Adjust the pH to 4.5 if necessary. Add 1 g. of takadiastase, and incubate the suspension 3 hours at 45–50° C. or preferably overnight at 38° C. Cool and dilute to 200 ml. Filter.

The apparatus used for the purification and concentration of the extract is shown in Fig. 301. A glass funnel is sealed to the top of a condenser. This is connected by means of a ground glass joint to a zeolite filter. The latter is a tube having an internal diameter of 8 mm. for a length of 12 cm. beyond the joint, followed by a constricted portion about 4 mm. in diameter. A

⁷² The fluorometer should be equipped with an ultraviolet light source and a filter with a transmission peak at 3700 Å. Between the glass cuvette and the photocell, insert a secondary filter with a transmission peak at 4600 Å. Since thiochrome is unstable to light, make the measurements rapidly and in a semi-dark room.

⁷³ Hochberg, Melnick, and Oser: Cereal Chem., 26, 83 (1945).

¹⁴ As much as 20 g. may be taken. Samples rich in protein should be hydrolyzed with 1 g. of pepsin at pH 1-2 after extraction.

plug of glass wool is placed above the constriction and the tube is filled with treated zeolite⁷⁵ to a height of 10 cm. This requires about 3 g. of the adsorbent. The zeolite filter is fastened to the bottom of the condenser by 2 two-inch steel springs, joined to glass hooks. At the bottom of the apparatus is a 2-liter suction flask which acts as a reservoir. This is equipped with a two-way stopcock for connection to suction or to the atmosphere. The receiving tube, calibrated at the 10-ml. mark, is suspended from glass hooks in the stopper of the flask to collect the eluate. The condenser, which acts intermittently as a steam jacket, is connected to a laboratory steam line, or to a 1-liter flask of boiling water equipped with a two-way stopcock.

Pass an aliquot of the filtered extract containing 15–50 γ of thiamine through the zeolite column at room temperature. Maintain a filtration rate of 3 or 4 drops per second with the aid of mild suction. Then pass steam through the outside jacket, and pour 30 ml. of water on the column. Allow to heat for one-half minute, then draw through with full suction to wash and heat the zeolite adsorbate. Elute the thiamine immediately by passing 10 ml. of 25 per cent potassium chloride solution in 0.1 N hydrochloric acid down the wall of the hot condenser. Collect at the rate of approximately 1 drop per 2 seconds, drawing through the final few drops by suction. Wash the zeolite column with 200 ml. of distilled water under full suction and with the steam on. Cool the column by running the last 50 ml. of wash through with the steam turned off. The apparatus is then ready for the next extract.

Pass a standard solution containing 30 γ of thiamine in 50 ml. of acidulated water at pH 4.5 through the column in the same manner as the test extract.

Colorimetric Procedure: Transfer the eluate to a 100-ml. centrifuge tube. Add [10 ml. of alcohol-phenol reagent, 76 previously poured into the receiving tube as a wash, then 2 drops of a 1 per cent alcoholic solution of thymol blue. Bring all samples to this point before proceeding. Handling one tube at a time, add 2 N sodium hydroxide dropwise, with constant stirring, till the first distinct blue color is produced, then immediately add 25 ml. of freshly prepared thiamine reagent. Add 5 to 15 ml. of xylene and shake vigorously for 3 minutes. Centrifuge. Transfer the xylene layer by means of a U-tipped pipet to a Nessler tube, a visual colorimeter cup, or the absorption cell of a photoelectric colorimeter (520 my filter), and evaluate versus the standard solution.

Calculation. The color intensity is linear in the range recommended. Calculate the thiamine content of the sample using the formula:

$$\frac{\mathrm{U}}{\mathrm{S}} \times 30 \times \frac{200}{\mathrm{G}} = \gamma$$
 of thiamine per g. of sample.

75 Prepare the adsorbent as directed in the thiochrome procedure above.

76 Dissolve 3.9 g. of phenol in 500 ml. of 95 per cent alcohol. Store in an amber glass bottle 77 Dissolve 0.635 g. of p-aminoacetophenone in 9 ml. of concentrated hydrochloric acid and dilute to 100 ml. with distilled water. Dissolve 22.5 g. of sodium nitrite in distilled water and dilute to 500 ml. Dissolve 20 g. of sodium hydroxide and 28.8 g. of sodium bicar-

bonate in distilled water and dilute to 1000 ml.

Diazonium Salt Solution: Pipet 5 ml. of p-aminoacetophenone solution into a 50-ml. cylinder surrounded with chopped ice and water and provided with a stirrer. Add 5 ml. of sodium nitrite solution slowly, and stir for 10 minutes. Add an additional 20 ml. of nitrite solution slowly with stirring and keep in the ice bath for 30 minutes longer. Store at a temperature below 5° C. and use the solution on the same day it is prepared.

Thiamine Reagent: Add 10 ml. of the diazonium salt solution to 137 ml. of sodium hydroxide-bicarbonate solution with vigorous stirring. Allow to stand till the initial pink coloration changes to pale yellow (5-20 minutes), then use immediately.

U/S is the ratio of the concentration of red pigment in the unknown to that in the standard (the ratio of the photometric densities when a photoelectric colorimeter is employed); G is the weight of the sample in grams.

Biological Methods. The symptoms of thiamine deficiency which have been adapted to biological assay are polyneuritis and anorexia. Pigeons. 78 chicks, 79 and rats 80 are employed in the methods based on cure or prevention of polyneuritis, which have the advantage of specificity but are not as adaptable to quantitative treatment as are growth methods. Curative methods are based on the duration of the cure of head retraction in birds or of paralytic convulsions in rats, resulting from feeding graded doses of the test material. The difficulty arises in determining precisely when the symptoms have advanced sufficiently to start the test and when "cure" is effected, the question being one of hours rather than days, and subject to considerable personal judgment. The pigeon curative method has strong defenders, particularly among English workers. Before the differentiation of vitamin B was established, most of the studies on the antineuritic properties of the vitamin B complex were conducted on pigeons, because rats, though they ceased to grow when deprived of this complex, rarely exhibited typical symptoms of polyneuritis. These can now be produced in rats by maintaining a state of partial deficiency in order that the rats survive long enough for the symptoms to appear. A method based on the growth response of rats to graded doses of thiamine has been adopted by the Association of Official Agricultural Chemists.

In the complete absence of thiamine, weanling rats show a gain in weight for the first week or so, followed by a rapid decline and death in 25–40 days. If life is prolonged on a submaintenance allowance of thiamine, the characteristic picture of polyneuritis appears, including lack of appetite, torpidity, spastic movements of the head and legs, and, in more severe cases, head retraction and paralysis of the hind legs. Lack of muscular coördination and a tendency to hold the head to one side and walk in circles are frequently manifested. (See Fig. 298, p. 1056.)

After 4–7 weeks, evidences of polyneuritis are seen, including incoördination, spasticity, and rolling movements. Spinning the rat by its tail will usually evoke convulsive seizures. When these become distinctive and consistent, the test foods or extracts are fed or injected in sufficient dosage to effect cure, the quantitative criterion being the minimum dose which will prevent a return of the symptoms for at least 5 days. This method, as adapted by the U.S. Pharmacopoeia, is described in full on p. 1070.

The rat growth method of Sherman and Chase⁸¹ has been the basis of many evaluations of the vitamin B₁ content of foods and, except for the

⁷⁹ Arnold and Elvehjem: J. Nutrition, 15, 403 (1937).

⁵⁰ Smith: U.S. Pub. Health Repts., 45, 116 (1930). The rat curative technic is the basis for the biological assay of the U.S. Pharmacopoeia for thiamine.

⁸¹ Chase, cited by Sherman and Smith: "The Vitamins," 2d ed., New York, Chemical Catalog Co. (now Reinhold Publishing Co.), 1931.

composition of the basal diet, is substantially the biological assay method for thiamine tentatively adopted by the A.O.A.C. see below, and Fig. 300).

Coprophagy must be prevented in assays for the B vitamins since bacterial synthesis in the intestinal tract may produce significant concentrations of vitamins. Thus rats may grow on a B-free diet, this condition being known as "refection." Partial digestion of the starch (dextrinization or gelatinization) in the diet by boiling is practiced to avoid refection.

Rat Assay for Thiomine: Method of Sherman and Chase with Modifications, Including Those of the Association of Official

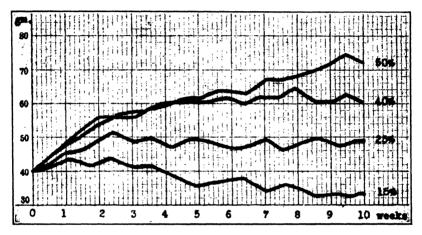

Fig. 300. Showing average growth response in a thiamine assay. Groups of 4 rats each received a ration in which 15, 25, 40, and 50 per cent, respectively, of whole wheat (replacing equivalent amounts of starch) was the sole source of thiamine. Body weight was maintained at the 25 per cent level.

Agricultural Chemists. 88 Principle. Rats, depleted of their thiamine reserves by means of a vitamin B₁-free basal diet, are fed graded supplements of thiamine in the form of the standard or test materials. The relative growth responses to the doses of assay material and of pure thiamine constitute the basis for evaluation.

Procedure: Healthy rats not exceeding 28 days of age and weighing between 40 and 50 g. are placed in individual cages with raised wiremesh floors (not less than 8×8 mm. mesh). Water and basal diet are fed ad libitum.

BASAL THIAMINE-DEFICIENT DIETS

Sherman and Chase	A.O.A.C.
Casein (thiamine-free)84 18 Starch85 53 Salt mixture85 4 Butterfat87 8 Codliver oil87 2 Autoclaved bakers' yeast88 15	Sucrose 60 Salt mixture*6 4 Liver extract 1 Codliver oil 2

The rats are weighed at intervals not exceeding 3 days. After 10 (but before 30) days the rats are depleted, as evidenced by stationary or declining weight over any 5-day period. They are then assembled into groups of 8 or more, one group being maintained on the basal diet as the negative control, the remainder receiving either graded doses of U.S.P. thiamine hydrochloride (0.1 ml. = 3.0 γ thiamine) fed directly into the mouth by means of a syringe with a blunt-edged 18-gauge needle, or measured doses of the assay material corresponding in expected thiamine content to the amounts of standard fed to the reference groups. The intervals between doses should be constant for both reference and assay groups; each dose is computed by multiplying the next lower dose by a constant factor (e.g., 1.5 or 2).

Calculation. During the 4-week assay period, weights are recorded at weekly intervals. The average net gains of the reference groups are plotted and the average gains of the assay groups interpolated on this curve in terms of thiamine content for each dose level of the assay material.

If desired the data may be treated statistically according to the analysis of variance illustrated for vitamin A in Appendix VIII.

Results are preferably expressed in gravimetric units—e.g., mg. of thiamine per 100 g. of assay material; the International or U.S. Pharmacopoeial unit is the potency of 0.003 mg. (3 γ) of crystalline thiamine hydrochloride.

BIOLOGICAL ASSAY FOR THIAMINE

Method of the U.S. Pharmacopoeia XIII.894

The biological assay, comprising the recording of observations of rats throughout

- Thiamine-free casein may be prepared as follows: Stir 400 g. of casein with 2 liters of 60 per cent (by weight) alcohol for ½ hour, let stand 5½ hours, filter with suction, and wash with 1 liter of 60 per cent alcohol. Repeat, letting stand 18 hours and adding a final wash with 1 liter of 90 per cent (by weight) alcohol. Spread on trays to dry in air. Vitamin-free casein is supplied by the Borden Co., Bainbridge, N. Y., and by General Biochemicals, Chagrin Falls, Ohio.
 - 55 See p. 1069.
 - ** See U.S.P. salt mixture 1, p. 1163.
- ⁸⁷ In place of butterfat and codliver oil, 10 per cent hydrogenated vegetable oil may be used together with 2000 U.S.P. units of vitamin A and 200 units of vitamin D per 100 g. of basal diet added in the form of high-potency fish liver oil or concentrate.
 - ⁸⁸ See footnote 93, p. 1072.
 - ** See footnote 94, p. 1072.

specified periods of their lives while being maintained on specified dietary regimens and the interpretation of such data, is as follows:

Preliminary Period. Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the thiamine hydrochloride intake may be restricted.

Depletion Period. A rat shall be suitable for the depletion period when the age of the rat does not exceed 30 days, and if the body weight of the rat does not exceed 50 g., and if the animal manifests no evidence of injury or disease or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the thiamine hydrochloride test diet and water (U.S.P.) ad libitum, and during this period no other dietary supplement shall be available to the animal. Throughout the depletion period and until the assay shall have been completed the rats shall be kept in cages provided with a wire-cloth bottom, each mesh of which shall be not less than 8 mm.

Assay Period. A rat shall be suitable for the assay period provided that the depletion period shall not have exceeded 75 days, and provided that the rat shall manifest evidence of thiamine hydrochloride deficiency characterized by acute polyneuritis. Throughout the assay period each rat shall be kept in an individual cage and provided with the thiamine hydrochloride test diet, compounded from the same lots of ingredients, and water (U.S.P.) ad libitum. On the day beginning the assay period there shall be administered to each rat a single dose of the reference standard of such size that it will produce in individual animals a curative period of not less than 5 days and not more than 15 days. All of the rats used in any one assay shall receive the same quantity of the reference standard. Each rat shall then be observed for the cure of and recurrence of polyneuritis, and when polyneuritis reaches the same acute stage observed when the reference standard was administered, a single dose of the assay product shall be administered. The animals shall then be observed to determine if polyneuritis is cured, and if so, observation shall be made of the duration of the period. Each assay shall include successive administration of the reference standard and assay product to not less than eight rats. The assay product may be administered orally or parenterally but in any one assay the reference standard shall be administered in the same manner as the assay product, and the quantity of the assay product administered to each rat shall be the same.

Recording of Data. On the day beginning the depletion period and at intervals of not more than 7 days during the depletion period, a record shall be made of the body weight of each rat. On about the twenty-fifth day and each day thereafter for the remainder of the depletion period, each rat shall be observed for symptoms of polyneuritis. The following dates shall be recorded:

- 1. The day on which the reference standard is administered.
- 2. The day on which cure of polyneuritis is observed following the administration of the reference standard.
- 3. The day on which acute polyneuritis recurs and the assay product is fed.
- 4. The day on which cure of polyneuritis is observed following the administration of the assay product.
- 5. The day on which acute polyneuritis recurs after the administration of the assay product.

Thiamine Hydrochloride or Vitamin B₁ Potency of the Assay Product. In determining the thiamine hydrochloride potency of the assay product the duration of the curative period following the administration of the reference standard and the assay product shall be considered. The dose of the assay product administered contains an amount of the thiamine hydrochloride equal to or greater than that contained in the dose of the reference standard administered if that quantity promotes in the assay animals a total curative period (the sum of the number of days of the curative period of each of the animals) equal to or greater than the total curative period produced by administration of the reference standard.

Definitions. As used herein, unless the context otherwise indicates, the term acute polyneuritis means that stage of thiamine hydrochloride deficiency in which the animal regains control of the voluntary muscles, as evidenced by standing or walking, a few seconds after extreme muscular contraction, which has been induced by twirling the rat by its tail (the onset of acute polyneuritis is invariably accompanied by loss in body weight). The term assay period means the interval in the life of a rat between the last day of the depletion period and the final observation following the administration of the assay product; the term assay product means a product under examination for its thiamine hydrochloride potency; the term curative period is the interval of time between the administration of thiamine hydrochloride and the subsequent recurrence of acute polyneuritis after a complete disappearance of polyneuritic symptoms, and the duration of the curative period is expressed as the number of days in that interval; the term cure of polyneuritis means the complete disappearance of polyneuritic symptoms and is invariably accompanied by increase in body weight; the term depletion period means the interval in the life of a rat during which its food intake is only the thiamine hydrochloride test diet and water (U.S.P.); the term preliminary period means the interval in the life of a rat prior to the depletion period; the term reference standard means the U.S.P. Thiamine Hydrochloride Reference Standard 90; the term thiamine hydrochloride test diet means a uniform mixture, which has not been compounded for more than 7 days, of the following food materials and in the proportions designated:

Thiamine Hydrochloride or Vitamin B₁ Test Diet-

Sucrose	60.25 per cent
Casein 91	18 per cent
Salt mixture 92	4 per cent
Autoclaved yeast ⁹³	5 per cent
Autoclaved peanuts ⁹⁴	10 per cent
Purified liver extract 95	
Codliver oil	

^{*} Suggestions for Using the U.S.P. Thiamine Hydrochloride Reference Standard.

Before preparing a solution of the Reference Standard, dry it to constant weight in a desiccator over phosphorus pentoxide.

Precautions to Be Taken in the Preparation of Solutions. Because of the hygroscopic nature of the completely desiccated U.S.P. Thiamine Hydrochloride Reference Standard, it is preferable to transfer the quantity required for a test to a small glass-stoppered weighing bottle, in which it can then be weighed on a microbalance, or an ordinary balance according to the number of tests for which it is to be used. Even without such precautions, however, exposure to the air during weighing will not cause an increase in weight of more than about 0.6 per cent, if the operations are completed within 5 minutes.

Neutral and alkaline solutions of thiamine hydrochloride are unstable, and water acid solutions are readily infected by molds, which inactivate the vitamin. Therefore, stock solutions should be prepared using 25 per cent alcohol and containing sufficient hydrochloric acid to make the solution approximately 0.05 normal. A convenient strength for a stock solution is 0.5 mg. of thiamine hydrochloride to each ml. These solutions are stable if stored at about 4°.

Solutions of suitable strength for animal dosage (20 to 100 micrograms per ml.) must be made at least twice weekly from the stock solution by dilution with water. Such dilutions must be kept at a low temperature and examined daily for mold.

- ⁹¹ The casein shall be free from demonstrable traces of thiamine hydrochloride. (See footnote 84 p. 1070.)
- ⁹² The salt mixture shall be either salt mixture No. 1, described on p. 1163, or a salt mixture having essentially the same proportions of the elements.
- ⁹³ Dried yeast which has been autoclaved in steam at 15 pounds pressure for 5 hours with the yeast spread in a layer not more than 6 mm. in depth and then dried at a temperature not exceeding 65°.
- ⁹⁴ Unroasted shelled No. 1 grade Virginia peanuts are crushed in a food chopper, autoclaved in steam at 15 pounds pressure for 5 hours with the ground peanuts spread in a layer not more than 12 mm. in depth, and then dried at a temperature not exceeding 65°. This preparation may be incorporated in the basal diet by grinding with the requisite quantity of sucross.
 - % Dissolve 100 g. of Liver Extract in 1 liter of 0.6 per cent sodium bisulfite solution. Let

RIBOFLAVIN

One of the most common vitamin deficiencies in man is ariboflavinosis. The disease occurs more frequently among infants and children⁹⁶ than among adults and since its prevention depends upon an adequate diet it occurs most often among low income groups.⁹⁷

The growth-promoting effect of certain water-soluble yellow dyes extracted from foods was noted by several investigators early in 1933. The biological activity was proportional not only to the intensity of the yellow color, but also to the fluorescence of the extracts. Kuhn, György, and Wagner-Jauregg isolated crystalline riboflavin from several foods and demonstrated the growth-promoting properties of the vitamin on rats. Riboflavin was synthesized shortly thereafter. The clinical syndrome of ariboflavinosis was first described in 1938 by Sebrell and Butler. 101

The naturally occurring flavins—lactoflavin, ovoflavin, hepatoflavin, and verdoflavin—isolated respectively from milk, eggs, liver, and grass, are all chemically identical with riboflavin. This is not true, however, of uroflavin, a fluorescent compound of unknown structure with properties similar to riboflavin and excreted in the urine along with the vitamin, following the ingestion of riboflavin.

Physiological and Clinical Aspects of Riboflavin. Vitamin B₂ deficiency affects primarily the ectodermal tissues, producing lesions of the skin, eve. and nervous system. One of the earliest symptoms is cheilosis. manifested at first by transverse fissures at the corners of the mouth, raw and scaly lips, and finally by many vertical, deep fissures. In ariboflavinosis. the tongue assumes a purplish or magenta tinge and glossitis (flattening of the papillae) is observed. A seborrheic dermatitis occurs at the body folds; e.g., at the alae nasi. The ocular manifestations of riboflavin deficiency include dryness, burning and itching, photophobia and lacrimation, and vascular invasion particularly at the scleral junction of the cornea. Cataracts due to pigmentation and capillary invasion of the cornea are known to occur in animals on a riboflavin-deficient diet, but it is uncertain to what extent human cataracts result from dietary causes. Though these symptoms may not individually be specific, cheilosis, glossitis, seborrheic dermatitis, and corneal vascularization constitute a group of signs which separately or in combination are observed in ariboflavinosis. The symp-

stand 24 hours in a well-stoppered bottle; acidify with hydrochloric acid to a pH of 1.5. Concentrate by distillation under reduced pressure at a temperature not exceeding 50° to one-half the original volume. Dry on vitamin B₁-free casein at a temperature not exceeding 65°. The Liver Extract used in this *Test Diet* must contain, in each g., at least that amount of material from liver which, when given daily to patients with pernicious anemia, has produced a satisfactory hematopoietic response.

tomatology of clinical riboflavin deficiency is outlined in the syllabus on p. 1186.

Clinical tests of the riboflavin content of blood and urine have been employed for the diagnosis of riboflavin deficiency. Normal individuals have a blood level of 0.5γ per ml. and when subsisting on an adequate diet excrete 500 to 800γ per day in the urine. Because the excretion and blood levels show diurnal variations depending upon the dietary intake immediately preceding the tests, a more reliable diagnostic procedure involves measurement of the urinary excretion for four hours following the intravenous injection of 1 mg. of riboflavin. 102 Blood riboflavin may be determined both by the microbiological procedure, employing Lactobacillus casei, and by the fluorometric method. In addition to riboflavin, the latter measures uroflavin, a metabolite of the vitamin.

Riboflavin is required by all animals and many microörganisms. A deficiency of the vitamin in young animals results in inhibition of growth terminated by death. In rats, the syndrome includes early atrophy of the testes, involution of the thymus, alopecia, cataract, and degeneration of the main peripheral nerve trunks. Riboflavin is essential for normal egg production and hatchability in fowls. Peripheral nerve degeneration in chicks is responsible for "curled toe paralysis." In monkeys, riboflavin deficiency results in anemia and leukopenia.

Riboflavin plays an important role in many enzyme systems. In 1932, Warburg and Christian isolated a vellow respiratory enzyme from yeast. 103 This enzyme has been shown to consist of a combination of riboflavin. phosphoric acid, and a protein. The riboflavin phosphate, a mononucleotide, can be separated from the protein (appenzyme) by dialysis against a weak acid. Neither fraction alone possesses enzymic activity, but the two may be recombined in neutral solution to produce the original enzyme. The vellow enzyme of Warburg and Christian can participate in a series of enzyme reactions involved in the metabolism of carbohydrates. It is capable of transporting hydrogen from reduced coenzyme II. a niacin enzyme which attacks hexosemonophosphate, for example, regenerating that enzyme of first attack. The reduced vellow enzyme may be reoxidized itself by molecular oxygen. This series of reactions, however, is extremely slow and is probably of no physiological significance. Two other enzymes. cytochrome c reductase¹⁰⁴ and *l*-amino acid oxidase.¹⁰⁵ contain riboflavin phosphate. The former transports hydrogen from reduced coenzyme II to cytochrome c at a rate which is sufficiently rapid to be physiologically important. This suggests that riboflavin functions in the oxidationreduction metabolism of plant and animal tissues. l-Amino acid oxidase catalyzes the oxidation of l-amino acids and of α -hydroxy

Riboflavin mononucleotide

Riboflavin-adenine dinucleotide

Riboflavin also participates in enzyme reactions as a dinucleotide prosthetic group, consisting of riboflavin, two phosphoric acids, ribose, and adenine. This coenzyme is found in xanthine oxidase, diaphorase, d-amino acid oxidase, a synthetic enzyme of Warburg and Christian, fumaric hydrogenase, liver aldehyde oxidase, and the Haas enzyme. Xanthine oxidase¹⁰⁶ (Schardinger enzyme, aldehydrase) is found in liver and milk and catalyzes the oxidation of aliphatic and aromatic aldehydes, reduced coenzyme I (another niacin enzyme) and of a number of purines (includ-

ing xanthine and hypoxanthine). In the presence of air, the reduced enzyme transfers its hydrogen to oxygen, forming hydrogen peroxide which inhibits further action. The accumulation of hydrogen peroxide is prevented by the presence of catalase, an iron-porphyrin-protein enzyme which catalyzes the decomposition of hydrogen peroxide to water and oxygen. The hydrogens of xanthine oxidase, like those of numerous other reduced enzymes, can be accepted also by methylene blue and by other oxidizing dyes. Two different diaphorases 107 have been found in plants, animal tissues, and microörganisms. In the presence of suitable proteins, one of these oxidizes reduced coenzyme I and reduced coenzyme II. d-Amino acid oxidase¹⁰⁸ found in animal tissues, notably kidney and liver, converts d- α -amino acids to α -keto acids. Different d-amino acids are acted upon at different rates by this enzyme. Fumaric hydrogenase, another enzyme which contains riboflavin dinucleotide, catalyzes the reduction of fumaric acid in the presence of certain reduced dyes¹⁰⁹ to succinic acid. Aliphatic and aromatic aldehydes are oxidized by liver aldehyde oxidase, 110 a riboflavin dinucleotide enzyme found in the liver of mammals.

The riboflavin enzymes, called flavoproteins, may be dissociated more or less easily and the original enzyme reconstituted by recombining the mono- or dinucleotide with the original protein. The synthetic enzyme of Warburg and Christian¹¹¹ consists of the dinucleotide added to the protein of the old yellow respiratory enzyme. The new enzyme differs from the natural enzyme obtained from yeast only in that it contains the dinucleotide in place of the mononucleotide as its prosthetic group; it has the same properties as the old yellow respiratory enzyme. The Haas enzyme consists of the dinucleotide plus a protein from yeast and has the same activity as the old yellow enzyme.

Free riboflavin is phosphorylated in the intestines of higher animals, probably by an enzymatic reaction in which a secretion of the adrenals plays an important part. When iodoacetic acid (an inhibitor of many enzymatic reactions) is administered, or when the adrenals are removed, phosphorylation does not take place and the vitamin is not absorbed from the intestinal tract. Under these conditions, riboflavin is unable to support growth, whereas the phosphate is effective. Human blood cells are capable of synthesizing the dinucleotide from free riboflavin both *in vivo* and *in vitro*. 112

Since flavoproteins are composed of both riboflavin nucleotides and specific proteins, disturbances in metabolism may result from diminished intake of either constituent. A deficiency of dietary riboflavin results in a decreased concentration of d-amino acid oxidase in liver and kidney¹¹³

and of xanthine oxidase in liver.¹¹⁴ Both of these conditions may be prevented or improved by feeding riboflavin. The d-amino acid oxidase activity of liver from animals on diets low in riboflavin may be restored by the *in vitro* addition of the nucleotide to the excised tissue.¹¹⁵ On the other hand, rats on a low protein diet do not retain dietary riboflavin in the liver, a condition which may be prevented by the administration of methionine. Likewise, liver slices from riboflavin-deficient rats are unable to inactivate estradiol; this ability is retained when methionine is fed. These observations illustrate the interrelationship of riboflavin with protein metabolism and with endocrine function.

Riboflavin is concerned with the regulatory function of the hormones involved in carbohydrate metabolism. The administration of thyroxine to rats causes the loss of liver glycogen unless riboflavin and thiamine are fed simultaneously. The administration of insulin is effective in depancreatized dogs only when these two vitamins are fed. Riboflavin has been employed successfully in the treatment of dark adaptation in certain cases where vitamin A was ineffective. The retina contains free riboflavin which is converted by light to a compound which is involved in stimulation of the optic nerve.

Riboflavin and its two nucleotides are the only naturally occurring compounds which have vitamin B₂ activity. However, several synthetic compounds have been prepared having approximately one-half of the activity of riboflavin. These vitamers lack a methyl group in the six or seven position, or have this group substituted by an ethyl group. Removal of both methyl groups results in the formation of a highly toxic compound. Substitution of an alkyl group in the three position destroys the vitamin activity of riboflavin.

The minimum requirement of riboflavin necessary to maintain tissue stores in man has been estimated as approximately 0.5 mg. per 1000 calories. ¹¹⁶ The recommended dietary allowances of the Food and Nutrition Board of the National Research Council are about 0.6 to 0.7 mg. per 1000 calories as indicated in the table on p. 1027. These allowances are more liberal than minimal requirements in order to provide a margin of safety. Under normal conditions, with an adequate dietary supply of riboflavin, humans excrete approximately one-third of their intake. When larger amounts are ingested, approximately half is excreted in the urine. Very large doses of riboflavin have been fed to dogs and rats with no evidence of toxicity.

Storage and Synthesis of Riboflavin. Riboflavin is not stored to any considerable extent in animal organs, though higher concentrations are found in the liver and kidney than in other tissues. In plants the younger parts are richer than the older. Broccoli leaves contain twice as much riboflavin as the flower buds; the latter contain more than the stems. Ungerminated seeds, other than peas, contain little riboflavin but appreciable amounts are formed during germination.

¹¹⁶ Williams, Mason, Cusick, and Wilder: J. Nutrition, 25, 361 (1943).

Riboflavin is synthesized by most higher plants, by yeasts, and by some bacteria. Though higher animals are unable to synthesize the vitamin themselves, it is produced to a variable extent by microörganisms in the intestinal tract. In the rat this process is influenced by the nature of the carbohydrate in the diet. The ingestion of dextrin and corn starch favors synthesis, whereas sucrose is ineffective. In ruminants, the contribution of riboflavin by bacteria in the rumen is so great that a dietary source of riboflavin is not necessary. 117

Riboflavin is synthesized commercially and the product is employed on a large scale in bread and flour enrichment and for pharmaceutical purposes. Natural concentrates prepared from whey, yeast, and the anaerobic bacterial fermentation of distillers' slops are widely employed in animal feeds.

Distribution of Riboflavin. 118 Riboflavin is widely distributed in plant and animal tissues as free riboflavin, as the phosphate, or as the adenine-dinucleotide phosphate. The free vitamin is found, for example, in milk, urine, and retina. Riboflavin nucleotides occur more or less firmly bound to proteins. Excellent dietary sources of riboflavin are heart, liver, kidney, muscle, eggs, milk, green leafy vegetables, yeast, and whole grain. The riboflavin content of the average American diet before and after enrichment of bread and flour was 1.4 and 1.6 mg, per day, respectively.

Chemistry of Riboflavin. Riboflavin crystallizes in orange-yellow needles which melt at 282° C. with decomposition. Riboflavin is insoluble in acetone, benzene, chloroform, and ether, and only slightly soluble in water (12 mg. per 100 ml. at room temperature), but very soluble in alkaline solution. Derivatives more soluble in water, such as the monosuccinate, borate, phosphate, and acetate, have been prepared for pharmaceutical use. The vitamin is adsorbed by fuller's earth in acid solution and by frankonit in neutral solution but not by tale, aluminum oxide, calcium carbonate, kaolin, or kieselguhr; it is eluted by 80 per cent acetone or by alkalies such as pyridine-methanol-water mixtures or ammonia water.

Riboflavin forms a yellow solution having a yellow-green fluorescence. It has a characteristic absorption spectrum in the ultraviolet and visible regions, with absorption maxima at 225, 269, 372, and 445 mµ. When exposed to ultraviolet radiation, it shows a fluorescence having a maximum at 565 mu at pH 6. In acid or alkaline solutions (below pH 3 or above pH 9) the fluorescence of riboflavin increases considerably. Riboflavin is amphoteric, having an isoelectric point at pH 6. It is optically active; $[\alpha]_{D}^{20} = -114^{\circ}$ in 0.1 N sodium hydroxide, this value decreasing in neutral or acid solution. Riboflavin is stable to heat in neutral and acid but not in alkaline solutions. It is also unstable to visible and ultraviolet radiation, especially at alkaline pH and at elevated temperatures. The riboflavin content of milk in clear bottles exposed to light may drop 50 per cent or more in a few hours. Alkaline irradiation of riboflavin produces lumiflavin, a fluorescent degradation product soluble in chloroform. In

118 See Appendix III.

¹¹⁷ McElroy and Goss: J. Nutrition, 20, 527 (1940).

neutral or acid solution, lumichrome is formed. Riboflavin is easily reduced by hydrogen in the presence of a catalyst, by zinc in acid, by sodium hydrosulfite, by hydrogen sulfide in alkaline solution, and by other reducing agents, as shown in the equation below.

Leucoriboflavin, the reduction product, is a colorless nonfluorescent compound which is easily reoxidized by shaking with air in solution. The oxidation-reduction reaction is probably of great importance in the function of riboflavin nucleotide in cellular respiration.

Riboflavin may be converted to its mononucleotide, riboflavin phosphate, by treatment with phosphorus oxychloride, or by suspending it in a phosphate buffer with intestinal epithelial powder.

Determination of Riboflavin. Chemical methods for the determination of riboflavin are based upon colorimetric 119 and fluorometric 120 measurements. These procedures are not generally applicable to food materials because of the presence of interfering colored and fluorescent compounds. Foreign pigments interfere not only with the colorimetric determination of riboflavin but also with the fluorometric procedure in which the activating and fluorescent light are quenched. Some interfering pigments may be destroyed in the chemical tests by oxidation with potassium permanganate or by reduction with stannous chloride. Reduction of riboflavin by treatment with sodium hydrosulfite has been employed for the estimation of the color or fluorescence produced by interfering substances. Correction is made for the quenching effect of foreign pigments or other factors by the internal standard procedure. One method for the chemical determination of riboflavin¹²¹ involves the conversion of the vitamin by irradiation with visible light in alkaline solution to lumiflavin. The latter is extracted

¹²¹ Kuhn, Wagner-Jauregg, and Kaltschmitt: Ber., 67, 1452 (1934).

by chloroform in acid solution and then determined colorimetrically or

fluorometrically.

The microbiological determination of riboflavin depending upon the growth stimulation of Lactobacillus casei is far more generally applicable to the determination of the vitamin in foods than the chemical methods. The microbiological procedure is sensitive and specific, and has been adopted as an official method by the U.S. Pharmacopoeia. It has been found that the growth of Lactobacillus casei in the presence of riboflavin is stimulated by suspended particles such as fat and starch. It is therefore essential to conduct the test on crystal-clear extracts. These are sometimes difficult to obtain when starchy samples are tested. Digestion with mylase or takadiastase is often helpful.

Determination of Riboflavin: Modified Microbiological Method of Snell and Strong: Principle. Riboflavin is determined by measurement of the growth stimulation of *Lactobacillus casci*. The acid produced by the microörganism is determined by titration with sodium hydroxide.

Procedure: Preparation of Sample: Conduct all operations in dim light. Weigh out a sample containing approximately 200 γ of riboflavin and heat in an autoclave with 400 ml. of 0.1 N hydrochloric acid for 30 minutes at 15 pounds pressure. Cool and adjust to pH 4.5 with 1 N sodium hydroxide. Dilute to 1000 ml. and filter through a fine filter paper which does not adsorb riboflavin. Adjust a 100-ml. aliquot of the clear filtrate to pH 6.8 with 1 N sodium hydroxide solution and dilute to 200 ml. Filter again if the solution is not clear.

Prepare the following solutions:

Yeast Extract Solution: Heat a suspension of 500 g. of fresh, starch-free bakers' yeast in 5 liters of distilled water for 2 hours in flowing steam, then autoclave for 40 minutes at 15 pounds pressure. Allow the suspension to settle, filter, and evaporate the filtrate to 125 ml. under reduced pressure below 50° C.

Yeast Supplement Solution: Add 125 ml. of an aqueous solution containing 38 g. of lead subacetate to 125 ml. of yeast extract solution. Filter and adjust the filtrate to pH 10 with ammonia. Filter and adjust the pH to 6.5 with glacial acetic acid. Treat the solution with hydrogen sulfide, filter off the lead sulfide, and dilute the filtrate to 250 ml. with water. Preserve under toluene in a refrigerator.

Photolyzed Peptone Solution: Dissolve 40 g. of peptone in 250 ml. of distilled water, and 20 g. of sodium hydroxide in 250 ml. of distilled water. Mix the solutions and irradiate 6 to 10 hours in a crystallizing dish (diameter 24 cm.) one foot from a 100-watt bulb fitted with a reflector; then allow the mixture to stand for the remainder of a 24-hour period, keeping the temperature below 25° C. during the entire treatment. Adjust to pH 7 with glacial acetic acid, add 7 g. of anhydrous sodium acetate, and dilute to 800 ml. Store under toluene in a refrigerator.

Cystine Solution: Dissolve 1 g. of *l*-cystine in 20 ml. of 10 per cent hydrochloric acid and dilute to 1000 ml. with distilled water. Store under toluene in a refrigerator not below 10°.

Salt Solution A: Dissolve 25 g. of monobasic potassium phosphate and 25 g. of dibasic potassium phosphate in distilled water and dilute to 250 ml. Salt Solution B: Dissolve 10 g. of magnesium sulfate, 0.5 g. of sodium chloride, 0.5 g. of ferrous sulfate, and 0.5 g. of manganese sulfate in distilled water and dilute to 250 ml.

¹²³ Snell and Strong: Ind. Eng. Chem., Anal. Ed., 11, 346 (1939). See also U.S. Pharma-copoeia XIII.

Reference Standard Solution: Dissolve 50 mg. of U.S.P. riboflavin reference standard in 500 ml. of distilled water containing 1 ml. of glacial acetic acid. Preserve this stock solution under toluene in an amber bottle in the refrigerator. For each set of assays, dilute 1 ml. of this solution to 1000 ml. with distilled water. This solution contains 0.1 γ of riboflavin per ml.

Basal Medium Stock Solution: Dissolve 15 g. of anhydrous dextrose in a mixture of 50 ml. of photolyzed peptone solution, 50 ml. of cystine solution, 5 ml. of yeast supplement solution, 2.5 ml. of salt solution A, and 2.5 ml. of salt solution B. Adjust to pH 6.8 with 1 N sodium hydroxide and dilute to 250 ml.

Preparation of the Stock Culture: Dilute 10 ml. of yeast extract solution to 100 ml. with distilled water, and add 1 g. of anhydrous dextrose and 1.5 g. of agar. Heat on a steam bath to dissolve the agar. Add approximately 10 ml. portions of the hot solution to test tubes, plug with non-absorbent cotton and sterilize in an autoclave at 15 pounds pressure for 20 minutes. Allow to cool in an upright position. Prepare several stab cultures of Lactobacillus casei (American Type Culture Collection No. 7469) and incubate for 16 to 24 hours at any constant temperature between 30° and 37° C. Finally store in a refrigerator. Prepare a fresh stab every week, and do not use for inoculum if more than 2 weeks old.

Preparation of the Inoculum: To each of two tubes containing 5 ml. of the basal medium stock solution, add 5 ml. of distilled water containing 1 γ of riboflavin. Autoclave at 15 pounds pressure for 20 minutes and cool. To one of the tubes make a transfer of cells from the stock culture of Lactobacillus casei and incubate for 16 to 24 hours at any constant temperature between 30° and 37°. Transfer one drop of this culture to the second tube and incubate again for 16 to 24 hours. Centrifuge the culture under aseptic conditions and decant the supernatant liquid. Suspend the cells in 10 ml. of sterile isotonic solution of sodium chloride.

Assay: In duplicate tubes, 16 by 150 mm. in size, place respectively 0.5, 1.0, 1.5, and 2.0 ml. of the extract of the test material. To each add 5 ml. of the basal medium stock solution and sufficient distilled water to bring the volume in each tube to 10 ml. Prepare a similar set of duplicate tubes containing respectively 0.00, 0.05, 0.10, 0.15, 0.20, 0.30, and 0.50 γ of standard riboflavin. Mix the solutions thoroughly, plug the tubes with non-absorbent cotton, and autoclave at 15 pounds pressure for 20 minutes. Cool aseptically, add 1 drop of inoculum to each tube, and incubate for 72 hours at any constant temperature between 30° and 37° C. Keep all the tubes in darkness or semidarkness during their preparation and incubation, and protect against contamination by foreign microörganisms. Transfer the contents of each tube to a small Erlenmeyer flask, using a fixed volume of distilled water for rinsing. Titrate with 0.1 N sodium hydroxide using bromthymol blue as the indicator.

Calculation. On ordinary graph paper, plot the average titrations in ml. of 0.1 N sodium hydroxide against γ of riboflavin in the series of standard tubes. From this standard curve, estimate the riboflavin content of each ml. of the test solution in each duplicate set of tubes. Calculate the riboflavin content of the test material from the average values obtained from not less than three sets of these tubes which do not vary by more than ± 10 per cent from the average.

Comment. The microbiological method for the determination of ribo-flavin employing *Lactobacillus casei* is highly sensitive and shows a good degree of specificity for the vitamin. It has the additional advantage that the determination may be conducted turbidimetrically after 18 hours of incubation (see p. 1109).

Principle. The fluorometric procedure for the determination of riboflavin depends upon the extraction of the vitamin with dilute acid, filtration, treatment of the filtrate with permanganate and hydrogen peroxide to destroy interfering pigments, and measurement of the fluorescence. The vitamin content of the extract is evaluated by means of an internal standard.

Procedure: Suspend a finely ground sample containing approximately 5 γ of riboflavin in 75 ml. of 0.1 N sulfuric acid. Heat in an autoclave for 15 minutes at 15 pounds pressure, or in a boiling water bath for 45 minutes with intermittent shaking. Cool the suspension and adjust the pH to 4.3 with 2.5 M sodium acetate. Dilute to 100 ml., shake well, and filter through Whatman No. 1 or No. 40 filter paper. Discard the first 15 ml. of filtrate. Treat 60 ml. of the filtrate with 2 ml. of 4 per cent potassium permanganate solution. After 3 minutes, discharge the permanganate color with freshly prepared 3 per cent hydrogen peroxide solution. Break the froth with a few drops of acetone, and dilute to 65 ml. with distilled water. Mix and filter. Pipet out two 15-ml. portions of the filtrate. To one, add 1 ml. of distilled water and measure the fluorescence (A) (see p. 1083). To the other, add 1 ml. of riboflavin standard solution containing 1 γ of the vitamin, and measure the fluorescence (B). Obtain the blank (C) after adding 20 mg. of sodium hydrosulfite to A or B.

Calculation. Obtain the riboflavin content of the sample using the formula,

$$\frac{A-C}{B-A} \times \frac{1}{15} \times \frac{65}{60} \times \frac{100}{G} = \gamma$$
 of riboflavin per g. of sample

where G is the weight of the sample taken and A, B, and C are as indicated above.

Comment. The fluorometric method may be employed for the determination of the riboflavin content of yeast, white flour, bread, milk powder, and similar products. However, for samples which yield highly pigmented extracts, or for materials containing less than 1γ of riboflavin per g. of solids, the microbiological procedure is preferred.

Determination of Riboflavin in Urine: Fluorometric Method of Najjar: 124 Principle. The riboflavin is extracted with acetic acid-pyridine-butanol mixture after interfering urinary pigments are oxidized with permanganate. The concentration of riboflavin in the extract is measured fluorometrically.

Procedure: Collect a 24-hour urine sample in a brown glass bottle containing 20 ml. of 10 per cent sulfuric acid. Since riboflavin is destroyed by light, conduct all of the following operations in semidarkness. Measure the volume. Transfer an aliquot containing approximately 5 γ of riboflavin to a 100-ml. centrifuge cup, and add sufficient water to make the volume 10 ml. Add 2 ml. of glacial acetic acid and 4 ml. of colorless pyridine and mix. For each ml. of urine, add 2 drops of 4 per cent KMnO₄. After exactly 1 minute, decolorize the excess permanganate with a few drops of freshly prepared 3 per cent hydrogen peroxide solution. Add 10 g. of anhydrous sodium sulfate, then 20 ml. of n-butanol. Shake vigorously for 5 minutes. Centrifuge.

¹²⁸ Arnold: Coreal Chem., 22, 455 (1945). ¹²⁶ Najjar: J. Biol. Chem., 141, 355 (1941).

Determine the fluorescence of the supernatant solution, that of a standard containing 5 γ of riboflavin, and of a water blank, the latter two likewise carried through the entire procedure.

For these measurements, a Pfaltz and Bauer fluorophotometer may be employed. The source of light should be a mercury vapor lamp equipped with a dark blue filter (Jena, No. BG12) and a yellow filter (Jena No. GG3). An orange filter (Jena, No. OG1) should be placed between the fluorescent solution and the photocell. Set the diaphragm so that the galvanometer reads 50 when the extract of the 5γ standard is in the instrument.

At the concentrations recommended in this procedure, the fluorescence of a riboflavin solution is directly proportional to its concentration. With most instruments, the galvanometer deflection is proportional to the fluorescence. Establish the linearity of the instrument employed by measuring the fluorescence of standard aqueous solutions of riboflavin as follows:

Dissolve 50.0 mg. of riboflavin in 1000 ml. of hot water in the dark. Cool. Prepare aqueous dilutions containing 0.00, 0.05, 0.10, 0.15, 0.20, 0.25, 0.30, and 0.40 γ of riboflavin per ml. Set the instrument at 100 with the most concentrated standard and measure the fluorescence of the other solutions. Plot the galvanometer readings against concentration of the vitamin on ordinary graph paper. Check the setting of the instrument before each reading.

Calculation. If the relation is linear, calculate the riboflavin content of the 24-hour sample by means of the following formula:

$$\frac{U-C}{50-C} \times 5 \times \frac{V}{A} = \gamma$$
 of riboflavin per 24-hour sample

where U is the galvanometer reading of the unknown, C is that of the reagent blank, V is the volume of the 24-hour sample in ml., and A that of the aliquot taken for test.

If the curve obtained above is not linear, standard solutions containing 0, 2, 4, 6, and 8 γ of riboflavin must be carried through the entire procedure and the concentration of riboflavin in the unknown determined from a standard curve. This value, multiplied by $\frac{V}{\Lambda}$ gives the amount of riboflavin in the 24-hour urine sample.

Comment. The fluorometric method for the determination of riboflavin in urine as described above measures in addition uroflavin, a metabolite of the vitamin. For diagnostic purposes, however, the total fluorescence following the ingestion of a test dose of the vitamin is a good index of the nutritional state with respect to riboflavin.

BIOLOGICAL ASSAY OF RIBOFLAVIN

The essential feature in the biological assay for riboflavin is to select a basal ration which includes all of the required factors of the vitamin B complex with the sole exception of riboflavin. In the past the practice has been to supplement a basal ration otherwise free from all sources of the vitamin B complex with alcoholic extracts of wheat germ or of rice polishings (so-called tiki-tiki). In the light of our present knowledge, however, such diets were undoubtedly deficient in more respects than riboflavin alone. Since crystalline preparations of each of the known B vitamins are now available, it is possible to supplement a diet of purified protein, ash,

and calories with all of the factors of the B complex except the one under assay.

There is at present no officially recognized procedure for the biological assay of riboflavin. Procedures employing both the rat and the chick have been described. The curative rat assay is more widely employed in the evaluation of foods or pharmaceutical products for human use. The customary procedure is to place rats on the riboflavin-free basal diet at weaning, making observations of weight changes at semiweekly intervals. Cessation of growth is one of the earliest symptoms of riboflavin depletion and, if the deprivation is complete, it is usually followed by decline in weight and death without the appearance of characteristic symptomatology. If the deficiency is prolonged (as may occur if the basal diet is not completely devoid of riboflavin) the symptoms of ariboflavinosis appear. These include bilaterally symmetrical patches of baldness around the nose, neck, back, and abdomen, corneal vascularization, and if the deficiency is particularly prolonged, cataracts are observed. It is interesting to point out that riboflavin-deficient rats are particularly susceptible to pediculosis. The occurrence of alopecia is noted in deficiencies of other factors of the B complex-e.g., biotin. Whether this phenomenon has a common origin in deficiencies of various members of this group of vitamins is not known.

After three to four weeks on the riboflavin-free diet, the weight of the rat reaches a plateau or a decline and at this point the material to be assayed is fed as a supplement to the basal ration. Comparable groups of animals receive graded dosages of crystalline riboflavin at levels which result in a graded dose response curve. For example, doses of 1, 2, 4, 8, and 16γ of crystalline riboflavin may be fed daily. Together with a resumption of growth, restoration of the body hair occurs over the denuded areas. For details of the composition of the basal diet and of other aspects of the bioassay procedure, see p. 1053.

NIACIN

The most common acute deficiency disease in this country is pellagra. Before the discovery of its relationship to niacin (nicotinic acid), this disease was responsible for thousands of deaths annually in the South. Pellagra occurs in endemic and epidemic form in many other countries including the Soviet Union, Egypt, Italy, Spain, and the Balkans. Epidemic pellagra follows any serious interruption of food supply or intake, especially after war, famine, disease, or economic depression.

Pellagra has been known for many centuries and was described as early as 1735 by Casal of Spain. That the disease was of dietary origin was not recognized until 1912 when Goldberger, Waring, and Willets¹²⁵ demonstrated that pellagra could be prevented by an adequate diet. At about the same time, nicotinic acid, a compound synthesized as early as 1867, ¹²⁶ was isolated by Funk while attempting to purify the antiberiberi vitamin. He failed to recognize the relationship between nicotinic acid and pellagra

Goldberger, Waring, and Willets: U.S. Pub. Health Repts., 30, 3117 (1915).
 Huber: Liebig's Ann. Chem., 141, 271 (1867).

but noted its beneficial effects when fed along with "vitamine B."¹²⁷ Deficiency syndromes analogous to human pellagra were demonstrated in dogs¹²⁸ in 1917 and in albino rats¹²⁹ in 1926. It was soon recognized that those foods which were effective for the cure of canine blacktongue were also effective for the cure of pellagra.¹³⁰ Following the discovery in 1937 of the importance of the amide of nicotinic acid, now commonly known as niacinamide, in the nutrition of certain unicellular organisms,¹³¹ the therapeutic effects of nicotinic acid in the treatment of blacktongue¹³² and of niacinamide in pellagra¹³³ were demonstrated.

Physiological and Clinical Aspects of Niacin. In niacin deficiency, the demonstrable tissue lesions are preceded by functional disturbances which are characteristic of deficiencies of a number of the B vitamins. These include weakness, anorexia, indigestion, diarrhea, and mental and emotional disturbances. Though pellagra is generally complicated by deficiencies of other B vitamins, certain lesions of the skin, the digestive tract, and the nervous system (the "three D's"—dermatitis, diarrhea, dementia) have been attributed solely to the deficiency of niacin. The skin lesion is an erythema, generally bilaterally symmetrical, which affects the back of the hands, the knees, elbows, dorsum of the feet, and ankles. Exposure to the sun increases the severity of the lesions. In chronic pellagra the affected areas become permanently pigmented and either atrophied or roughened and thickened. Epithelial lesions are also noted in the digestive tract, particularly on the tongue (glossitis) and in the rectum. The organic nerve lesions of pellagra include myelin degeneration of the spinal column fibers and degeneration of the axis cylinders of pyramidal cells of the cortex. Mild mental disturbances are common in pellagra, and acute delirium and dementia occur in severe cases.

Though anemia is not generally recognized as a symptom of pellagra, it is frequently accompanied by a macrocytic anemia. Since this condition responds to pteroylglutamic (folic) acid, its occurrence in pellagra may be due to the multiple nature of the clinically observed condition. Dogs with blacktongue also show anemia which responds to the administration of niacin.¹³⁴

Dramatic cures of pellagra occur upon the administration of niacinamide. Therapeutic doses of 50 to 500 mg, of niacinamide per day cause the disappearance of glossitis in 24 hours and of lesions of the tongue and lips in 3 to 5 days. Since uncomplicated niacin deficiency is comparatively rare, other members of the vitamin B complex are usually also administered in treating the disease.

Niacinamide is an essential constituent of coenzymes I and II, (code-hydrogenase I and II), which are involved in a large number of physiologically important oxidation reactions. These coenzymes occur in practically all cells and have been synthesized from niacin and niacinamide in vitro by nucleated cells. The probable structures of coenzyme I and of its reduction product dihydrocoenzyme I are shown below:

Coenzyme II differs from I in that it contains an extra phosphoric acid group. These codehydrogenases, in the presence of specific proteins, catalyze physiological oxidation reactions. Among the 35 different known reactions in which coenzyme I participates are the oxidation of alcohol to acetaldehyde, of glucose to gluconic acid, of malic acid to oxalacetic acid, of lactic acid to pyruvic acid, and of glycerophosphate to phosphoglyceraldehyde. Among the enzyme reactions catalyzed by coenzyme II are the conversion of Robison's ester (glucose-6-monophosphate) to phosphohexonic acid and of glutamic acid to iminoglutamic acid. These enzymatic reactions are all reversible, and the dihydrocoenzymes may combine with their apoenzymes to catalyze physiological reductions. In practice there is a dynamic equilibrium which depends on the relative concentrations of the reduced and oxidized forms of the substrates and coenzymes and on other conditions. In vitro experiments indicate that reduced coenzymes I and II may be reoxidized by flavoprotein enzymes, and that coenzyme II may be converted to I by a phosphatase. 135 Both coenzymes are inactivated by enzymatic destruction when cells of brain, liver, kidney, or muscle are ruptured. In contrast to the riboflavin coenzymes, which are present in flavoproteins in simple numerical proportion to their apoenzymes, coenzymes I and II are found in great excess and are bound only loosely to the protein molecules. The niacinamide prosthetic groups have been designated mobile coenzymes.

That dietary niacin is important in the maintenance of physiological enzyme systems is indicated by the positive correlation between the intake of the vitamin and the concentration of the coenzymes in the

muscles. 186 Niacin is essential to the physiology of animals, plants, and microörganisms. All plants and some microörganisms synthesize the vitamin. Others—e.g., B. diphtheriae, lactic acid bacteria, and B. dysenteriae—require an external source, and still others—e.g., B. influenzae require an external source of the coenzymes. Though the mold Neurospora does not ordinarily require niacin, a mutant strain produced by irradiation requires an external supply of the vitamin. Whereas niacin is essential to all animals, some—e.g., the rat and the horse—do not require it in their diet because their intestinal flora synthesize enough to meet metabolic needs. A dietary supply is required by the cotton rat, dog, pig, rabbit, chick, monkey, and man. However, even in these species, the contribution by intestinal microorganisms is as important as the dietary intake. Urinary excretion studies¹³⁷ show that human subjects on a constant diet excrete lower concentrations of N¹-methylnicotinamide (the principal known metabolite of niacin and niacinamide found in urine) after dosage with sulfaguanidine and succinvlsulfathiazole which destroy intestinal bacteria. Microörganisms have been isolated from the human cecum 138 which synthesize niacin in vitro.

The amount of macin required by animals from external sources depends upon the nature of other dietary factors consumed, particularly protein and carbohydrate. Endemic pellagra occurs almost exclusively in localities where corn is employed as a staple cereal. Populations which consume large quantities of rice rarely show pellagra even though their dietary intake of niacin is no more than 5 mg. per day, whereas maize eaters develop pellagra despite much higher intakes. 139 Rats, which ordinarily synthesize their own niacin, show a typical niacin deficiency syndrome when fed a corn diet. 140 This may be prevented by adding either tryptophane or more protein. On an otherwise adequate diet, young growing pigs show little sign of niacin deficiency, though the amount of the vitamin ingested is small. A decrease in the protein of the ration, however, produces symptoms of niacin deficiency which may be prevented by administration of more of the vitamin.¹⁴¹ Since niacin deficiency in white rats on a corn diet is prevented by the administration of tryptophane, it appears that the lack of this amino acid, which is present in only low concentrations in corn, is responsible for the apparent increased requirement of many species for niacin. This effect may possibly be attributed to changes in the intestinal flora resulting in the loss of microorganisms which require tryptophane and which are capable of synthesizing niacin. That pellagra is a dual deficiency of both tryptophane and niacin has also been suggested. The possibility that a pellagragenic antivitamin (see Chapter 36) is present in corn merits serious consideration.

The effect of corn on the growth of white rats depends upon the nature

of the carbohydrate ingested. When the latter is sucrose, considerable inhibition of growth occurs. However, when sucrose is replaced by glucose and dextrin, or partially replaced by lactose, the inhibition of growth does not occur. 142 Further evidence that the increased requirement for niacin is associated with the nature of dietary carbohydrate and with a diminished intake of tryptophane is provided by observations on white rats subsisting on a diet containing wheat gluten and gelatin, and deficient only in niacin and tryptophane. With sucrose as the source of carbohydrate, very poor growth results. The administration of tryptophane or niacin, or the substitution of glucose and dextrin for sucrose, restores normal growth.

The principal metabolite excreted in the urine following the ingestion of niacin or niacinamide is N¹-methylnicotinamide. This compound, after alkaline hydrolysis, reacts like niacin with cyanogen bromide and aniline, and because of its physical and chemical similarity to trigonelline (the betaine of N-methylniacin) was at first believed to be that compound.¹⁴³ N¹-methylnicotinamide has the following structure:

N¹-Methylnicotinamide

Pellagrins were observed to excrete only small quantities of this metabolite. Early tests for the diagnosis of niacin deficiency were based upon the colorimetric determination of urinary "trigonelline" after the ingestion of a test dose of the vitamin. It was subsequently discovered144 that administration of niacin or niacinamide was followed by excretion of a metabolite which was readily converted to a highly fluorescent substance by alkalinization and subsequent extraction with butanol. The urine of niacin-deficient subjects contained only small amounts of this compound. even after dosage with the vitamin. The metabolite was identified as N1-methylnicotinamide145 and found to be identical with the compound measured colorimetrically after alkaline hydrolysis which had been erroneously designated "trigonelline." Humans in a normal state of nutrition excrete approximately 20 per cent of their intake of niacinamide in the form of the N¹-methyl compound on a molar basis and approximately half of this amount when ingesting niacin. 146 The conversion of the latter to N¹-methylnicotinamide requires both an amidation and a methylation.

whereas niacinamide requires only the latter step. In vitro studies¹¹⁷ show that rat liver is capable of converting niacinamide, but not niacin, to N¹-methylnicotinamide.

The possibility that niacin or its amide act physiologically in the form of N¹-methylnicotinamide has been investigated with conflicting results. Some observers have found that the compound is capable of curing blacktongue, ¹⁴⁵ but this has been disputed by others. ¹⁴⁵ In man, N¹-methylnicotinamide has been found to improve the dermatitis and glossitis of pellagra but simultaneously to aggravate the psychomotor symptoms. ¹⁵⁰ The latter condition, however, could be cured by the administration of thiamine and riboflavin. In view of these findings, the metabolic role of N¹-methylnicotinamide remains to be established.

Certain derivatives of niacin and niacinamide are biologically active in higher animals when administered orally. These include the ethyl ester and the ureide of niacin, and niacin-diethylamide. These compounds are probably hydrolyzed in the gastrointestinal tract to niacin and niacinamide. Trigonelline, the betaine of N-methylniacin, is biologically inactive. It occurs naturally in a number of foods, especially legumes, coffee, and tobacco. A synthetic analog of niacin, pyridine-3-sulfonic acid, has been found to inhibit the growth of microörganisms requiring niacin or its amide. ¹⁵¹ 3-Acetylpyridine does not inhibit microbial growth but induces niacin deficiency in mice, a species which normally does not require a dietary supply of niacin. ¹⁶² This compound, because of its chemical similarity to niacin, probably acts by competition with the vitamin in physiological enzyme systems (see Chapter 36).

Wheat bran and other natural materials contain a compound which, upon heating with strong acid or alkali, behaves like niacin toward Lactobacillus arabinosus. This compound is extracted from natural materials by heating with water or dilute acid, but must be subsequently hydrolyzed with strong acid or with alkali before it can stimulate the microörganism. Concentrates of the unhydrolyzed material have been prepared and found to be inactive when fed to chicks. After hydrolysis, the compound meets the niacin requirements of both the chick and the dog. Coramine, niacin-diethylamide, exhibits similar behavior in that it is inactive for L. arabinosus but is active after heating with alkali. Coramine is biologically active in higher animals.

Large doses of niacin dilate the superficial blood vessels. The administration of 50 mg, or more orally or of 10 mg, intravenously to humans not deficient in the vitamin produces flushing, itching, and burning of the skin, especially in areas subjected to pressure. Individuals vary greatly in

their sensitivity to this reaction. The effect is observed only with the free acid and not with niacinamide, so that the latter is preferred for therapeutic purposes. The flushing reaction may be prevented by simultaneous administration of glycine which provides amino groups for conversion of the free vitamin to its amide.

Large doses of niacin or niacinamide are toxic to the rat because of the depletion of the methyl donor, methionine. ¹⁵⁵ Niacinamide is more toxic than the free acid, since more N¹-methylnicotinamide is excreted when the amide is fed. The toxicity is seen only in animals which excrete N¹-methylnicotinamide after dosage with the vitamin. Large doses of niacinamide are not toxic to young rabbits and guinea pigs which do not excrete the methylated derivative. The toxicity of large doses of the vitamin in rats may be prevented by feeding methionine, or cholline plus homocystine (see p. 943).

For further discussion of the clinical aspects of niacin, see the American Medical Association syllabus, p. 1186.

Storage and Synthesis of Niacin. No significant amount of niacin or its amide is stored passively in animal tissue. Higher concentrations are found in the liver, muscle, and kidney for the performance of metabolic functions. A decrease in the niacin intake of man is followed by a diminished concentration of the niacin coenzymes in the striated muscles, but has little effect on the coenzyme content of the erythrocytes.

The synthesis of niacin by plants and microörganisms, the importance of the contribution by intestinal flora in the nutrition of animals, and the effect of other dietary factors have been discussed above. A possible clue to the biological synthesis of niacinamide is the formation of the vitamin when glutamic acid is heated with air at 100°. 156

A number of practical syntheses for niacin and niacinamide are available for commercial use. The simplest of these include the nitric acid oxidation of nicotine obtained from tobacco or the oxidation of β -picoline or quinoline with potassium permanganate. Niacinamide may be prepared from the free acid by heating with ammonia, or from esters by treatment with alcoholic ammonia. The annual production of the synthetic vitamin for enrichment purposes and for pharmaceutical preparations is approximately a half-million pounds.

Distribution of Niacin.¹⁵⁷ In natural materials, niacin occurs predominantly as the amide, the form in which it is active biologically in enzyme systems. Good sources of the vitamin are liver, adrenal glands, meats, wheat, rye and enriched flour. The vitamin occurs in relatively high concentration as coenzyme I in yeast, red blood cells, and heart muscle.

Chemistry of Niacin. Niacin is a white crystalline solid which melts at 236° and may be sublimed without destruction. The vitamin is stable to boiling in neutral, acid or alkaline solution. The vitamin has an absorption maximum in the ultraviolet region at 385 m_{μ} .

¹⁶⁷ See Appendix III.

Niacinamide

Niacin (Nicotinic Acid) (Pyridine-3-carboxylic acid, mol. wt. 123.1)

Niacinamide crystallizes in light needles from benzene and melts at 129°. It may be distilled at 150 to 160° at 5×10^{-4} mm. Niacinamide is more soluble in organic solvents than the free acid and, unlike the latter, may be extracted from water with ether. The amide has a characteristic absorption curve in the ultraviolet region with maxima at 210, 220, and 260 m μ . Niacinamide is readily hydrolyzed to free niacin by heating with acid or alkali.

Niacin and niacinamide react with cyanogen bromide in the presence of a primary or secondary amine to produce a compound having a yellow-green color. Colors are also formed with trigonelline, nicotinuric acid, and nicotine, as well as certain other pyridine compounds. This reaction is employed in the chemical determination of niacin. Since the amide produces only half the color of the free acid, it must first be hydrolyzed for the colorimetric test.

Coenzymes I and II are colorless, water-soluble compounds, insoluble in organic solvents. Coenzyme II, however, is soluble in methanol-hydrochloric acid mixtures. Both coenzymes are stable in acid, but are readily decomposed in alkali. Coenzyme I has an absorption maximum at 260 m μ . It is nonfluorescent but is optically active, [a] 546 m $\mu = -70^{\circ}$. Coenzyme I is not precipitated by lead acetate but does produce an insoluble cuprous salt. Reduced coenzyme I has an absorption maximum at 340 m μ . This compound is stable in alkali but is destroyed by acid in which it reverts to the oxidized form. In contrast to the latter, dihydrocoenzyme I fluoresces upon ultraviolet irradiation.

Coenzyme II has an absorption maximum at 360 m μ . Its optical rotation [α] 546 m μ = -29.4°. Coenzyme II differs from coenzyme I in having one extra phosphoric acid group in the molecule. The cuprous salt of coenzyme II is soluble but the coenzyme is precipitated by lead acetate.

Determination of Niacin: Introduction. Accurate chemical and microbiological methods for the determination of niacin in natural materials are available. The chemical procedures involve reaction of the vitamin with cyanogen bromide in the presence of an amine. Extracts are prepared for chemical or microbiological assay by acid or alkaline hydrolysis, both to facilitate extraction and to hydrolyze niacinamide and a niacin precursor found in natural materials. In the chemical procedure, hydrolysis with acid results in the formation of furfural from the degradation of pentoses, which interferes with colorimetric reaction. This compound is separated from the niacin by adsorption of the vitamin on a hydrated aluminum silicate which does not adsorb the furfural. The niacin is subsequently eluted from the adsorbate by washing with alkali.

Because niacin and niacinamide have somewhat different physiological effects, it is sometimes desirable to determine their relative concentrations in mixtures. This may be accomplished chemically by time-reaction measurements conducted on the hydrolyzed and unhydrolyzed extracts. The assay is based on the differences in the rate of formation of the yellow-green pigment with cyanogen bromide and aniline.

The microbiological determination of niacin is based upon the growth stimulation of Lactobacillus arabinosus. This organism responds equally to niacin and its amide. These compounds, however, may be differentiated microbiologically by destruction of the amide with bromine and potassium hydroxide (Hoffman degradation), converting it to β -amino-pyridine which is microbiologically inert. 159 Differential microbiological assays may also be conducted to distinguish between the several metabolites of the vitamin, including macin, its amide, nicotinuric acid, and N¹-methylnicotinamide. Two microörganisms are employed, Lactobacillus arabinosus which utilizes niacin, niacinamide, and nicotinuric acid, and Leuconostoc mesenteroides for which only niacin is active. Hydrolysis with 0.6 N sulfuric acid at 15 pounds pressure for one hour is also employed to convert the amide completely to free niacin without affecting nicotinuric acid. The microbiological assays are conducted in conjunction with the fluorometric test which measures only N¹-methylnicotinamide. Differential assays such as those described above show that the major part (about 90 per cent) of the niacin metabolites excreted after the ingestion of the vitamin appears as N¹-methylnicotinamide. Small amounts of niacin and niacinamide also occur in urine and somewhat larger amounts of the latter after the administration of large doses of the free acid. Human urine contains little if any nicotinuric acid except after large doses of free nicotinic acid.

The biochemical diagnosis of niacin deficiency is based upon the measurement of urinary excretion of N¹-methylnicotinamide, the chief excretory product after ingestion of the vitamin.¹60 This procedure is to be preferred to the old colorimetric test for "trigonelline" since it eliminates the necessity of excluding from the diet coffee and legumes which furnish large amounts of trigonelline. A satisfactory clinical test involves measurement of the 6-hour urinary excretion of N¹-methylnicotinamide following the oral administration of 300 mg. of niacinamide.¹61

Earlier clinical tests based upon measurement of urinary "porphyrins" are not reliable, since the color reaction obtained when testing the urine of pellagrins has been found to be due to urorosein rather than to porphyrin and depends on the presence of other compounds in the urine.

Modified Colorimetric Method of the Research Corporation.¹⁶²
Principle. The method involves strong acid hydrolysis to convert derivatives to nicotinic acid, adsorption of the vitamin on Lloyd's Reagent, clari-

fication of the eluate with lead hydroxide, and reaction of nicotinic acid with cyanogen bromide and aniline to produce a yellow pigment which is measured photometrically.

Procedure: Preparation of the Sample: Hydrolyze a sample of tissue or food containing 100-500 y of niacin by heating in a boiling water bath with 75 ml. of 4 N hydrochloric acid for 30-40 minutes. Cool and dilute to 100 ml. Transfer 25 ml. of the suspension to a narrow (18 mm. diameter) centrifuge tube calibrated at the 26.5-ml. mark. Adjust the pH to 0.5-1.0 with 18 N sodium hydroxide using 0.1 per cent methyl violet as an outside indicator,163 Cool, add 2.5 g. of Lloyd's Reagent, 164 and shake 1 minute. Centrifuge and discard the supernatant liquid. Wash the residue twice with 10 ml. of 0.2 N sulfuric acid, each time centrifuging and discarding the supernatant. Add 0.5 N sodium hydroxide to the 26.5-ml. mark and break up the precipitate with a stirring rod. Immerse the tube in a boiling water bath for five minutes, stirring the contents occasionally. Cool and centrifuge. Transfer the supernatant to another tube, add 1.6 g. of finely divided lead nitrate, and shake vigorously for 1 minute. If the solution is still alkaline, add more lead nitrate until acid. Centrifuge and pour the clear supernatant into another tube. Neutralize with tertiary potassium phosphate and 20 per cent phosphoric acid.

Colorimetric measurements are made in a photoelectric colorimeter. Two center settings are necessary, one for evaluating the residual color in the test solution, the other for the color developed in the chemical reaction. Set the colorimeter at 100 per cent transmittance with 3 ml. of water and 7 ml. of alcoholic buffer. With this setting read a solution of 3 ml. of the test extract plus 7 ml. of alcoholic buffer (A). Now set the colorimeter at 100 per cent transmittance with the reagent blank; 3 ml. of water, plus 6 ml. of cyanogen bromide solution. In l. of aniline solution. Remove the tube and record the center setting. To 3 ml. of the test extract, add 6 ml. of cyanogen bromide and 10 minutes later 1 ml. of aniline; read the solution 5 minutes later using the center setting obtained with reagent blank (B). Similarly read a solution containing 3 ml. of test extract, 10 γ of nicotinic acid in 0.1 ml. of an alcoholic solution, 6 ml. of cyanogen bromide, and 1 ml. of aniline (C).

Calculation. Convert galvanometer readings, G, to photometric density, P.D., as follows:

$$P.D. = 2 - \log G$$

Then:

$$\frac{B-A}{1.01 \text{ C}-B} \times 10 \times \text{dilution factor} = \gamma \text{ of nicotinic acid per g. of sample.}$$

Comment. Values obtained by the colorimetric method for nicotinic acid agree well with those obtained by microbiological assay of acid or alkaline extracts. Exhaustive aqueous extraction, without preliminary

¹⁴³ Use one drop of sample to one drop of indicator on a spot plate. Match with the blue color given by one drop of 0.2 N sulfuric acid.

¹⁴⁴ A hydrated aluminum silicate obtained from Eli Lilly and Co., Indianapolis, Ind. When suspended in water, 2.5 g. occupies a volume of 1.5 ml.

¹⁶⁶ Mix 980 ml. of water, 15 ml. of 15 per cent sodium hydroxide, 4 ml. of S5 per cent phosphoric acid, and 167 ml. of absolute ethyl alcohol.

¹⁴⁶ In a well-ventilated hood dissolve 20 g, of cyanogen bromide crystals in 500 ml, of cold water. Do not allow the crystals to come in contact with the skin since they produce serious burns.

¹⁶⁷ Four per cent redistilled aniline in absolute alcohol.

hydrolysis, removes all the nicotinic acid from cereal products but yields lower microbiological and chemical values. A nicotinic acid derivative other than nicotinamide is broken down by the hydrolytic procedure. (See p. 1091.)

Determination of Ni-Methylnicotinamide in Urine. Fluoromet-

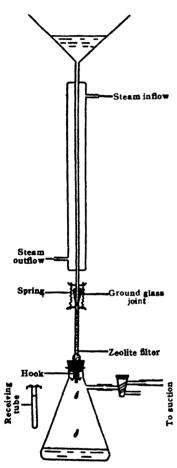

Fig. 301. Apparatus for the adsorption and elution of N1methylnicotinamide in urine.

ric Method of Hochberg, Melnick, and Oser:168 Principle. The method involves adsorption of a small urine aliquot at pH 4.5 on a column of synthetic zeolite. elution with potassium chloride solution, alkalinization, extraction of the resulting compound with n-butanol, and measurement of the fluorescence.

Procedure: Preparation of Sample: Collect a 24-hour urine sample in an amber bottle containing 20 ml. of 10 per cent sulfuric acid. Measure the volume. Dilute 6-minute aliquot¹⁶⁹ with buffer¹⁷⁰ to 50 ml., and pass the solution through the special adsorption column shown in Fig. 301, following the directions given for the colorimetric determination of thiamine. Elute the N1methylnicotinamide with 15 ml. of a neutral 25 per cent solution of potassium chloride, passed down the wall of the hot condenser. Regenerate the column by washing with water (see p. 1067). Pass a standard solution containing 50 y of N1methylnicotinamide chloride¹⁷¹ in 50 ml. of acetate buffer through the column in the same manner as the diluted urine samples.

Fluorometric Measurement: Mix the eluate and pipet a 5-ml. aliquot into each of two 30-ml. separatory funnels. To one, the blank, add 1 ml. of water followed by 16.5 ml. of n-butanol. To the other, the test, add 16.5 ml. of butanol, then 1 ml. of 15 per cent sodium hydroxide. Stopper the vessels immediately and shake vigorously for 3 minutes. Centrifuge for 0.5 minute and discard the aqueous layer. Clarify the butanol by shaking with approximately 1 g. of anhydrous sodium

sulfate. Allow the butanol extracts to stand in the dark for 15 minutes during which the fluorescence reaches a maximum, then read in a fluorometer

¹⁴⁴ Hochberg, Melnick, and Oser: J. Biol. Chem., 158, 265 (1945).

¹⁴⁹ Larger aliquots should not be taken, since incomplete absorption on the seolite may

¹⁷⁶ Dissolve 7.5 g. of sodium acetate in 1000 ml. of distilled water containing 1.0 ml. of concentrated sulfuric acid. The pH is 4.5.

¹⁷¹ The compound may be prepared by the method of Karrer, Schwazenbach, Benz, and Solmssen: Helv. Chim. Acta, 19, 826 (1936); or it may be purchased from W. A. Taylor and Company, 7300 York Road, Baltimore, Md.

with appropriate light filters. Use a solution of quinine sulfate containing 0.2 γ per ml. in 0.1 N sulfuric acid to check the setting of the instrument.

Calculation. Calculate the 24-hour urinary excretion of N¹-methyl-nicotinamide chloride, expressed in terms of niacinamide, using the formula,

 $50 \times \frac{G_u}{G_u} \times \frac{60}{M} \times 0.707 = \gamma$ of niacinamide per 24 hr.

G_u and G_s are the galvanometer deflections of the unknown and the standard, both corrected for their respective blanks. M is the period represented by the urinary aliquot, expressed in minutes, and 0.707 is the factor for conversion of N¹-methylnicotinamide chloride to niacinamide.

Comment. N¹-Methylnicotinamide is the principal derivative of niacinamide found in human urine. Average basal excretion values approximate 25 per cent of the dietary intake, with wide individual variations. The metabolite is excreted rapidly following ingestion of the vitamin, approximately 20 per cent appearing in the urine within 24 hours following dosage with 50-200 mg. of niacinamide.

MICROBIOLOGICAL ASSAY FOR NIACIN

Method of the U.S. Pharmacopoeia XIII. 1718

Test Solution of the Material to Be Assayed. Place an accurately weighed quantity of the material to be assayed, sufficient to represent approximately 0.1 mg. to 1.0 mg. of nicotinic acid, in a 300-ml. flask, add 100 ml. of normal sulfuric acid, and mix thoroughly. Heat the mixture in an autoclave at 121.5° for 30 minutes, cool, add 1.0 N sodium hydroxide to produce a pH of 6.8, and add sufficient distilled water to make 1000 ml.

Standard Nicotinic Acid Solution. Dissolve an accurately weighed 50-mg, portion of U.S.P. Nicotinic Acid Reference Standard in alcohol, and add sufficient alcohol to make 500 ml. Store this stock solution in a refrigerator. Prepare the Standard Solution by diluting 1 ml. of the stock solution, which has been warmed to room temperature, with sufficient distilled water to make 1000 ml., representing $0.1~\gamma$ of the Reference Standard in each ml, of solution. Prepare fresh Standard Solution for each assay.

Basal Medium Stock Solution:

Acid-hydrolyzed casein solution	25 ml.
Cystine-tryptophane solution	25 ml.
Dextrose anhydrous.	10 g.
Sodium acetate anhydrous	5 g.
Adenine-guanine-uracil solution	
Riboflavin-thiamine-biotin solution	5 ml.
p-Aminobenzoic acid-calcium pantothenate-pyridoxine solution.	5 ml.
Salt solution A	5 ml.
Salt solution B	5 ml.

Mix the ingredients, adjust the solution to a pH of 6.8, and add sufficient distilled water to make 250 ml.

Acid-hydrolyzed Casein Solution: Mix 100 g. of vitamin-free casein with 500 ml. of constant-boiling hydrochloric acid (approximately 20 per cent HCl), and reflux the mixture for 24 hours. Remove the hydrochloric acid from the mixture by distillation under reduced pressure until a thick paste remains. Redissolve the resulting

1716 Grateful acknowledgement for permission to reproduce this method is made to Prof. E. Fullerton Cook and the Board of Trustees of the U.S. Pharmacopoeial Convention.

paste in distilled water, adjust the solution to a pH of 3.5 (± 0.1) with 1.0 N sodium hydroxide, and add sufficient distilled water to make 1000 ml. Add to the solution 20 g. of activated charcoal, stir for 1 hour, and then filter. Repeat the treatment with activated charcoal if the filtrate does not appear straw colored to colorless. Store this solution under toluene in a refrigerator, Filter the solution if a precipitate forms on storage.

Cystine-Tryptophane Solution. Suspend 4 g. of *l*-cystine and 1 g. of *l*-tryptophane (or 2 g. of *d*,*l*-tryptophane) in 700-800 ml. of distilled water, heat to 70-80°, and add 20 per cent hydrochloric acid, dropwise, with stirring, until the solids are dissolved. Cool to room temperature and add sufficient distilled water to make 1000 ml. Store the solution in a refrigerator.

Adenine, Guanine, Uracil Solution. Dissolve 0.1 g. each of adenine sulfate, guanine hydrochloride, and uracil, with the aid of heat, in 5 ml. of 20 per cent hydrochloric acid, and add sufficient distilled water to make 100 ml. Store the solution in a refrigerator.

Riboflavin, Thiamine Hydrochloride, Biotin Solution. Prepare a solution containing in each ml. 20 γ of riboflavin, 10 γ of thiamine hydrochloride, and 0.04 γ of biotin by dissolving crystalline riboflavin, crystalline thiamine hydrochloride and crystalline biotin (free acid) in fiftieth-normal acetic acid. Store the solution, protected from light, under toluene in a refrigerator.

p-Aminobenzoic Acid, Calcium Pantothenate, Pyridoxine Hydrochloride Solution. Prepare a solution in neutral 25 per cent alcohol to contain 10γ of p-aminobenzoic acid, 20γ of calcium pantothenate, and 40γ of pyridoxine hydrochloride in each ml. Store the solution in a refrigerator.

Salt Solution A. Dissolve 25 g. of monobasic potassium phosphate and 25 g. of dibasic potassium phosphate in sufficient distilled water to make 500 ml. of solution. Add 5 drops of concentrated hydrochloric acid and store under toluene.

Salt Solution B. Dissolve 10 g. of magnesium sulfate, 0.5 g. of reagent sodium chloride, 0.5 g. of ferrous sulfate, and 0.5 g. of manganese sulfate in sufficient distilled water to make 500 ml. Add 5 drops of concentrated hydrochloric acid and store under toluene.

Stock culture of Lactobacillus arabinosus 17-5. Dissolve 2 g. of yeast extract in 100 ml. of distilled water, add 0.5 g. of anhydrous dextrose, 0.5 g. of anhydrous sodium acetate, and 1.5 g. of agar, and heat the mixture on a steam bath until the agar has dissolved. Add approximately 10-ml. portions of the hot solution to test tubes, plug the tubes with non-absorbent cotton, sterilize in an autoclave at 121.5° for 20 minutes, and allow to cool in an upright position. Prepare stab cultures in 3 or more of the tubes, using a pure culture of Lactobacillus arabinosus 17-5, 172 incubate for 16 to 24 hours at any selected temperature between 30° and 37°, but held constant to within $\pm 0.5^{\circ}$ C., and finally store in a refrigerator. Prepare a fresh stab of the stock culture every week, and do not use for inoculum if the culture is more than 1 week old.

Culture Medium. To each of a series of tubes containing 5 ml, of the basal medium stock solution add 5 ml, of distilled water containing 1 γ of nicotinic acid. Sterilize in an autoclave at 121.5° for 20 minutes.

Inoculum. Make a transfer of cells from the stock culture of *Lactobacillus* arabinosus 17-5 to a sterile tube containing 10 ml. of culture medium. Incubate this culture for 16 to 24 hours at any selected temperature between 30° and 37°, but held constant to within ± 0.5 °. The cell suspension so obtained is the inoculum.

Assay procedure. Prepare standard nicotinic acid tubes as follows: To duplicate tubes, 16×150 mm. in size, add 0.0 ml., 0.5 ml., 1.0 ml., 1.5 ml., 2.0 ml., 2.5 ml., 3.0 ml., 3.5 ml., 4.0 ml., 4.5 ml., and 5.0 ml., respectively, of the Standard Nicotinic Acid Solution. To each of these tubes add 5 ml. of basal medium stock solution and sufficient distilled water to bring the volume in each tube to 10 ml.

172 U.S. Pharmacopoeia XIII. Pure cultures of Lactobacillus arabinosus 17-5 may be obtained from the American Type Culture Collection, Georgetown University Medical School, Washington, D.C., as No. 8014.

Prepare tubes containing the material to be assayed as follows: To duplicate tubes add, respectively, 1.0 ml., 2.0 ml., 3.0 ml., and 4.0 ml. of the test solution of the material to be assayed. To each of these tubes add 5 ml. of basal medium stock solution and sufficient distilled water to bring the volume in each tube to 10 ml.

After thorough mixing, plug the tubes of the two series mentioned above with non-absorbent cotton, and autoclave at 121.5° for 15 minutes. Cool, aseptically inoculate each tube with 1 drop of inoculum, and incubate for 72 hours at any selected temperature between 30° and 37°, but held constant to within \pm 0.5°. Contamination of the assay tubes with any organism other than Lactobacillus arabinosus invalidates the assay.

Transfer the contents of each tube to a suitable container, using approximately the same quantity of distilled water in each instance for rinsing. Titrate the contents of each container with tenth-normal sodium hydroxide using bromthymol blue as the indicator, or to a pH of 6.8 measured electrometrically.

Calculation. Prepare a standard curve of the nicotinic acid standard titration by plotting the average of the titration values expressed in ml. of tenth-normal sodium hydroxide for each level of nicotinic acid standard solution used, against γ of nicotinic acid contained in the respective tubes. From this standard curve determine by interpolation the nicotinic acid content of the test solution in each tube. Discard any values which show more than 0.4 or less than 0.05 γ of nicotinic acid in each tube. Calculate the nicotinic acid content in each ml. of test solution for each of the tubes. The nicotinic acid content of the test material is calculated from the average of the values obtained from not less than 6 of these tubes which do not vary by more than ± 10 per cent from the average. If the titration values of two or more of the tubes containing the test solution fall below the titration-values of the Nicotinic Acid Standard tubes containing 0.05 to 0.4 γ of nicotinic acid, the nicotinic acid content of the test solution is too low to permit calculation of nicotinic acid content of the test material. Titration values exceeding 2 ml, for the tubes of the standard nicotinic acid solution series containing 0.0 ml. of the solution indicate the presence of an excessive amount of nicotinic acid in the basal medium stock solution and invalidate the assay.

PYRIDOXINE (VITAMIN B₆)

Goldberger and Lillie, in 1926, reported the development of a characteristic dermatitis, called acrodynia, in rats fed a diet deficient in what they regarded as the pellagra-preventive (P-P) factor. In 1934, recognizing the multiple nature of the vitamin B complex, P. György¹⁷³ designated the missing factor vitamin B₆, the rat pellagra-preventive factor, the deficiency being characterized by edema and denuding of the paws and the areas around the nose and mouth, and thickening of the ears. Lack of this vitamin was also shown to induce microcytic hypochromic anemia and neurologic lesions in dogs and pigs. Vitamin B6 attracted so much attention that within one year, 1938, it was isolated independently by five groups—Lepkovsky; Keresztesy and Stevens; P. György; Kuhn and Wendt; and Itiba and Miti. In the following year, the chemical structure was elucidated and the compound was synthesized independently by Keresztesy, Stevens, Harris, Stiller, and Folkers in the United States and by Kuhn, Westphal, Wendt, and Westphal in Germany, following which the vitamin was named pyridoxine.

Because of the anomalous results obtained in microbiological 174 and

¹⁷³ György: Nature, 133, 498 (1934).

¹⁷⁴ Snell: J. Biol. Chem., 157 491 (1945).

chemical assays¹⁷⁵ for vitamin B₆, it has become recognized that the vitamin occurs in a variety of forms in nature. Two other compounds, the aldehyde and amine derivatives, pyridoxal and pyridoxamine, have biological activity equal to that of pyridoxine for higher animals, though their utilization by microorganisms varies considerably. Evidence suggests the existence of members of the vitamin B₆ complex which are as yet

Fig. 302. Pyridoxine-deficient rat. Note edema and dermatitis of paws and nose.

unknown.¹⁷⁶ Whether these are new forms or the known forms bound in such a way that they are not released by conventional methods of hydrolysis remains to be determined.

Physiological and Clinical Aspects of Pyridoxine. Deficiency of vitamin B₆ in rats causes acrodynia (see Fig. 302), edema, inhibition of growth, and nerve degeneration. The vitamin is also essential for the chick, rat, dog, and pig, and for numerous microörganisms. The signifi-

Hochberg, Melnick, and Oser: J. Biol. Chem., 154, 313 (1944); 155, 119 (1944).
 Melnick, Hochberg, Himes, and Oser: J. Biol. Chem., 166, 1 (1945).

cance of the vitamin has been claimed to be related to the metabolism of unsaturated fatty acids. The dermatitis observed in vitamin B_6 deficiency closely resembles that noted in cases of fatty acid deficiency. Some observers have reported that the addition of certain unsaturated fatty acids to a diet deficient in vitamin B_6 protects against the appearance of the deficiency syndrome of the vitamin.

The role of vitamin B₆ in protein metabolism has also been demonstrated. Pyridoxine deficiency in rats and swine is characterized by the appearance in the urine of xanthurenic acid, a metabolite of tryptophane. All three known members of the vitamin B₆ group—pyridoxine, pyridoxal, and pyridoxamine—are converted by organisms capable of utilizing them into amino-acid decarboxylases.¹⁷⁷ Pyridoxal may be phosphorylated chemically into the coenzyme which, when combined with the apoenzyme (the protein moiety of the enzyme), obtainable from Streptococcus faccalis R grown in a medium deficient in vitamin B₆, catalyzes the decarboxylation reactions. Amino acids reported to require the vitamin B₆ coenzyme for decarboxylation include tyrosine, lysine, arginine, ornithine, glutamic acid, and dioxyphenylalanine ("dopa").

The same coenzyme, pyridoxal phosphate, has been demonstrated to function as a glutamate-aspartate transaminase. ¹⁷⁸ Evidence also indicates that vitamin B_6 participates in enzyme systems involved in the synthesis of amino acids by microörganisms.

The role of pyridoxine in human nutrition is not definitely known; the daily requirement as estimated from animal experiments is about 2 mg. Although the vitamin has been used clinically in acne and other dermatologic disorders, its value has yet to be conclusively demonstrated. Parkinson's disease and muscular dystrophy have been treated with pyridoxine, but the results were too indefinite to justify associating these conditions with vitamin deficiencies.

In man, vitamin deficiencies, particularly of the B group, generally are of a multiple nature. Pellagrins who responded only partially to the administration of thiamine, riboflavin, and niacin showed considerable improvement after intravenous administration of pyridoxine. Large doses of the vitamin together with thiamine have also been effective in the treatment of nausea and vomiting of pregnancy.

Storage and Synthesis of Vitamin B₆. Vitamin B₆ is present in most animal tissues, with high concentrations in the liver. It is synthesized by bacteria in the rumen of sheep and cattle.

Distribution of Vitamin $\hat{\mathbf{B}}_{6}$.¹⁷⁹ In natural materials vitamin $\hat{\mathbf{B}}_{6}$ occurs principally bound to proteins. Rich sources are yeast and rice polishings. Seeds and cereals are good sources, especially the germ. In rice bran the vitamin is present to a small extent in the free form, but a major portion is a bound complex of pyridoxine, readily hydrolyzable by heating with strong acids. Pyridoxine was isolated from rice polishings in 1932 by

17 See Appendix IV.

¹⁷⁷ Gunsalus and Bellamy: J. Biol. Chem., 155, 357 (1944); Bellamy, Umbreit, and Gunsalus: J. Biol. Chem., 166, 461 (1945).

¹⁷⁶ Lichstein, Gunsalus, and Umbreit: J. Biol. Chem., 161, 311 (1945).

Ohdake before its identity as a vitamin was known. In yeast and liver, it is present chiefly as bound pyridoxamine, though small concentrations of pyridoxine and pyridoxal are also found.

Chemistry of Vitamin B₆. Pyridoxine hydrochloride is a white, odorless, slightly bitter, crystalline solid, melting at 207° with slight decomposition. It is optically inactive and very soluble in water, slightly soluble in 95 per cent alcohol and in acetone, and insoluble in ether. The free base is also a colorless, crystalline solid, melting at 160° C. It is soluble in water, acetone, and alcohol, and slightly soluble in ether and chloroform. The aqueous solution of pyridoxine hydrochloride has a pH of approximately 3. It is adsorbed from acid solution on zeolite, charcoal, or fullers' earth, and may be eluted from zeolite with 10 per cent potassium chloride or from fullers' earth with a weak alkali. The structure of pyridoxine is indicated in the scheme on page 1101 which shows one of the procedures employed in its commercial synthesis. In place of the CH₂OH group in the 4 position, pyridoxal contains a CHO group, while pyridoxamine contains CH₂NH₂.

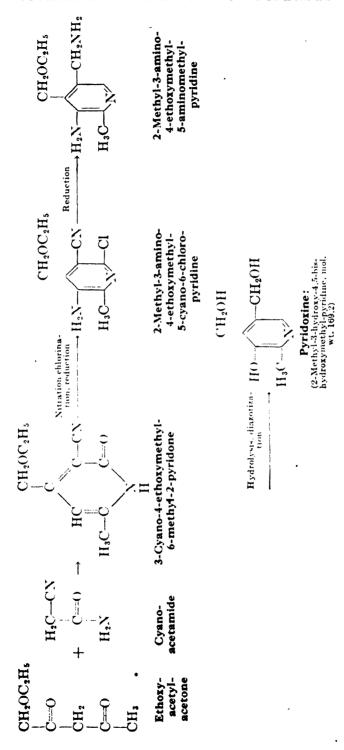

Pyridoxine reacts with ferric chloride to produce a compound having an orange-red color. Pyridoxine is phenolic and reacts with diazonium salts to produce dyes. The other forms probably have similar reactions. Pyridoxine, pyridoxal, and pyridoxamine couple with 2,6-dichloroquinone chloroimide to produce a blue dye. The reaction with pyridoxine is shown in the following equation. In the presence of boric acid, pyridoxine alone forms a stable complex which does not couple with the reagent, thus permitting its differentiation from pyridoxal and pyridoxamine.¹⁷⁶

Pyridoxine 2,6-Dichloroquinone Blue dye chloromide
$$CH_{2}OH$$
 $CH_{2}OH$ $CH_{2}OH$ $CH_{3}OH$ CH

Early chemical and microbiological studies of vitamin B_{δ} were complicated by the presence of the several forms, and by the facility of transformation of one compound to another. Conditions favoring amination or partial oxidation of pyridoxine result in the formation of some of the amine or aldehyde. This is attended by considerable change in the capacity for growth stimulation of certain microörganisms.

The three known forms of vitamin B₆ possess characteristic absorption curves in the ultraviolet region of the spectrum.

These curves show no absorption maximum common to all three compounds. However, the total concentration of vitamin B_6 present in a solution relatively free of interfering substances may be determined by measurement at 325 m μ and pH 6.75. Under these conditions, the $E_1^{t,\infty}$ value for each of the compounds is 440.

Pyridoxine, pyridoxal, and pyridoxamine are destroyed by exposure to light. Destruction is most rapid in the ultraviolet region of the spectrum in neutral or alkaline solution. Though all three compounds are comparatively stable to light in 0.1 N acid, pyridoxamine is slightly sensitive. The photolysis of vitamin B₆ is not affected by the presence of air. All three forms of the vitamin are stable to heating at 100° C. with 5 N sulfuric or hydrochloric acid; only pyridoxal is unstable to heat in alkaline solutions. All three compounds are stable to mild oxidizing agents like manganese dioxide in alkaline solution or hydrogen peroxide in neutral solution at room temperature. However, they are destroyed by potassium permanganate or by manganese dioxide in acid solution at room temperature, or by heating with nitric acid, potassium permanganate, or hydrogen peroxide.

Determination of Vitamin B_6 : Introduction. Since a major proportion of the vitamin B_6 present in natural materials occurs in bound forms, assays must be preceded by hydrolysis by enzymes or by heating with acid. Among the chemical methods for the determination of the vitamin are the relatively nonspecific phenol tests. Diazonium salts, ferric chloride, and 2,6-dichloroquinone chloroimide have been employed. A specific chemical test for pyridoxine involves coupling with 2,6-dichloroquinone chloroimide both in the presence and absence of boric acid. The latter couples with the vitamin to form a stable complex which fails to react with the reagent, thus providing a blank correction for other reacting materials. The low values for the pyridoxine content of natural materials obtained by this procedure indicated the existence of other forms of vitamin B_6 .

Microbiological methods for the determination of vitamin B₆ are based on the growth stimulation of yeast or bacteria. These are complicated by the variable responses of the microorganisms to the different forms of the vitamin. All three forms have equal activity on a molar basis for Saccharomyces carlsbergensis. For Saccharomyces cerevisiae, however, the amine has 40 per cent, and the aldehyde 46 per cent, of the activity of pyridoxine. Though pyridoxine itself is inactive for Lactobacillus casci and Streptococcus faccalis R, pyridoxal is active and pyridoxamine inactive for the former, whereas pyridoxamine is active and pyridoxal 36 per cent as active as pyridoxamine for the latter. Assuming that vitamin B₆ complex contains no other members than pyridoxine, pyridoxal, and pyridoxamine. differential assays may be conducted on natural materials or on mixtures of the three synthetic forms, employing several microorganisms. Such assays are difficult, however, because of the ease of conversion from one form to any other. Pyridoxal when autoclaved with hydrolyzed casein produces some pyridoxamine, resulting in increased activity for S. faecalis. The reverse of this transamination reaction occurs when pyridoxamine is autoclaved with α -ketoglutaric acid. Such treatment results in increased activity for L. casei and decreased activity for S. faecalis. Autoclaving pyridoxine with cystine, glycine, ammonia, or thioglycollic acid or treating with hydrogen peroxide results in the formation of "pseudopyridoxine" (probably pyridoxal and pyridoxamine), having increased biological activity for lactic acid organisms. Attempts have been made to prevent these transamination or partial oxidation reactions by sterilizing the hydrolyzed samples and the microbiological media separately, then combining them aseptically. Such procedures, however, may not give a true picture of the concentrations of the various forms originally present in the test materials, since the undesirable conversions may occur during the sterilization of the samples themselves. When animal tissues are autoclaved with pyridoxine, the activity for certain lactic acid bacteria may increase several thousand-fold. Moreover, the differential assays are based on the tenuous assumption that pyridoxine, pyridoxal, and pyridoxamine are the only existing forms of vitamin B₆.

Certain anomalous results obtained in the assay of natural materials for vitamin B_6 have been interpreted to indicate the presence of forms of the vitamin as yet unknown. The bound pyridoxine in rice bran concentrates is completely liberated by autoclaving with 2 N sulfuric acid, so that analysis of such hydrolysates with Saccharomyces carlsbergensis gives values agreeing with those of the rat assay. Hydrolysis of yeast and liver samples by the same treatment, however, gives low values by the microbiological procedure. Only when the sample is hydrolyzed by heating with comparatively weak acid, 0.055 N sulfuric, do the values agree with those found in the rat assay. The low results may not be attributed to destruction of the known forms of vitamin B_6 by the strong acid treatment, since pyridoxine, pyridoxal, or pyridoxamine may be heated in the presence of yeast and liver without measurable destruction.

Since all members of the vitamin B₆ complex, both known and unknown, have equal activity for Saccharomyces carlsbergensis and for the rat, reliable microbiological assays of natural materials may be made employing the former organism. However, since some products require autoclaving in 2 N and others in 0.055 N sulfuric acid, careful attention should be given to the hydrolytic procedures employed.

A reliable biological procedure for the determination of vitamin B_6 is that of Dimick and Schreffler, which is based upon the growth of rats and upon the cure of specific rat dermatitis. The more recent method of Sarma, Snell, and Elvehjem 180 eliminates certain natural materials from the basal ration and is claimed to be more specific.

The ingestion of pyridoxine by man results in the urinary excretion of pyridoxic acid (2-methyl-3-hydroxy-4-carboxy-5-hydroxymethyl pyridine). This compound is converted by heating with strong acid to a highly fluorescent lactone which can be determined by simple fluorometric means. This reaction is useful in studies of vitamin B₆ in human metabolism.

Determination of the Vitamin B₆ Complex: Microbiological Method of Atkin, Schultz, Williams, and Frey: 181 Principle. The growth stimulation of a strain of the yeast Saccharomyces carlsbergensis by vitamin B₆ is employed in the microbiological assay of the vitamin.

¹⁸⁰ Dimick and Schreffler: J. Nutrition, 17, 23 (1939).

¹⁸⁰a Sarma, Snell, and Elvehjem: J. Biol. Chem., 165, 55 (1946).

¹⁸¹ Atkin, Schults, Williams, and Frey: Ind. Eng. Chem., Anal. Ed., 15, 141 (1943).

Procedure: Preparation of Yeast Inoculum: Prepare a fresh slant of Culture 4228 (American Type Culture Collection), a strain of Saccharomyces carlsbergensis, on Difco malt agar and incubate for 24 hours at 30°. Remove a quantity of fresh growth with a sterile wire loop and suspend in 10 ml. of sterile 0.9 per cent saline in a colorimeter tube. With the aid of a densitometer or photoelectric colorimeter, adjust the concentration to an equivalent of 1 mg. of moist yeast per ml. by adding sterile saline. Dilute 5 ml. of the adjusted suspension with 45 ml. of saline in a sterile Erlenmeyer flask.

Preparation of the Sample: Suspend a portion of the sample containing between 2 and 4γ of vitamin B₆ in 180 ml. of 0.055 N sulfuric acid. 183 Autoclave at 15 pounds pressure for 1.5 hours, cool, neutralize to pH 5.2, and dilute to 200 ml. Centrifuge if turbid and assay the clear supernatant extract.

Preparation of Basal Medium: Mix 100 ml. of sugar and salts solution, 184 20 ml. of potassium citrate buffer, 20 ml. of casein hydrolysate, 10 ml. of thiamine solution, 10 ml. of inositol solution, 4 ml. of biotin solution, and

5 ml. of calcium pantothenate solution. Dilute to 200 ml.

Microbiological Assay: Place 5 ml. of basal medium in each of a series of 18 mm. pyrex test tubes. In successive tubes pipet respectively 0.25, 0.50, 1.00, 2.00, 3.00, and 4.00 ml. of extract. With each assay series also include a reference series consisting of tubes containing 0, 5, 10, 15, 20, 30, and 40 millimicrograms of pyridoxine hydrochloride. Adjust the total volume in each tube to 9 ml. Plug the tubes and steam for 10 minutes and cool. Under aseptic conditions introduce into each tube 1 ml. of the yeast inoculum. Place the tubes in a mechanical shaker for 16–18 hours at 30°. Immediately thereafter estimate the yeast growth turbidimetrically in a densitometer or photoelectric colorimeter with a 660 or 720 my filter. 145

Calculation. On ordinary graph paper plot the results of the reference series in per cent absorption against millimicrograms of pyridoxine hydrochloride. Estimate the values for the unknowns from the graph. Calculate the pyridoxine content of the sample for each tube. Average all values which agree within 10 per cent of their mean.

Interpretation. The vitamin B₆ group consists of pyridoxine, pyridoxal, pyridoxamine, and one or more unidentified labile factors. All members of the complex show comparable activity for Saccharomyces

182 Calibrate the densitometer with a suspension of moist bakers' yeast.

¹⁸³ Some materials, wheat, and wheat products require more acid. For such samples use 2.0 N sulfuric acid.

184 Sugar and Salts Solution: Dissolve 200 g. of C.P. dextrose (anhydrous), 2.2 g. of monopotassium phosphate, 1.7 g. of potassium chloride, 0.5 g. of calcium chloride dihydrate, 0.5 g. of magnesium sulfate, 0.01 g. of ferric chloride, and 0.01 g. of manganese sulfate in distilled water and chlute to 1000 ml.

Polassium Citrate Buffer: Dissolve 100 g. of potassium citrate monohydrate and 20 g. of citric acid monohydrate in distilled water and dilute to 1 liter.

Casein Hydrolysate Solution: Neutralize 80 ml. of "vitamin-free" casein hydrolysate (10 per cent solution, obtainable from General Biochemicals, Inc., Chagrin Falls, O.) to pH 4-6 and dilute to 100 ml.

Thiamine Solution: 10 γ per ml. Inositol Solution: 1 mg. per ml. Biotin Solution: 0.8 γ per ml.

Calcium Pantothenate Solution: 200 y per ml.

186 In almost every case pigments, when present in the test extracts, absorb light maximally in the visible spectrum at about 400 to 450 mµ but not to any extent in the range 660 to 720 mµ. Thus, with the use of a proper filter, no interference results from the increasing pigmentation of the solution with increasing quantities of test extract. In any case it is recommended that a separate tube containing 4.00 ml. of test extract plus 1 ml. of water (no inoculum) be included in the series. Readings of this solution allows proportional corrections of the photometric densities of the serial tubes for absorption due to interfering pigments.

carlsbergensis (Culture 4228) and the rat. Hence this procedure measures biological vitamin B_6 activity rather than the concentration of pyridoxine or any single derivative.

PANTOTHENIC ACID

Bios, a growth stimulant essential for yeast, was described in 1901 by Wildiers. 186 Numerous attempts were made to elucidate the nature of this factor (or, as later discovered, factors), but not until 1933 was a crystalline product isolated by R. J. Williams and his co-workers, 187 who called it pantothenic acid (and later suggested pantothen) to indicate its universal distribution. In the meantime, other groups of workers were interested in an extract prepared from liver, variously designated "filtrate factor." chick antidermatitis factor, or Factor II, which was found to be necessary to restore growth and prevent a severe dermatitis in chicks receiving a diet of heated grains. The introduction of microbiological assays using lactic acid bacteria stimulated progress along these lines which were merged in 1939. Jukes, 188 testing potent concentrates of William's yeast growth factor on chicks, showed it to be identical with the "filtrate factor," and Woolley, Waisman, and Elvehjem189 showed that it was a derivative of β -alanine which Williams had reported to be a cleavage product of pantothenic acid.

The crystallization of pantothenic acid, its structure, and finally its synthesis were reported in 1940 by the Merck group of investigators. Pantothenic acid is available commercially as the calcium or sodium salt.

Physiological and Clinical Aspects of Pantothenic Acid. Pantothenic acid is widely distributed in animal and plant tissues, indicating that the vitamin plays a fundamental role in metabolism. It is required by the chick, rat, pig, dog, and other vertebrates. Deficiency symptoms are quite varied in different species. In the chick, the syndrome includes keratitis, dermatitis, fatty liver, lesions of the spinal cord, and involution of the thymus; the vitamin is necessary for reproduction in hens but not for egg production. In rats, insufficient intake of dietary pantothenic acid results in necrotic lesions of the adrenal cortex and other related symptoms. Regulation of salt and water balance are functions of the adrenal cortex. Pantothenic acid deficiency results in increased appetite for salt and a low salt diet promotes the graying of hair which results from pantothenic acid deficiency. Deprivation of water produces "bloody whiskers" (i.e., porphyrin staining) in rats, a condition also brought about by pantothenic acid deficiency.

Achromotrichia or graying of hair in black rats ("rusting" in white rats) on diets lacking pantothenic acid, and similar phenomena in dogs and foxes, probably are due to a complex deficiency, since pantothenic acid itself is less effective than extracts containing mixtures of B-complex

factors. Pantothenic acid has not been established to be of value in restoring the color to human gray hair.

The metabolism of pantothenic acid is related to other vitamins of the B group—e.g., pantothenic acid can cure inositol deficiency by stimulating the synthesis of the latter by intestinal bacteria. Even when inositol is supplied in the diet, deficiency symptoms of that vitamin can develop in the absence of pantothenic acid. The "spectacled eye" condition in rats, associated with a deficiency of inositol or biotin, may develop in the absence of sufficient pantothenic acid.

Pantothenic acid is required in the metabolism of all bacteria. Those which do not require an external supply synthesize it themselves.

The physiological role of pantothenic acid probably is related to the metabolism of carbohydrates. The vitamin causes an increase in the production of carbohydrate by alfalfa seedlings and stimulates the storage of glycogen in yeast. Oxygen consumption by living cells deficient in pantothenic acid is stimulated by the addition of the vitamin when pyruvate is employed as the substrate. The pantothenic acid content of the blood of rabbits is lowered by the administration of glucose.

The physiological effect of pantothenic acid is highly specific for that molecule. Replacement of the β -alanine portion with α -alanine, or with other amino acids having structures similar to β -alanine, produces inactive compounds. The optical antipode of the natural l-isomer is also inactive. The β -alanine portion alone is sufficient for some yeasts and diphtheria bacilli, and is partly available for rats, but not for chicks. These organisms probably utilize the β -alanine for the synthesis of pantothenic acid. Certain hemolytic bacteria require only the dihydroxydimethylbutyryl portion of the molecule. Hydroxypantothenic acid has a biological activity varying from 2 to 25 per cent of that of pantothenic acid, depending upon the organism employed and the conditions of assay.

Pantothenic acid occurs bound in natural materials in forms available to higher animals but not to microörganisms. For the latter, it must first be released by suitable hydrolytic procedures. Certain synthetic forms of bound pantothenate have been investigated. Ethyl monoacetylpantothenate is active for the rat and chick, and ethyl pantothenate for the rat. However, neither of these forms show activity for microörganisms unless they are previously hydrolyzed by procedures similar to those employed for the release of bound pantothenate in natural materials.

Certain structurally related compounds behave as antivitamins toward pantothenic acid. Pantoyltaurine (the sulfonic analog), pantoyltauramine, and homopantoyltaurine inhibit the growth of bacteria which require an external source of the vitamin. These antivitamins probably operate by competing in some enzyme systems. One observer has found that the administration of pantoyltaurine to mice produces symptoms similar to those of pantothenic acid deficiency. This observation could not be confirmed by other investigators. For a further discussion of antivitamins, see Chapter 36.

Possibly because of intestinal synthesis, pantothenic acid deficiency has not been observed in man and hence its importance in human nutrition

has not been clarified. As indicated above, early claims of its value in the restoration of color to gray hair have been disproved. However, the vitamin is undoubtedly essential for other functions in man. The daily requirement, as estimated from the analysis of good diets and from urinary excretion, is approximately 5–10 mg. per 2500 calories.

Storage and Synthesis of Pantothenic Acid. Pantothenic acid from external sources is not required by sheep and cattle, since the vitamin is synthesized by microörganisms in the rumen of these animals. It may be synthesized by certain molds, bacteria, and yeast, when grown in media devoid of pantothenic acid. Some yeasts require an external supply of β -alanine. Pantothenic acid is produced by green plants after they have developed sufficiently to perform their photosynthetic functions.

Distribution of Pantothenic Acid.¹⁹¹ Pantothenic acid is present in all living tissues. Excellent sources are liver, kidney, rice bran, molasses, egg yolk, peanuts, and peas. Appreciable concentrations are also found in sweet potatoes, oats, wheat, rye, barley, and broccoli. Pantothenic acid occurs in natural materials both free and combined, though a major fraction of the vitamin in animal sources is bound.

Chemistry of Pantothenic Acid. Pantothenic acid is a pale yellow viscous oil having the following formula.

Pantothenic Acid (C₉H₁₇O₁N, mol. wt. 219.2)

The free acid has a specific rotation, $[\alpha]_D^{26} = +37.50^\circ$. The synthesized vitamin is obtainable commercially as the white, crystalline calcium salt $(C_9H_{16}O_5N)_2Ca$, $[\alpha]_D^{26} = +24.30^\circ$. Pantothenic acid is adsorbed by norit at pH 3.5 or by aluminum oxide previously activated with hydrochloric acid. It may be eluted from norit with ammonia or pyridine and methanol. It is not adsorbed by fullers' earth. Pantothenic acid is soluble in water, ethyl acetate, dioxane, and glacial acetic acid, and is slightly soluble in ether and amyl alcohol, and insoluble in chloroform and benzene. It is unstable to heat in the dry state or in acid or alkaline medium. In the pH range 5 to 7 it may be autoclaved at 15 pounds pressure for one-half hour without loss. β -alanine has been found in alkaline hydrolysates of pantothenic acid; a lactone has been noted in acid-treated samples.

Determination of Pantothenic Acid. No satisfactory chemical test is available for the determination of the vitamin. In early studies, the biological test involving measurement of the rate of growth of chicks and the prevention or cure of specific chick dermatitis¹⁹² showed poor agreement with microbiological assays. However, when the presence of bound pantothenate in biological materials was established and satisfactory methods developed for liberating the vitamin without loss, thereby making it available to the microörganisms, the discrepancies disappeared.

¹⁹¹ See Appendix IV.

¹⁹⁹ Jukes: J. Biol. Chem., 117, 11 (1937); J. Nutrition, 21, 193 (1941).

Since pantothenic acid is labile when heated with acid or alkali, the bound form of the vitamin must be hydrolyzed by means of enzymes.

Pantothenic acid may be determined by any of several microbiological

procedures. The most satisfactory of these is described below.

Determination of Pantothenic Acid: Modified Microbiological Method of Skeggs and Wright.¹⁹³ Pantothenic acid is determined by measurement of the growth stimulation of Lactobacillus arabinosus 17-5 by titration of the lactic acid formed or by turbidimetric determination of the cell population. The bound vitamin is first liberated by digestion with clarase.

Procedure: Prepare the basal medium having the composition shown in the table below. Five liters may be prepared as a stock solution at one time provided the glucose and synthetic vitamins are omitted. This solution keeps indefinitely at room temperature under benzene even without sterilization. Prepare a stock vitamin solution containing 4 mg. each of thiamine, riboflavin, and niacin, 8 mg. of pyridoxine hydrochloride, 0.4 mg. of p-aminobenzoic acid and 10 γ of biotin per 100 ml. Store the vitamin supplement in a dark bottle in the refrigerator and renew monthly. Prepare a solution containing 100 γ per ml. of calcium pantothenate.

Carry stab cultures 194 of Lactobacillus arabinosus 17-5 by monthly transfer in a medium containing 1 per cent yeast extract, 1 per cent glucose, and 1.5 per cent agar. After transfer, incubate the culture at 33° for 24 to 48 hours, then store in the refrigerator. Prepare the inoculum for the assay tubes by transferring from the stock culture to a sterile tube containing 10 ml. of the basal medium to which $0.2~\gamma$ of calcium pantothenate have been added. Incubate for 24 hours at 33°, centrifuge, and discard the supernatant liquid. Resuspend the cells in 10 ml. of physiological saline, centrifuge, and discard the supernatant. Resuspend the cells in sufficient physiological saline to produce a very light suspension.

BASAL MEDIUM

Ingredient	Per 100 ml. Medium (Double Strength)	Ingredient	Per 100 ml. Medium (Double Strength)

¹⁹³ Skeggs and Wright: J. Biol. Chem., 156, 21 (1944).

¹⁸⁴ A culture of the organism may be obtained from the American Type Culture Collection, Georgetown University Medical School, Washington, D. C., under the classification number 8014.

¹⁹⁸ Hydrochloric acid-hydrolyzed, norit-treated, vitamin-free casein is employed. A 10 per cent solution of casein hydrolysate suitable for this medium may be obtained from General Biochemicals, Inc., Chagrin Falls, Ohio.

Preparation of the Sample: Suspend the finely ground sample containing approximately 10 y or more of pantothenic acid in 100 ml. of water. Adjust the pH to 6.8 and heat in an autoclave for 20 minutes at 15 pounds pressure. Cool and add 100 mg. of clarase. Cover the suspension with a thin layer of benzene, and incubate at 45° C. for 48 hours. Readjust the pH if necessary to 6.8. Place the sample in an autoclave and heat with steam for 10 minutes. Dilute, if necessary, so that the concentration of the suspension is approximately 0.1 y of pantothenic acid per ml., centrifuge, and test the clear supernatant solution. Into a series of test tubes, pipet the following volumes: 0.00, 0.25, 0.50, 0.75, 1.00, 1.25, 1.50, 1.75, and 5.00 ml. Similarly prepare a standard series of tubes from a dilution of the standard solution of calcium pantothenate containing 0.1 y per ml. Dilute the aliquots in both the standard and unknown series with distilled water so that each tube contains a total volume of 5 ml. To each tube add 5 ml. of the double strength medium, cover with cotton plugs or metal caps and heat in an autoclave at 15 pounds pressure for 15 minutes. Add to each tube aseptically one drop of the inoculum prepared as described above. Incubate at 33° C. for 72 hours and determine the lactic acid produced by titration with 0.1 N sodium hydroxide, employing bromthymol blue as the indicator.

Equally satisfactory results may be obtained by measurement of the population of the microörganisms turbidimetrically after 18 hours of incubation at 33°. A photoelectric colorimeter is employed for this purpose. The instrument is set at 100 per cent transmittance with the solution from the assay tube containing no added pantothenic acid.

Calculation. Prepare a standard reference curve, employing the data obtained in the standard series by plotting on ordinary graph paper, γ of calcium pantothenate as the abscissae and ml. of 0.1 N sodium hydroxide, or photometric density, as the ordinates. From this reference curve, estimate the "calcium pantothenate" content of each tube in the unknown series. Divide this value by the volume of the extract, originally placed in each tube, in order to obtain the concentration per ml. of extract. Determine the average of at least four values which differ from each other by no more than 10 per cent. Calculate the pantothenic acid content of sample using the formula:

$$C \times \frac{D}{G} \times 0.92 = \gamma$$
 of pantothenic acid per g. of sample,

where C is the concentration of calcium pantothenate per ml. of extract, D is the final volume to which the extract was diluted, G is the weight of the sample taken for analysis, and 0.92 is the factor for converting calcium pantothenate to pantothenic acid.

Comment. The microbiological determination of pantothenic acid employing Lactobacillus arabinosus 17-5 gives values which are in agreement with microbiological procedures employing other microörganisms and also with the biological chick assay. Since the microörganisms do not respond to bound pantothenic acid and since the vitamin is labile to heat in acid or alkaline solution, digestion of the sample must be accomplished at a neutral pH by means of digestive enzymes.

PTEROYLGLUTAMIC ACID ("FOLIC ACID")

In early investigations, this vitamin was described under various names including vitamin M, factor U, yeast norit eluate factor, vitamin

B., and L. casei factor. The multiplicity of the nomenclature was occasioned by the fact that various conjugates of pteroylglutamic acid exist in natural materials. These conjugates vary in their physical and chemical

properties, and in their biological potencies.

Physiological and Clinical Aspects of Pteroylglutamic Acid. This vitamin is a growth factor for various bacteria. Its deficiency in chicks leads to slow growth, poor feathering, and macrocytic anemia. In rats, a deficiency of pteroylglutamic acid may be produced by adding sulfonamides to purified diets. Anemia, leukopenia, and agranulocytosis are produced, and may be cured by administering pteroylglutamic acid. Monkeys on a purified diet develop a syndrome characterized by leukopenia, anemia, necrosis of the gums, loss of appetite, diarrhea, and eventual death. The syndrome responds to either "fermentation L. casei factor" or to pterovlglutamic acid.

Pteroylglutamic acid produces responses in certain diseases that are characterized by macrocytic anemia associated with megaloblastic arrest in the bone marrow. It is used in the treatment of sprue, Addisonian pernicious anemia, nutritional macrocytic anemia, and the macrocytic anemias of pregnancy and infancy. The blood picture in these diseases is marked by a low number of erythrocytes per unit volume of blood, a low per cent hemoglobin, high color and volume indices of the erythrocytes, and lowered leukocytic and platelet counts.

In pernicious anemia a characteristic response is produced by oral or parenteral administration of pteroylglutamic acid in doses of from 1 mg. to 10 mg. daily. A feeling of subjective improvement commonly occurs within three to five days. At the same time a sharp increase in the reticulocyte content of the blood is noted and a peak reticulocyte value is usually reached in about one week, following which a fairly rapid drop takes place. A slow increase takes place in the erythrocyte count and a simultaneous increase in the hemoglobin content of the blood lasting over a period of three to eight weeks and tending toward the establishment of normal values. Simultaneously there is an increase in the white cell count and the platelet count. The bone marrow in pernicious anemia upon supravital staining is seen to contain a predominating number of ervthroid cells with a so-called "left shift" to the immature megaloblastic stage. Administration of pteroylglutamic acid produces a change in the bone marrow picture toward normal. The change is characterized by megaloblastic maturation, an increase in normoblasts, and a normal picture is reached in about 10 days. 196 No change has been reported as being produced by pteroylglutamic acid in the achlorhydria of pernicious anemia. Certain aspects of changes in the blood of a patient with Addisonian pernicious anemia who received pteroylglutamic acid are illustrated in Fig. 303.

In sprue, the administration of pteroylglutamic acid either parenterally or orally results first in the disappearance of the symptom of glossitis. A reticulocyte peak is commonly reached in six to nine days. Increases occur in the erythrocyte count, the per cent hemoglobin, the white cell count.

¹⁰⁶ Doan, Wilson, and Wright: Ohio State Med. J., 42, 139 (1946).

and the number of platelets in a manner similar to that described above for pernicious anemia. There is an improvement in the sense of well-being, an increase in appetite, a subsidence of diarrhea, and a gain in body weight. The bone-marrow picture shows a disappearance of the more primitive red blood cells and a return of the white cell series to normal proportions.

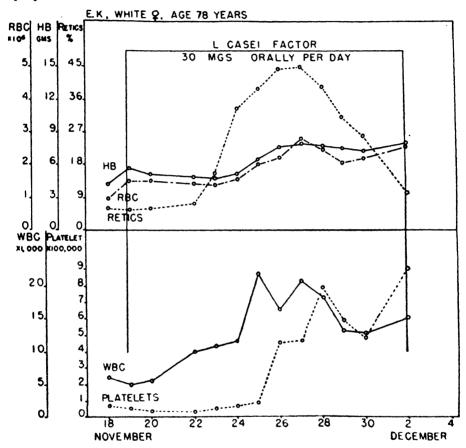

Fig. 303. Hematological response of a patient with Addisonian pernicious anemia to the daily oral administration of 30 mg. of pteroylglutamic acid (*L. casei* factor). From Moore, Bierbaum, Welch, and Wright: *J. Lab. Clin. Med.*, 30, 1056 (1945).

Nutritional anemia and the macrocytic anemias of pregnancy and infancy show hemopoietic responses along lines similar to those described for pernicious anemia and sprue.

Relation of Pteroylglutamic Acid to the Erythrocyte Maturation Factor ("e.m.f.") Present in Liver Extracts. Injectable liver extracts corresponding to the standards of the U.S. Pharmacopoeia are effective in producing hematological responses in patients with Addisonian pernicious anemia. Such extracts contain pteroylglutamic acid in

amounts far too small to produce clinical responses. The effective substance in liver extract has not been isolated, but it appears to have several characteristics which differ from those of pterovlglutamic acid, including the fact that animals with pteroylglutamic acid deficiency do not respond to the administration of the erythrocyte maturation factor. Pteroylglutamic acid conjugate has been reported to be ineffective in the treatment of pernicious anemia, and it has been suggested that the erythrocyte maturation factor is concerned with activation of a "conjugase" enzyme, which liberates pteroylglutamic acid from its conjugate. 197 It has been reported 198 that folic acid is required by certain lactic acid organisms for the synthesis of thymine, 5-methyl-uracil (see p. 192). When the latter is present in excess, a typical folic acid response is not observed microbiologically. Spies and co-workers 198 have observed thymine to be effective in the treatment of pernicious anemia in relapse.

Distribution of Pteroylglutamic Acid. 200 Pteroylglutamic acid is widely distributed in biological materials, often in "conjugated" form. Good dietary sources include liver, yeast, and green leaves. The amount required in the case of chicks appears to be about 0.5 part per million of diet.

Chemistry of Pteroylglutamic Acid. The structure and synthesis of pteroylglutamic acid were described in 1946.201 The molecule consists of a pteridyl group connected in methylene linkage through p-aminobenzoic acid to l(+)glutamic acid and the structural formula is as follows:

The pteridyl group is chemically related to xanthopterin, a yellow pigment which is present in certain natural materials including urine and

the wings of butterflies.

Pteroylglutamic acid is a substance of low toxicity as measured by toxicological tests with mice, rats, guinea pigs, rabbits, cats and dogs. The LD₅₀ for mice and rats is about 0.5 g. per kilogram of body weight when injected intravenously.

A second form of the vitamin, "fermentation L. casei factor," was isolated from an aerobic fermentation of an organism of the genus Corunebacterium. It was found to yield three molecules of glutamic acid upon

¹⁹⁷ Welch, Heinle, Nelson, and Nelson: J. Biol. Chem., 164, 787 (1946).

¹⁹⁸ Stokes: J. Bact., 48, 201 (1944). 159 Spies, et al.: J. Lab. Clin. Med., 31, 643 (1946).

²⁰⁰ See p. 1249. ²⁰¹ Angier, et al., Science, 102, 227 (1945); 163, 667 (1946).

degradation. Upon partial degradation with alkali, "fermentation L. casei factor" yielded dl-pteroylglutamic acid. "Fermentation L. casei factor" is relatively inactive as a growth factor for S. faecalis R by comparison with pteroylglutamic acid. However, on a molar basis, "fermentation L. casei factor" appears to be just as active as pteroylglutamic acid for L. casei, for chicks, for rats, and for monkeys. When the p-amino-benzoyl-glutamic-acid radical in the pteroylglutamic acid molecule is

Fig. 304. Synthetic pteroylglutamic acid crystals. Viewed through crossed polarizers. (Photographed by Dr. A. F. Kirkpatrick, Stamford Laboratories, American Cyanamid Co. Courtesy, Dr. T. H. Jukes.)

replaced by p-aminobenzoic acid, the resultant substance is termed "pteroic acid." This substance is active for S. faecalis R but not for L. casei or for animals.

Pteroylglutamic acid is a yellow, tasteless substance which is only slightly soluble in water; about 0.01 mg. per ml. dissolves at room temperature. It is destroyed rapidly by boiling with dilute hydrochloric acid. Its sodium salt is fairly soluble. Light has a destructive action on the solution. Pteroylglutamic acid has an absorption spectrum which shows characteristic maxima in the ultraviolet range. 202 The substance crystallizes from water in the form of thin lenticular crystals (Fig. 304) which exhibit birefringence and parallel extinction.

²⁰² Stokstad: J. Biol. Chem., 149, 573 (1943).

Determination of Pteroylglutamic Acid: Microbiological Assay. The assay is carried out with either Lactobacillus casei E or Streptococcus faecalis R and the method for either organism is described below.

Pteroylglutamic Acid Standard Solution.

- a. Preparation: 20 mg. of pteroylglutamic acid are washed with water into a 100-ml. volumetric flask. Add 2 ml. of 0.1 N NaOH. Shake until material is in solution. Add 5 ml. of 1.0 M sodium phosphate buffer, pH 7.0, 25 ml. of absolute ethanol, and make up to 100 ml. with water.
- b. DILUTIONS: Dilute to 0.001 γ per ml. for assay with L. casei E; to 0.005γ per ml. for assay with S. faecalis R.
- c. Assay Levels of Diluted Standard Solutions: 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0 ml. for L. casei E; 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0 ml. for S. faecalis R.

Note: Since folic acid, in dilute solution, breaks down in direct or indirect sunlight, all such solutions should be kept in the dark or in brown bottles out of strong light.

BASAL MEDIUM

Modifications of This Medium.

- 1. Peptone omitted for assay with L. casei E.
- 2. Biotin supplement of 0.01 γ per 10 ml. final volume added for assay with S. faecalis R.

²⁰⁰ Tepley and Elvehjem: J. Biol. Chem., 157, 303 (1945).

²⁶⁴ Salts: MgSO₄·7H₂O, 10 g.; NaCl, 0.5 g.; FeSO₄·7H₂O, 0.5 g.; MnSO₄·2H₂O, 0.337 g.; H₂O, 250 ml.

The preparation of the various constituents of the medium is as follows:

Vitamin-free, Acid-hydrolyzed Casein. 50 g. of Labco casein are mixed with 500 ml. of 5 N HCl and refluxed for 48 hours. The hydrolysate is concentrated in vacuo to a thick syrup, redissolved in water, and reconcentrated. It is then taken up to 500 ml. with water, neutralized to pH 3 with NH₄OH, and 5 g. of norit A are added. The mixture is stirred for 30 minutes and filtered. The filtrate is neutralized with 5.0 N NaOH. This, as well as other biological solutions, is preserved with toluene and kept cold.

Peptone Treated with Norit. 50 g. of peptone in 200 ml. of water are adjusted to pH 3 and stirred with 5 g. of norit for one hour, filtered, and diluted to 500 ml. This material is tested to determine its effect on the blank titration and the maximum amount which does not cause an excessively high blank is then included in the medium. This amount usually lies between 1 and 3 mg. per tube.

Adenine and Guanine. These are dissolved together in a small amount of 1.0 N HCl with heat and diluted to 250 γ per ml.

Xanthine and Uracil. These are dissolved in dilute NH₄OH and diluted to 1 mg. per ml.

Cystine and Tryptophane. Each of these is dissolved in a small amount of 1.0 N HCl and diluted to 1 mg. per ml. and 10 mg. per ml., respectively.

Vitamins. 60 mg. of pyridoxine hydrochloride, 20 mg. of calcium pantothenate, 30 mg. of nicotinic acid, 10 mg. of thiamine hydrochloride, 10 mg. of riboflavin, and 20 γ of biotin are added to 100 ml. of distilled water. 0.5 mg. of p-aminobenzoic acid may be incorporated with the above vitamin mixture, or, if it is desired to omit p-aminobenzoic acid in the S. faccalis R assay, a separate stock solution can be made. This mixture is shaken well before being added to the basal medium (0.02 ml. per tube).

Asparagine. 1 g. of asparagine is dissolved in 100 ml. of water and 0.1 ml. added per tube.

Preparation of the Inoculum. The inoculum medium for S. faecalis R contains 1.0 mg. of solubilized liver extract per 10 ml. of medium and the L. casci inoculum contains 0.1 mg. of solubilized liver extract per 10 ml. of medium. Other crude liver extracts may be used. The inoculum is incubated for 20 to 24 hours. For S. faecalis R, the cells are centrifuged out, resuspended in 0.9 per cent saline, and 1 drop added per tube. For the L. casci inoculum the cells are centrifuged out, resuspended in saline, and 1 drop added to 10 ml. of 0.9 per cent saline. One drop of this cell suspension is added per tube.

The samples are placed in tubes $\frac{34}{4}$ by 6 inches, the volume in each is made up to 5 ml., 5 ml. of basal medium are added, and the tubes are plugged 205 and sterilized for 15 minutes at 15 pounds pressure. After

¹⁰³ A pure grade of absorbent cotton is suggested from the work of Sherwood and Singer: J. Biol. Chem., 155, 361 (1944), who found nonabsorbent cotton to contain appreciable amounts of "folic acid."

cooling to room temperature, 1 drop of the inoculum is added to each tube. The S. faecalis R assay is incubated at 30° for the desired length of time. The growth response may be determined after 16 hours' incubation by use of a photoelectric turbidimeter or after 30 to 72 hours' incubation by titration of the formed acid with 0.1 N NaOH. Thymol blue is a satisfactory indicator. The L. casci assay is incubated for 72 hours at 37° and the growth response measured by titration with 0.1 N NaOH. Bromthymol blue is a recommended indicator.

BIOTIN

A striking example of how the isolation of an active principle in pure form can lead to coordination of a vast amount of seemingly unrelated observations may be seen in the story of biotin. Kögl and Tönnis²⁰⁶ in 1936 reported the isolation from egg yolk of a yeast growth factor (bios II) in the form of its methyl ester. They assigned the name biotin to the free acid. Recognition by West and Wilson²⁰⁷ of the probable identity of this factor with coenzyme R, a growth and respiratory stimulant for the legume nodule organism Rhizobium, was followed by the demonstration by György, Melville, Burk, and du Vigneaud²⁰⁸ of the identity of biotin with both coenzyme R and vitamin II. The latter had been previously reported to protect against a form of dermatitis induced by feeding raw egg white. The identification of biotin also illustrates the contribution to the advance in nutritional science made possible by the application of microbiological methods. The structure of biotin was established by du Vigneaud and associates. Synthetic biotin is available commercially.

In terms of the minimum protective dosage, biotin is one of the most potent physiological substances known, less than 0.03 γ (about 1/30,000,000 g.) per day being sufficient for the rat. The role of biotin in human nutrition is not known although experimental evidence in other species suggests that its function is effected through a respiratory enzyme system. The high concentration of biotin in embryonic and tumor tissue has attracted considerable interest in the possible clinical significance of this vitamin.

Physiological Properties of Biotin. Biotin has been shown to be an essential nutrient for various lower organisms (including yeast, molds, bacteria, and fungi), for the rat, chick, turkey, monkey, rabbit, dog, and guinea pig, and for man. Deficiencies of this vitamin are difficult to produce experimentally because it may be synthesized by intestinal flora in higher animals. Deficiency symptoms may be induced, however, by feeding materials which either combine with the biotin to form nonabsorbable complexes (such as avidin of egg white, see below) or by feeding sulfa drugs which interfere with bacterial synthesis of the vitamin in the intestines.

In 1937 Boas discovered that the inclusion of large amounts of raw

Kögi and Tönnis: Z. physiol. Chem., 242, 43 (1936).
 West and Wilson: Science, 89, 608 (1939).

²⁹⁸ Győrgy, Melville, Burk, and du Vigneaud: Science, 91, 243 (1940).

(but not cooked) egg white in the diet of rats resulted in loss of hair, loss of weight, dermatitis, and death. It was also found that certain foods could cure or prevent these symptoms. Raw egg white contains a distinctive protein, later designated as avidin, capable of combining stoichiometrically with biotin, thus preventing its absorption from the digestive tract or its utilization by yeast. Symptoms of a biotin deficiency may be induced even in man by feeding a sufficient amount of raw egg white. Crystallized avidin (mol. wt. 70,000) has 15,000 times the biotin-combining power of raw egg white. Though the biotin-avidin complex is not absorbed from the gastrointestinal tract, the compound is biologically active when administered parenterally. The reported relationship between avidin and lysozyme (a mucolytic enzyme found in egg white and elsewhere which causes lysis or dissolving of certain microörganisms) appears to be incorrect.

The feeding of biotin to rats has been observed to cause an increase in fat and cholesterol synthesis in the liver. This can be prevented by adding egg white, lipocaic (a substance obtained from the pancreas), or inositol. Choline, however, is ineffective. Tumor tissue and embryonic tissue, both characterized by rapid growth, have high biotin concentrations, suggesting the possible association of this vitamin with the growth of malignancies.

Biotin deficiency in animals is associated with the development of dermatitis, loss of fur, disturbances of the nervous system, and death. The "spectacled eye" condition in rats (due to loss of hair around the eyes) may be associated with biotin deficiency. In the chick the deficiency symptoms are similar to those of pantothenic acid deficiency. Parenteral administration of biotin is three to five times more effective than oral administration in the treatment of deficiency symptoms.

Most microorganisms require biotin in the form of the free acid, though the methyl ester is biologically active for yeast and partially so for *Lactobacillus casci*. The diaminocarboxylic acid obtained from biotin by the hydrolysis of the urea portion of the molecule possesses 10 per cent of the activity of the original vitamin. Oxidation to the sulfoxide does not affect the activity of biotin, whereas conversion to the sulfone causes considerable inhibition of the growth stimulation of yeast.

Desthiobiotin, obtained by reduction of biotin with Raney nickel (replacing the sulfur atom with two hydrogen atoms), is as active as biotin for yeast, but is inactive for Lactobacillus casci and Lactobacillus arabinosus. Desthiobiotin has been shown to occur naturally.

The presence in urine of a substance having biotin potency for yeast which is not inhibited by avidin has been reported. The existence of other similar substances has been demonstrated, but in no instance have they been shown to be chemically similar to or related to biotin. Interference by such substances in the microbiological assay for biotin may be avoided by utilizing the ability of avidin to combine specifically with biotin.

Storage and Synthesis of Biotin. Biotin may be stored in the liver and kidneys, although newborn infants have no such reserves. It is probable that infants obtain some of their biotin from bacterial synthesis

1118

in the gastrointestinal tract. That such synthesis furnishes a considerable proportion of the biotin requirements of higher organisms is indicated by the fact that humans have been known to excrete via stools and urine three to six times as much biotin as they ingest. Rats do not require an external supply of biotin and excrete more than they consume. The vitamin is synthesized to a considerable extent in the rumen of the calf and cow. In the case of the rat the oral administration of sulfaguanidine or succinylsulfathiazole produces symptoms of biotin deficiency which are curable by administration of biotin.

Distribution of Biotin.²⁰⁹ Biotin is present in most animal tissues but in higher concentration in liver, kidneys, egg yolk, yeast, pancreas, and milk. It is also found in vegetables, grains, nuts, feeds, pollens, and molasses. Biotin exists in the free state in fruits and grasses, partly bound in nuts, vegetables, and grains, and mostly in combined form in yeast and liver. For assay with microörganisms it may be liberated by autolysis, acid hydrolysis, or enzymatic digestion.

Chemistry of Biotin:

 $\begin{array}{c} \textbf{Biotin} \ \ (C_{1n}H_{1n}O_3N_2S) \\ \textbf{Hexahydro-2-oxo-1-thieno(3,4)imidazole-4-valeric acid} \end{array}$

Biotin is a crystalline compound soluble in water and alcohol and insoluble in chloroform, ether, and petroleum ether. The compound melts at 230°-232° C, and has a specific rotation $[\alpha]_D^{25}$ of +90.7° and an isoelectric point at pH 3-3.5. Biotin has an ultraviolet absorption maximum at 234 m μ with a specific extinction coefficient of 42.5. It has a molecular weight of 244.3. The stability of biotin toward heat in the presence of acid or alkali has not yet been established. It has been reported that biotin in natural materials resists autoclaving with strong mineral acids (4-6 N HCl for two hours at 120°), a procedure used for the liberation of the vitamin in natural materials for microbiological assay. Some authors, however, have reported a loss of biotin by this hydrolytic procedure. In natural materials the vitamin is destroyed by heating with strong alkali, and is even less stable to this treatment in pure solutions. Both free and combined biotin are inactivated by oxidizing agents. Though esterification impairs the biological activity of biotin for microorganisms, acylation or alkylation do not affect it.

Biotin isolated from liver is identical with that isolated from milk.

However, biotin obtained from egg yolk (so-called α -biotin) is claimed to differ from that isolated from liver (β -biotin) in the chemical nature of the side chain. This difference is not as yet conclusively established.

Determination of Biotin. Biotin may be determined microbiologically by measurement of its effect upon the growth of microörganisms. The method of Snell, Eakin, and Williams²¹⁰ involves measurement of the growth stimulation of Saccharomyces cerevisiae. The procedure is similar to that described on p. 1103. The extremely high physiological potency of biotin is illustrated by the fact that it stimulates yeast growth when present in a concentration as low as one part in 5×10^{11} parts of medium. Biotin may also be determined by its growth stimulation of other microörganisms including Lactobacillus arabinosus and Lactobacillus casei. A rat assay such as was used in studies of the anti-egg-white-injury factor (vitamin II) may also be employed, though it requires large groups of animals and is not as satisfactory as the microbiological determination. One mg. of biotin methyl ester is equivalent to 27,000 units of vitamin H. the unit being the minimum daily dose required to cure the egg-white dermatosis in rats in 30 days. One great difficulty in the rat assay is that of producing biotin deficiencies, since rats obtain a considerable portion of their biotin from products of bacterial synthesis in their intestines. The assay for biotin using chicks is somewhat more satisfactory because they require greater amounts from dietary sources so that the deficiency is easily produced. Of the various assay methods, the microbiological procedure is generally preferred. See p. 1052.

PARA-AMINOBENZOIC ACID

The earliest indications of the nutritional importance of p-aminobenzoic acid were observations that the compound counteracted the bacteriostatic effect of sulfanilamide.²¹¹ Its importance in the nutrition of microörganisms and of higher animals was established shortly thereafter as well as its presence in certain natural materials, particularly yeast.²¹² p-Aminobenzoic acid is a unit in the structure of another vitamin, pteroylglutamic acid.

Physiological and Clinical Aspects of p-Aminobenzoic Acid. p-Aminobenzoic acid (often called PABA) is an essential nutrient for many microorganisms. The vitamin probably plays a physiological role by participation in essential enzyme reactions, although the specific effects of PABA deficiency in man are not known. An excess of p-aminobenzoic acid opposes the bacteriostatic effect of sulfonamides, possibly because of structural similarities (see Chapter 36). This antagonism obeys the mass action law, thus indicating that the inhibition is competitive. The antisulfonamide effect of the vitamin has been noted in vitro²¹³ as well as in vivo in mice infected with Streptococcus hemolyticus. Sulfonamideresistant strains of Staphylococcus have been developed in which the

²¹² Blanchard: J. Biol. Chem., 140, 919 (1941).

¹¹⁴ Woods: loc. cit.

resistance is proportional to the ability of the microörganism to synthesize p-aminobenzoic acid. p-Aminobenzoic acid interferes with the malaricidal action of sulfanilamide drugs, but not with that of quinine and atropine, which probably attack the microörganism through a different channel. The use of p-aminobenzoic acid derivatives as local anesthetics and their possible incompatibility with sulfonamides administered subsequently as bacteriostatic agents has been considered. Observations relating to the behavior of p-aminobenzoic acid under physiological conditions, however, indicate that p-aminobenzoic acid therapy probably does not interfere with subsequent administration of sulfonamides. Furthermore, it has been found that small amounts of p-aminobenzoic acid often potentiate sulfonamides.

p-Aminobenzoic acid is essential for normal growth²¹⁴ in the nonlactating rat,215 for lactation in albino rats and in sows,216 and for the maintenance of hair color in the black rat.217 Its successful use in the treatment of nutritional achromotrichia in man, reported in a few isolated cases, has been refuted on the basis of more carefully controlled studies. Anti-gray-hair properties have also been claimed for pantothenic acid, biotin, and "folic acid." These members of the vitamin B complex as well as p-aminobenzoic acid are synthesized by intestinal bacteria. Stimulation of the growth of microörganisms by the administration of one of the vitamin B complex may cause an increased synthesis or utilization of another member by the intestinal flora. This makes it difficult to ascribe particular physiological effects to specific B vitamins when administered orally. Thus the action of p-aminobenzoic acid in the prevention of achromotrichia has been ascribed by some observers to alterations in the intestinal flora thereby promoting the synthesis of pteroylglutamic acid

In some species, p-aminobenzoic acid has been found to increase the physiological potency of insulin and penicillin. PABA may also play a role in the metabolism of hormones—for example, by inhibiting the production of thyroid hormones. In addition, the rate of enzymatic inactivation of stilbestrol by mushroom tyrosinase, as well as the oxidative destruction of adrenaline, are inhibited by p-aminobenzoic acid.

p-Aminobenzoic acid absorbs ultraviolet radiations in the range which produces sunburn and suntan in human skin. The maximum effect is noted at 297.5 m μ . Erythema results when PABA is irradiated in saline solution and injected intracutaneously. The activation probably is due to a decomposition.

p-Aminobenzoic acid participates in detoxication reactions. The injection of hydroquinone in cats or mice results in graying of the fur, which can be prevented or cured by p-aminobenzoic acid. In rats PABA detoxifies high doses of pentavalent and trivalent arsenical drugs used in the treatment of various forms of syphilis, without interfering with their

bacteriostatic potency. It also detoxifies antimony compounds used in tropical diseases.

Large doses of p-aminobenzoic acid are toxic in dogs and rats. The oral administration of more than 1 g. per kg. of body weight in dogs is fatal. The vitamin has a greater toxicity for mice. On the other hand, the administration of 1.4 g. per kg. to rats is nontoxic. Moderate doses are acetylated in the human and excreted in the urine.

Distribution of p-Aminobenzoic Acid.²¹⁸ p-Aminobenzoic acid is present in most tissues. It occurs in nature in both the free and the combined form. Relatively high concentrations are found in yeast, liver, rice bran, rice polishings, and whole wheat. In the latter it is found mostly in the germ.

Chemistry of p-Aminobenzoic Acid. p-Aminobenzoic acid was synthesized by Fischer²¹⁹ as early as 1863, by reduction of p-nitrobenzoic acid with ammonium sulfide. It crystallizes in colorless needles which melt at 186°. It is soluble in water to the extent of 0.5 per cent at room temperature, but is freely soluble in alcohol or boiling water.

p-Aminobenzoic acid

Determination of p-Aminobenzoic Acid. No satisfactory chemical method is available for the determination of p-aminobenzoic acid. It reacts with p-dimethylaminobenzaldehyde in glacial acetic acid to produce a compound having a yellow color. However, this reaction, as well as other coupling reactions, is nonspecific and is given by isomers of p-aminobenzoic acid as well as by aniline and its derivatives, and by sulfonamides. In the analysis of biological materials, the bound vitamin must first be freed by strong acid or alkaline hydrolysis.

p-Aminobenzoic acid is required for the growth of several microorganisms, including Brucella abortus, Streptococcus hemolyticus and Clostridium acetobutylicum. A satisfactory microbiological method for the determination of PABA is based upon the growth stimulation of Acetobacter suboxydans. 220 Determinations may also be made employing organisms which do not require an external supply of the vitamin by measuring the degree of inhibition of the bacteriostatic effect of sulfa drugs resulting from the addition of p-aminobenzoic acid.

CHOLINE

Choline has occupied a prominent place in biochemical literature because of its relationship both to the phospholipids and to its acetyl ester.

^{*18} See Appendix IV.

²¹⁰ Fischer: Ann., 127, 142 (1863).

²¹⁰ Cheldelin and Bennett: J. Biol. Chem., 161, 751 (1945),

Acetylcholine, first studied as a synthetic product, then found in plant and animal tissues, plays an important role in the humoral transmission of parasympathetic and other nerve impulses to effector organs. More recently, choline has achieved added significance because of its role in the process of transmethylation (see below and p. 943).

Choline, probably of phospholipid origin, was isolated independently by numerous investigators and has been variously designated sinkalin, bilineurine, fagin, amatin, and neurine, the latter term being now reserved for the unsaturated base, trimethylvinylammonium hydroxide. The early confusion was cleared up following the elucidation of its structure and its subsequent synthesis.

Physiological Properties of Choline. Choline is essential for normal growth of the rat, chick, and dog, and for lactation in the rat. Dietary deficiency has been demonstrated to be responsible for paralysis in the hind legs of nursing rats, inhibition of egg production in chicks, slipped tendon in young turkeys, and diffuse nodular cirrhosis of the liver in rats, dogs, rabbits, and guinea pigs. Choline deficiency has also been reported to result in involution of the thymus gland, enlargement of the spleen, and hemorrhages of the kidney and eye.

Choline performs several physiological functions: it enters into the molecular structure of phospholipids and acetylcholine, and supplies labile methyl groups for transmethylation reactions. Phospholipids are concerned with the mobilization of fat in the body. In the absence of choline, neutral fat and, to some extent, cholesterol esters accumulate in the liver. Choline is also lipotropic in that it prevents fatty livers in depancreatized dogs. However, this condition, when induced in rats by high cholesterol feeding, does not respond to choline feeding.

Certain specific compounds with labile methyl groups, or otherwise related in structure, can replace choline in some of its biological functions. Methionine mobilizes liver fat in a manner similar to choline. and both the d- and l-forms are equally effective. The mechanism probably involves the transfer of labile methyl groups from methionine to ethanolamine with the formation of choline. In support of this hypothesis is the observation that choline containing deuterium may be isolated from the animal organism after feeding methionine whose labile methyl group contains deuterium. Betaine and other lipotropic factors may also supply methyl groups to ethanolamine. Conversely, methionine, an essential amino acid, can be replaced by homocystine when choline. betaine or dimethylethylammonium chloride is fed. The methyl-diethyl and the triethyl homologs do not support growth, but are strong lipotropic agents, and prevent the occurrence of hemorrhagic kidneys. Arsenocholine behaves similarly. There is no diminution of activity when phosphorus is substituted for the nitrogen of choline. The hydroxyl group must be free, however, since ethers are inactive. The methyl groups of creatine, S-methyl cysteine, or of the betaines from threonine. serine, or allothreonine, are not available for transmethylation.

Choline serves as a methylating agent in the physiological process:

guanidoacetic acid -- creatinine. Here, too, methionine and betaine can replace choline.

Choline is involved in the transmission of nerve impulses in the form of its acetyl ester, acetylcholine, a powerful agent which lowers the blood pressure. The organism maintains a delicate balance between acetylcholine and choline (the latter does not affect the blood pressure) by means of specific enzyme systems which can acetylate to acetylcholine or hydrolyze to free choline when necessary.

Storage and Synthesis of Choline. Choline is present in the animal organism chiefly in the form of the phosphatids; i.e., the lecithins and sphingomyelins. The fatty matter of brain, kidney, and liver is distinguished from that of adipose tissue by the fact that it consists largely of phosphatids. Lecithin is the glyceryl ester of a pair of fatty acids and a substituted phosphoric acid group attached to a choline radical. Sphingomyelin contains a fatty acid, sphingosine, and a choline-phosphoric acid group. In beef liver, only 2 per cent of the total choline is present in the free form.

As discussed above, choline may be synthesized in vivo from ethanolamine and a methyl donor, methionine or betaine. Rats on a diet containing ample methionine, for examine, need no dietary supply of choline.

Distribution of Choline.²²¹ The concentration of choline in animal tissues is proportional to their phospholipid constituents. Thus, egg yolk, liver, kidneys, brain, heart, and nervous tissue are rich sources. Good sources of choline are muscle tissue, green, leafy and leguminous vegetables, seed oil meals, and grain germs. In corn meal, 75 per cent of the choline is concentrated in the germ, while 50 per cent of that in wheat is lost in the preparation of white flour. In general, seed meals and seeds are considerably better sources than the cereal grains. Butter, lard, and refined vegetable oils are almost devoid of choline.

Chemistry of Choline. Choline was first isolated by Strecker in 1849 and synthesized by Wurtz in 1867. It possesses the following structure:

The early synthesis of choline by Wurtz involved warming trimethylamine with ethylene chlorohydrin in a sealed tube for 24 hours:

$$(CH_3)_3N + ClCH_2CH_2OH \rightarrow Cl(CH_3)_3NCH_2CH_2OH$$
Choline Chloride

The chloride was converted into the gold and platinum double salts, and then to the free base. Free choline can be prepared directly by mixing a

concentrated aqueous solution of trimethylamine with ethylene oxide at room temperature:

$$(CH_3)_3N + \begin{pmatrix} CH_2 \\ O + H_2O \rightarrow HO(CH_3)_3NCH_2CH_2OH \\ CH_2 \end{pmatrix}$$
Choline

The free base is a colorless, ervstalline, extremely hygroscopic compound. It is a stronger base than ammonia and easily forms salts with acids. Pure choline, when heated, decomposes to trimethylamine and ethylene glycol. Aqueous solutions containing less than 4 per cent choline may be heated without decomposition, but losses occur in more concentrated media. Choline is more stable to heat in acid than in neutral or alkaline solution.

Choline is readily soluble in water, methyl alcohol, ethyl alcohol, and formaldehyde; slightly soluble in dry amyl alcohol, dry acetone, and chloroform; and insoluble in dry ether, petroteum ether, benzene, toluene, carbon bisulfide, and carbon tetrachloride. The salts are soluble in water and alcohol, forming aqueous solutions which are nearly neutral.

Choline may be precipitated from aqueous solution by potassium triiodide, phosphotungstic acid, phosphomolybdic acid, or reinecke salt. These precipitants, especially the latter, have been employed in quantitative methods for its determination.

Microbiological Determination of Choline: Method of Horowitz and Beadle²²²: Principle. Choline may be measured by the growth stimulation of a mutant strain of Neurospora crassa designated as cholineless, produced artificially by exposure to ultraviolet radiation. Methionine, which can replace choline for the microorganism, is removed by adsorption of the extract on permutit followed by elution with sodium chloride solution. The microbiological procedure for the determination of choline is far more sensitive and possibly more specific than the chemical procedure.²²³ The latter involves precipitation and isolation of the reineckate, followed by colorimetric measurement of the red pigment at 520 m μ in acetone solution.

Procedure: Heat 100 mg. of sample in an autoclave for 2 hours at 15 pounds pressure in 10 ml. of 3 per cent sulfuric acid, or reflux for 7 hours. Neutralize to congo red with saturated barium hydroxide solution. Centrifuge and filter the supernatant through a Whatman No. 50 paper. Add 3 ml. of distilled water to the precipitate and bring to a boil with stirring. Cool, centrifuge, and add the washing to the previous supernatant. Neutralize the solution to litmus with 1 N sodium hydroxide solution and dllute with distilled water to a concentration of approximately 15 y per ml. Pass 5 ml. of the neutralized extract224 through a column 100 mm. long and 5 mm. wide (internal diameter) containing 1 g. of permutit. Wash the column

²²² Horowitz and Beadle: J. Biol. Chem., 150, 325 (1943).

²²³ U.S. Pharmacopoeia XIII.

²²⁴ If the solution is known to contain less than 3 γ of choline per ml., pass 10 ml. through the column.

with 5 ml. of 0.3 per cent sodium chloride and discard the filtrate and washings. Elute the choline with 10 ml. of 5 per cent sodium chloride.²²⁵

Prepare a basal medium having the following composition in g. per liter: ammonium tartrate 5, ammonium nitrate 1, monobasic potassium phosphate 1, magnesium sulfate 711.0 0.5, sodium chloride 0.1, calcium chloride 0.1, sucrose 20, biotin 5×10^{-6} . In addition, add the following trace elements as salts in mg. per liter: boron 0.01, molybdenum 0.02, iron 0.2, copper 0.1, manganese 0.02, and zinc 2.0.

Maintain stock cultures of the cholineless mutant No. 34486 of *Neurospora crassa* on agar slants composed of the basal medium plus 1.5 per cent agar, 0.2 per cent Difco yeast extract, 0.2 per cent malt extract, and 1 γ per ml. of choline. For inoculum, prepare a spore suspension in a few ml. of distilled water.

Pipet 0.5, 1.0, and 2.0 ml. aliquots of the sodium chloride eluate in duplicate into 250-ml. Erlenmeyer flasks, and dilute each to 25 ml. with basal medium. The final concentration of choline should lie between 2.0 and 20 γ per 25 ml. At the same time set up a series of standards having 0, 2, 4, 8, 12, 16, 20, 25, and 30 γ of choline per flask. Autoclave the solutions at 15 pounds pressure for 10 minutes, cool, and add one drop of inoculum to each. Incubate at 25° for 3 days. At the end of this period, collect the mold pads on tared, fritted glass filters of medium porosity, and wash with distilled water. Dry in an oven at 90° and determine the dry weight.

Calculation. Prepare a reference curve from the data obtained with the standard series, plotting γ of choline as the abscissa and weight of dry mold as the ordinate. From this curve read off the choline concentration, C, per ml. of eluate. Then

$$C \times \frac{10}{A} \times \frac{V}{0.1} = \gamma$$
 of choline per g. of sample

where V is the volume to which the original extract was diluted, and A is the volume of the aliquot which was passed through the permutit column.

INOSITOL

Though inositol was long known to be a constituent of heart muscle, and of many plants (in the form of phytin, the calcium-magnesium salt of inositol hexaphosphate), its functional similarity to the vitamins was not recognized until recently. Eastcott²²⁶ isolated from yeast the factor previously known as bios I and demonstrated its identity with inositol. The biologically active compound is optically inactive (designated *i*-inositol or meso-inositol) as distinguished from its biologically inert stereoisomers. In addition to its role as a yeast growth factor, inositol has been identified with the mouse alopecia factor of Woolley.²²⁷ and the rat anti-spectacled-eye factor of Paycek and Baum.²²⁸

Physiological Properties of Inositol. Though the metabolism or mode of action of inositol has not yet been elucidated, its importance in the nutrition of several species has been demonstrated. An external

²¹⁵ If more filtrate is required in case the approximate choline content is unknown, adsorb two or more portions of the solution simultaneously on separate columns.

²²⁴ Eastcott: J. Phys. Chem., 32, 1094 (1928).

²²⁷ Woolley: J. Biol. Chem., 136, 113 (1940).

²¹⁸ Pavcek and Baum: Science, 92, 384 (1940).

source is required by some yeasts and fungi, but not by all. Young mice on a deficient diet suffer an inhibition of growth and loss of hair, both of which are corrected by supplementation with inositol. Growth of a transplanted mouse tumor has been inhibited by inositol. It is also essential for proper growth in the chick and rat. The spectacled-eye condition in rats due to loss of hair about the eyes is a result of dietary deficiency. The vitamin also has lipotropic properties for this species, but more for the "cholesterol" than the "fat" type of fatty livers. Inositol stimulates gastrointestinal peristalsis in dogs. Though the vitamin must be present in the free state to be available to yeast, it is readily utilized by the mouse in natural bound forms such as phytin and soybean cephalin, as well as synthetic methyl inositol and inositol hexacetate.

The metabolism of inositol is related to that of other vitamins. It has been suggested that pantothenic acid regulates absorption of inositol from the intestine, for a diet containing inositol produces symptoms of inositol deficiency if pantothenic acid is lacking. A relationship to p-aminobenzoic acid has also been established. In one series of experiments, black rats showed little signs of deficiency when both inositol and p-aminobenzoic acid were either absent or present, but exhibited typical symptoms when either nutrient alone was eliminated from the diet.

Because of its similarity in structure both to the carbohydrates and to the aromatics, inositol has been designated as a possible physiological link between these two classes of compounds. Recent analyses of highly purified enzyme preparations indicate that the vitamin is a structural unit in the pancreatic amylase molecule.

Storage and Synthesis of Inositol. The wide distribution and variety of forms of inositol in animal and plant tissues indicate that it is present for some physiological purpose rather than merely for storage of phosphoric acid or hydroxyl groups. It has been reported that inositol may be synthesized by intestinal flora, a process stimulated by the presence of pantothenic acid.

Distribution of Inositol.²²⁹ In animal tissues, high concentrations are found in kidney, heart, spleen, thyroid, and testes. Inositol is found in the free form in muscle and other tissues; hence the name muscle sugar. In liver and heart muscle it is found combined, probably with a protein. Excellent dietary sources are cereal brans and seeds (in the form of phytin) and fruits, particularly of the citrus variety. A compound of inositol has been found in the phosphatid fraction of the soybean.

Chemistry of Inositol. Inositol is a sweet-tasting crystalline compound and is isomeric in molecular formula with the hexose sugars. It crystallizes as the anhydride (M.P. 225°-226°) from water at temperatures above 50° and from anhydrous solvents. Below 50° C., the dihydrate (M.P. 215°-216°) appears. The molecule is stable to strong acid and alkaline hydrolysis. Inositol can exist in nine different stereoisomeric

forms. The biologically active molecule is the optically inactive or meso form. It has a molecular weight of 180.2.

Cyclohexanehexol

Determination of Inositol. The microbiological method for determination of vitamin B₆, depending on the growth stimulation of Saccharomyces cerevisiae (p. 1052), may be used for the determination of inositol by simple modification of the basal medium to exclude inositol and include an excess of pyridoxine.

ASCORBIC ACID (VITAMIN C)

Scurvy was once an extremely common disease particularly prevalent among navigators on long voyages. Its etiological relationship to the absence of fresh fruits and vegetables was forecast as far back as the sixteenth century, when the curative value of a decoction of spruce needles, an herb called scurvy grass, and especially of "sower Oranges and Lemmons" were recognized. The regulation requiring British vessels to carry a supply of lemons or limes for their crews gave rise to the name Limehouse for London's shipping district, whence the term "limey" or "lime juicer" for a sailor.

The dietary origin of the disease was confirmed experimentally in guinea pigs by Holst and Frölich²³⁰ in 1907, and the deficient factor was among the first to receive the designation of a vitamin. Outbreaks of scurvy among infants, prisoners, explorers, troops, and in war-ridden countries where the diets are restricted or unbalanced, continue to be reported even today. Under normal conditions, however, scurvy is comparatively rare. Far more prevalent is the incidence of subclinical vitamin C deficiency which is manifested only by vague and indefinite symptoms and which may be diagnosed only with the aid of accurate dietary histories and laboratory determinations of the blood levels or urinary excretion of the vitamin. Several studies of the ascorbic acid nutrition of large population groups have revealed widespread subclinical vitamin C deficiency. In the examination of large segments of the population in Puerto Rico and Newfoundland, 58 and 72 per cent respectively of the individuals examined showed low plasma ascorbic acid levels.²⁸¹ The status of ascorbic acid nutrition shows seasonal variation, and depends upon the fluctuation of available dietary sources. Because of the relatively high cost of fresh fruits and vegetables as compared with the less expensive cereal grains, subclinical vitamin C deficiency is more prevalent among low income groups.

The isolation of crystalline vitamin C from lemon juice was first announced in 1932 by King and Waugh.²³² Szent-György²³³ concluded from his own studies on adrenal cortex, cabbage, and citrus juices that vitamin C was identical with "hexuronic acid," but later, with the collaboration of Haworth, established a different structural configuration and named vitamin C "ascorbic acid" because of its antiscorbutic properties. This name has persisted despite the attempt (later abandoned) of the American Medical Association to substitute "cevitamic acid" for the therapeutically suggestive name. Rapid progress was made toward establishing the structure of the vitamin and effecting its synthesis.²³⁴ Ascorbic acid is an important article of commerce today not only for its nutrient and medicinal value but because it is a powerful antioxidant.

Physiological and Clinical Aspects of Ascorbic Acid. Vitamin C is concerned fundamentally with the maintenance of intercellular substances, including the collagen of fibrous tissue structures, the matrices of bone, cartilage, and dentin, and all nonepithelial cement substance, including that of the vascular endothelium. In the absence of the protection afforded by this vitamin, the condition known as scurvy develops.

The onset of the disease is gradual in humans, a period of indolence, fleeting pains in the joints, and shortness of breath being followed by decline in weight and anemia. Soon the complexion becomes sallow, subcutaneous hemorrhages occur upon slight injury, the gums become spongy and bleed easily, the teeth become loose and fragile, and often there is marked edema of the extremities. Hemorrhage is a predominating feature of the disease, and when it occurs internally it is frequently the cause of death. Various methods have been devised to measure the reduction in capillary resistance which occurs (not exclusively, however) in scurvy. These tests²³⁵ are based on the production of small, subcutaneous hemorrhages (petechiae) by applying suction or pressure to circumscribed skin areas.

Histological studies have emphasized the importance of the vitamin C content of the diet on tooth development.²³⁶ Scurvy is attended by

profound pathological changes in the teeth and gums, affecting particularly the vascular pulp, and the periodontal and gingival tissues. Resorption of normal dentin and cementum occurs. In scurvy, bone formation stops, but resorption continues so that there is a resultant atrophy and bone fragility. Skeletal defects are demonstrated first at the costochondral junctions where the lesions are similar to those of rickets.

The severity of the lesions observed in scurvy is dependent upon other factors such as growth and mechanical stress. Gum damage occurs only when there are teeth, and hemorrhages appear chiefly from mechanical injuries or from the irritation of clothing. Bone lesions appear mainly at the joints and are particularly severe in infants and children. The response of scorbutic patients to treatment with ascorbic acid is dramatic. Histological evidence of bone repair may be observed within a few hours after administration of the vitamin, and signs of connective tissue regeneration in 24 hours. Evidence has been presented that an optimal level of ascorbic acid nutrition favors rapid repair of tissues in wounds and bone fractures, and is an important factor in determining resistance to infection. An outline of the clinical symptoms of ascorbic acid deficiency is given in the American Medical Association syllabus on p. 1186.

That ascorbic acid may play a role in endowing the organism with increased powers of resistance to disease is indicated by studies with guinea pigs receiving injections of diphtheria toxin following graded allowances of ascorbic acid,²³⁷ and by experiments in which sensitized guinea pigs fed liberal doses of ascorbic acid showed dinanished skin hypersensitivity to arsphenamine.²³⁸

An increased requirement for vitamin C in man has been reported in Hodgkin's disease, protracted fevers, active rheumatic heart disease, and tuberculosis. In rats the synthesis and excretion of ascorbic acid is stimulated by feeding certain cyclic ketones related to the terpenes and certain simple aliphatic ketones.²³⁹ This increased synthesis may be related to greater requirements for detoxification purposes. The beneficial effects of vitamin C in the detoxification of other unrelated poisons have been reported; e.g., lead and arsenic compounds, benzene, and the toxins of several pathogenic microörganisms.

Under normal conditions a dietary supply of ascorbic acid is required only by man, other primates, guinea pigs, and some microörganisms. In its absence, the symptoms of scurvy appear. However, the vitamin is essential for the normal development of most species, so that, for the most part, ascorbic acid plays the role of a hormone. Interference with the normal synthesis of the vitamin in the bovine species results in the impairment of the reproductive functions of both the male and female. A dietary deficiency of vitamin A results in decreased synthesis of ascorbic acid in the rat, though this relationship with vitamin A has not been observed in mature hens or bulls. In the latter species, the adminis-

¹¹⁷ King and Menton: J. Nutrition, 10, 129 (1935); Greenwald and Harde: Proc. Soc. Expl. Biol. Med., 32, 1157 (1935).

¹²⁰ Longenecker, Musulin, Tully, and King: J. Biol. Chem., 129, 453 (1939).

tration of chlorobutanol stimulates the synthesis of ascorbic acid, raises the plasma level and restores fertility in the deficient animals.

The recommended dietary allowances of ascorbic acid are shown on p. 1027. Approximately 1 mg. per day per kilogram of body weight is required for the maintenance of tissue saturation. These allowances are quite liberal since clinical signs of scurvy do not appear even at considerably lower levels of intake. However, in order to avoid the possible harmful effects of subclinical vitamin C deficiency, a margin of safety has been included in the recommendations. When healthy subjects have been subsisting on diets containing the recommended levels of intake for prolonged periods, the administration of a test dose of ascorbic acid (400 to 1000 mg.) is followed in the next 24 hours by an increase in the urinary excretion of from 25 to 50 per cent of the test dose. At lower levels of intake for prolonged periods there is a tendency for the body to conserve the test dose of the vitamin and lower excretion values are noted, indicating that body tissues are unsaturated.

No toxic symptoms have been noted in man following the administration of large doses of ascorbic acid. One to 6 g. have been given orally and intravenously. Though ascorbic acid has been found in sweat, the amount lost through this channel even in excessive physical labor and in hot climates is not significant when the dietary intake approximates the recommended allowances.

A synergism between ascorbic acid and vitamin A has been noted in the rat as well as between C and E in the guinea pig. Ascorbic acid enhances the growth-promoting effect of vitamin A in the rat in a manner similar to tocopherol. The mechanism may be through stabilization of vitamin A in the gastrointestinal tract. The administration of vitamin E increases the storage of dietary ascorbic acid in the organs of the guinea pig.

The ease with which ascorbic acid undergoes reversible oxidation-reduction has suggested that the vitamin plays a role in cellular respiration. The oxidation of ascorbic acid is catalyzed by ascorbic oxidase, found in plant juices. The reverse reaction, the reduction of dehydro- to reduced ascorbic acid, is catalyzed by ascorbic reductase (an enzyme found in plant juices)²⁴⁰ in the presence of reduced glutathione. Though no similar enzyme systems have been observed in animal tissues, the administration of dehydroascorbic acid to man is followed by increased urinary excretion of reduced vitamin C in an amount comparable to that which is excreted when the reduced form of the vitamin is fed. It is believed that this reduction occurs in the liver.

Certain in vitro findings lend credence to the view that ascorbic acid functions in vivo in oxidation-reduction reactions. Vitamin C plus minute amounts of iron cause a considerable increase in the oxygen uptake by phospholipids and by brain and liver suspensions. Liver slices obtained from scorbutic guinea pigs are unable to oxidize l-tyrosine unless ascorbic acid is added. The oxidation is performed readily, however, by slices

²⁴⁶ Crook and Morgan: Biochem. J., 38, 10 (1944); Bukin: Biochimia, 8, 60 (1943).

from normal animals. The action of urease, an enzyme which catalyzes the decomposition of urea to ammonia and carbon dioxide, is inhibited by vitamin C. This inhibition has been found to be due to the presence of small quantities of dehydroascorbic acid, and is prevented by cysteine which reduces the dehydro form. Quinone, another oxidizing agent, can inhibit urease activity.

Ascorbic acid exhibits optical specificity. The *l*-configuration about the fourth carbon atom is essential for biological activity, the *d* compound being biologically inactive. *d*-Arabo-ascorbic acid (isoascorbic acid) which differs from *l*-ascorbic acid in the *d*-configuration about the fifth carbon atom, possesses only one-twentieth of its activity. 6-Desoxy-*l*-ascorbic acid, which lacks the hydroxyl group on the sixth carbon atom, has one-fifth the activity of *l*-ascorbic acid. Other analogs of vitamin C, *l*-glucoascorbic acid, *l*-fucoascorbic acid, and *d*-gluco-heptoascorbic acid have one-fortieth, one-fiftieth, and one-hundredth of the activity of vitamin C, respectively. However, the only naturally occurring forms of vitamin C are *l*-ascorbic acid and dehydroascorbic acid, both of which have equal biological activity. The occurrence of an active combined form of ascorbic acid, ascorbigen, has been postulated but has not yet been established. The sodium, copper, manganese, iron, monoethanolamine, and quinine salts of ascorbic acid are biologically active.

Storage and Synthesis of Ascorbic Acid. As previously stated, all animal species other than man, monkeys, and guinea pigs, as well as higher plants and many microorganisms, are capable of synthesizing vitamin C. The promptness with which scurvy develops when the susceptible species are deprived of vitamin C would seem to indicate the absence of a large store in their bodies. In man, a diminished intake of ascorbic acid results in an immediate drop in the blood level of ascorbic acid, though tissue stores may not yet be depleted. Guinea pigs show histological symptoms of ascorbic acid deficiency after one week of a vitamin C-free diet. Higher concentrations of the vitamin are found in tissues of high metabolic activity—e.g., the adrenal and pituitary glands and the intestinal wall. It is likely that the vitamin is present in these depots in order to meet tissue requirements, rather than for the purpose of storage. Certain animals which synthesize vitamin C store it in their livers in sufficient amounts to meet their immediate requirements. The fruits and vegetables consumed by man as sources of ascorbic acid represent storage depots for plants which synthesize the vitamin.

Distribution of Ascorbic Acid.²⁴¹ The outstanding sources of vitamin C are fresh fruits and vegetables. Special mention may be made of cabbage, cauliflower, kohlrabi, spinach, parsley, kale, broccoli, cresses, peppers,²⁴² oranges, lemons, grapefruit, tangerines, limes, strawberries, and gooseberries. Other excellent dietary sources are cantaloupe, currants, papaya, persimmons, pineapple, asparagus, lima beans, green snap beans, and Brussels sprouts. Unfortunately, much of the vitamin C originally

²⁴¹ For ascorbic acid values of foods, see Appendix III.

¹⁴³ The large scale preparation of ascorbic acid from Hungarian pepper (capsicum annuum) is described by Banga and Szent-György: Biochem. J., 28, 1625 (1934).

present in foods is lost through processing so that, for practical purposes. the fruits and vegetables which are consumed raw contribute a major portion of the dietary ascorbic acid. For economic reasons, these are outside the reach of low income groups which obtain their vitamin C from the relatively inexpensive potato. Hess stated that "a failure of the potato crop is followed by scurvy in the spring"—because this tuber, though not very high in vitamin C, is often a major dietary constituent and the chief source of the vitamin. During the germination of legumes as well as of cereal grains, marked synthesis of vitamin C takes place from an unidentified precursor within the seed. Meat products are poor sources of vitamin C, although blood and glandular organs contain more than muscle. Milk varies in its content of vitamin C according to the cow's ration and hence the season of the year. Fresh raw milk is a good source of vitamin C but most of it is lost in pasteurization, evaporation, or dehydration. Where milk is a major constituent of the diet, as it is in children, it is best to provide antiscorbutic protection from other sources; e.g., orange juice or synthetic ascorbic acid. The leaves and flowers of the gladiolus, nettle, hip, and paprika are exceptionally rich in vitamin C. During World War II, rose hips, green walnuts, and wild cherries were used in Europe for the preparation of vitamin C concentrates.

Chemistry of Ascorbic Acid. Ascorbic acid crystallizes in white, colorless, odorless crystals having a melting point of 190° to 192° C. One g. dissolves in 3 ml. of water, in 50 ml. of absolute ethyl alcohol, and in 100 ml, of glycerol. The vitamin is insoluble in benzene, ethyl ether, petroleum ether, and most organic solvents. Ascorbic acid possesses two asymmetric carbon atoms. The vitamin has a specific rotation $[\alpha]_0^{(2)} = +23^{\circ}$ in water and +48° in methanol. d-Ascorbic acid, which differs from the *l*-isomer only in its configuration about the fourth carbon atom, is physiologically inactive. The acidic properties of ascorbic acid are due not to the carboxyl group, which is tied up in lactone form, but to ionization of the enol group on the third carbon atom. The vitamin is a comparatively strong acid, as indicated by the acidic dissociation constants, $pK_1 = 4.17$ and $pK_2 = 11.57$. A one-half per cent solution of ascorbic acid in water has a pH of approximately 3. The vitamin has an absorption maximum in the ultraviolet region of the spectrum at 265 mm which shifts toward the shorter wavelengths with decreasing pH. Ascorbic acid is precipitated by lead ion at pH 7.6, but the salt can be redissolved in mineral acid at pH 2.

Ascorbic acid crystals are stable in air for years. In solution the vitamin is easily oxidized, the instability increasing with increasing pH. Mild oxidation such as that produced by air, hydrogen peroxide, ferric chloride, quinone, iodine in acid or neutral solutions, or 2,6-dichlorophenol indophenol converts the vitamin to dehydroascorbic acid as shown in the reaction below. Dehydroascorbic acid retains the biological activity of the vitamin and is reduced in animal tissues, a reaction in which sulf-hydryl compounds like glutathione play an important part. The reduction of the dehydroascorbic acid may be accomplished in vitro by means of hydrogen sulfide. Above pH 5 dehydroascorbic acid readily undergoes a

rearrangement in which the lactone ring is split. The product, diketogulonic acid, is no longer biologically active and is not reducible by hydrogen sulfide. Treatment with hydrogen iodide, however, converts this compound to dehydroascorbic acid which may subsequently be reduced with hydrogen sulfide to reduced ascorbic acid. Once the lactone ring has opened, the molecule readily undergoes further oxidation and may be degraded to oxalic acid. The oxidation of ascorbic acid by molecular oxygen is catalyzed by cupric and silver ions. Plant tissues contain several enzymes, including ascorbic acid oxidase, polyphenol oxidase, and peroxidase which even more strongly catalyze the oxidation of the vitamin by molecular oxygen to dehydroascorbic acid. It is interesting to note that ascorbic acid oxidase is a copper-protein complex and that cupric ion in the presence of nonspecific protein is a stronger oxidation catalyst for vitamin C than cupric ion alone. Ascorbic acid is a strong reducing agent, its capacity to reduce silver nitrate, iodine, ferricyanide, methylene blue, and 2,6-dichlorophenol indophenol, serving as the bases of methods for its histological detection and chemical estimation. The ease of oxidation of ascorbic acid is responsible for considerable losses of the vitamin during the processing of foods, which may be diminished by such measures as blanching (heat denaturation of enzymes), the use of an inert atmosphere (nitrogen or carbon dioxide), and storage at low temperatures. The ready solubility of ascorbic acid in water is also responsible for processing losses through extraction of the vitamin by the cooking water.

The destruction of ascorbic acid is catalyzed by light, especially in the presence of flavins. The vitamin reacts with niacin (or niacinamide) when the two are mixed in a thick paste, forming a colored compound. Ascorbic acid undergoes a similar reaction with other pyridine and quinoline compounds. The reaction is not attended by a decrease in the reducing properties of vitamin C. It has not been established whether any loss in the biological activity of either ascorbic acid or niacin occurs during the reaction.

The synthesis of ascorbic acid can be effected by enolization of ketohexonic acids or by condensation of lower aldehydes or of oxyesters. The commercial synthesis in common use is represented by the following scheme:

$$\begin{array}{c} \text{action of} \\ B. \text{ xylinum} \\ l\text{-Sorbitol} \xrightarrow{\hspace*{1cm} l\text{-sorbose} \hspace*{1cm}} l\text{-sorbose} \xrightarrow{\hspace*{1cm} HCl} \\ & \text{MeOH} \\ \textbf{2-keto-}l\text{-gulonic acid} \xrightarrow{\hspace*{1cm} MeOH} l\text{-ascorbic acid} \\ \end{array}$$

Though the synthetic methods involving the 2-keto-hexonic acids are economically more practical, the preparation of vitamin C concentrates from natural materials continued to receive attention, especially in Europe, because of the greatly increased demand for ascorbic acid during World War II.

Determination of Ascorbic Acid: Introduction. Chemical methods for the determination of vitamin C are based, for the most part, upon the reducing properties of the vitamin. These procedures include titration of an acid extract with iodine, methylene blue in the presence of light, 2.6-dichlorophenol indophenol or other oxidizing agents. Various acids have been used for the extraction including acetic, trichloroacetic, metaphosphoric, and oxalic. The latter two acids serve not only to reduce the pH of the extracting medium, thereby stabilizing vitamin C, but also to form complexes with heavy metal ions, e.g., copper, thereby preventing the catalytic oxidation of the vitamin. Titration with an oxidizing agent is not a specific reaction, other reducing materials interfere, e.g., stannous and ferrous sulfate, sulfhydryl compounds, sulfides, thiosulfates, and reducing materials found in caramelized and fermented foods. Errors arise particularly in food products because of the presence of reductinic acid and reductones. Actually, reductone is hydroxypyruvic aldehyde, a compound formed by the alkaline hydrolysis of sugars. Reductinic acid is formed when pentoses are treated with acids. The terms reductone and reductinic acid, however, are used rather loosely to signify other reducing compounds which are formed during heat-processing and storage of foods.

Numerous attempts have been made to increase the specificity of the oxidation-reduction methods, particularly that employing the 2,6-dichlorophenol indophenol dye. A number of these are based on the fact that ascorbic acid reacts very rapidly with the oxidizing agent whereas many of the interfering substances react more slowly. The simplest expedient for increasing the specificity is to conduct the titration very rapidly though it presents little improvement over the original method. A far more satisfactory procedure involves measurement of the rate of reaction by means of a photoelectric colorimeter. When observations are made five and ten seconds after mixing the ascorbic acid solution with the oxidant, and the values are extrapolated to "zero-time," the determination possesses sufficient specificity for vitamin C in most food products.

A number of modifications of the indophenol titration have been aimed particularly at eliminating the interference of reductiones and reductinic acid. These compounds are similar to vitamin C in structure, stability, and chemical reaction. Like ascorbic acid, their oxidative destruction is catalyzed by copper and by ascorbic acid oxidase. A number of procedures for eliminating their interference involve condensation of the reducing substances with formaldehyde. The latter eliminates the reducing properties of ascorbic acid, reductones, and reductinic acid, but the interfering compounds may be differentiated from the vitamin by conducting the condensations at different pH levels.²⁴³ There is no doubt that these procedures increase the specificity of indophenol titration, though the interference of reductone or reductinic acid is not completely eliminated Moreover, errors arise because the procedures fail to take into account the presence of materials which affect the rate of combination of *l*-ascorbic acid with formaldehyde.²⁴⁴

One method of improving the specificity of the determination of vitamin C involves the destruction of ascorbic acid with ascorbic acid oxidase, thereby providing a blank correction value.²⁴⁵ This procedure, however, is based on the false assumption that the action of ascorbic acid oxidase is specific for vitamin C whereas actually compounds such as reductones are also destroyed.²⁴⁶ Natural pigments and stubborn turbidities frequently interfere with the determination of vitamin C. Several modifications of the indophenol methods eliminate these interferences. These involve extraction of an excess of the unreacted dye by means of organic solvents immiscible with water.²⁴⁷

Dehydroascorbic acid, the reversibly oxidized, biologically active form of vitamin C, does not possess reducing properties. Since this form of the vitamin is frequently present in considerable proportion in processed foods, 248 it must first be reduced before it can be determined with oxidizing agents. Hydrogen sulfide has been used most frequently for this purpose but this reagent has been criticized on the ground that it creates other reducing materials which interfere with the procedure. This objection is valid when simple titrimetric methods are employed for the determination of vitamin C. However, very little interference arises from this source when the more specific photometric method, involving measurements at five and ten seconds, is employed. Other methods for reducing the dehydroascorbic acid have been suggested but have not yet been widely employed. These include the reduction of the oxidized vitamin by a resting suspension of E, $coli^{249}$ and by electrolytic reduction.

Dehydroascorbic acid couples with 2,4-dinitrophenylhydrazine to produce a compound which when treated with strong sulfuric acid yields a red color. These reactions have been employed²⁵¹ for the direct determination of dehydroascorbic acid, as well as for the measurement of the

reduced form of the vitamin after oxidation by treatment with activated charcoal. Reductones interfere with this procedure to a greater extent than they do in the five and ten second photometric procedures involving reaction with 2,6-dichlorophenol indophenol,²⁵² though less than in the titrimetric procedure.²⁵¹ A serious objection to this method is the fact that diketogulonic acid, a biologically inactive oxidation product of vitamin C, reacts like the vitamin with dinitrophenylhydrazine.²⁵³ The error which may arise from this source when the procedure is applied to foods which have undergone considerable processing may be indicated from the finding that an aerated orange juice known to be very low in ascorbic acid by guinea-pig assay and found to contain only 4 mg. per 100 ml. by the hydrogen sulfide procedure, was demonstrated to contain 60 to 70 mg. per 100 ml. by the dinitrophenylhydrazine method.²⁵⁴

The determination of ascorbic acid in blood and urine has been employed for the diagnosis of clinical and subclinical vitamin C deficiency. Both blood and urinary ascorbic acid values even in normal individuals fluctuate widely depending upon the ascorbic acid intake just prior to the test. For this reason blood tests are conducted preferably when the subject is in a fasting state. A serum or plasma level greater than 0.7 mg. per 100 ml, is regarded as normal whereas values less than 0.4 mg, are observed in scurvy. Some clinicians set 1.2 mg. per 100 ml. as the minimum normal level. Individuals in a normal state of nutrition excrete from 20 to 50 mg. of ascorbic acid when fed a diet containing 100 mg. per day. Since both blood levels and urinary excretion values depend upon the ascorbic acid intake for one or two days prior to the test, a more satisfactory index of ascorbic acid nutrition may be obtained by measurement of the response of the subject to a large test dose (500 to 1000 mg.) of ascorbic acid. Saturated subjects excrete approximately 25 to 50 per cent of the test dose in 24 hours, and show a continued high blood level for hours following dosage. In one saturation test, an excretion of 20 mg. of ascorbic acid in the four-hour period following the ingestion of 200 mg. is regarded as normal.

Plasma ascorbic acid values fall very rapidly when a deficient diet is consumed, though tissue stores including those of blood cells have not yet become depleted. It has been suggested that the ascorbic acid content of the leukocytes or of whole blood²⁵⁵ is a better index of the state of vitamin C nutrition of the tissues than the blood plasma level. Oxyhemoglobin interferes with the determination of ascorbic acid in whole blood by oxidation-reduction procedures unless it is saturated with carbon monoxide²⁵⁵ or reduced.²⁵⁶ The 2,4-dinitrophenylhydrazine method (see p. 1138) is suitable for determination of ascorbic acid in whole blood.

One procedure intended for clinical diagnosis of ascorbic acid deficiency involves intradermal injection of 2,6-dichlorophenol indophenol followed by measurement of the rate of decolorization of the dye.²⁵⁷

Modified Titrimetric Method of Bessey:²⁵⁸ Principle. The method depends on the stoichiometric reduction of the dye 2,6-dichlorophenol indophenol to a colorless compound by ascorbic acid. The titration is conducted in the presence of acetic and metaphosphoric acids in order to inhibit aerobic oxidation catalyzed by certain metallic ions, to inactivate enzymes, and to precipitate proteins and liberate protein-bound ascorbic acid.

Procedure: Macerate an aliquot of the sample containing 5 to 50 mg. of ascorbic acid with 150 ml. of metaphosphoric-acetic acid solution²⁵⁰ in a Waring Blendor. Dilute to 200 ml. and filter. Titrate a 10 to 100 ml. aliquot with standard indophenol solution.

Preparation of Standard Indophenol Solution: Dissolve 42 mg. of sodium bicarbonate and 52 mg. of sodium 2,6-dichlorophenol indophenol in 50 ml. of water. Dilute to 200 ml. Filter and store in the refrigerator not more than three days. Dissolve 100 mg. of crystalline ascorbic acid in 100 ml. of metaphosphoric-acetic acid solution. Dilute a 10-ml. aliquot with 25 ml. of metaphosphoric-acetic acid solution, and titrate with indophenol solution until the pink color persists for five seconds. Calculate and express the strength of the indophenol solution as mg. of ascorbic acid equivalent per ml. of reagent. Repeat the standardization each day with a freshly prepared standard ascorbic acid solution.

Calculation. Calculate the ascorbic acid content of the sample using the formula,

 $V \times S \times D = mg$, of ascorbic acid per g. of sample

where V is the volume of dye in ml. employed in titrating the unknown, S is the standardization value expressed in mg. of ascorbic acid per ml., and D is the dilution factor.

Interpretation. The simple titrimetric method is applicable to the determination of ascorbie acid only in the absence of other reducing substances, and where only the reduced form of the vitamin is present. Thus it may be applied to fresh orange, grapefruit, lemon, lime, or tomato juice, and to some pharmaceutical preparations. For heat-processed materials and other foods, it is necessary to eliminate interfering substances, and to determine the reversibly oxidized, biologically active form of the vitamin, dehydroascorbic acid. Ferrous ion reduces the dye in the presence of metaphosphoric acid so that pharmaceutical preparations containing reduced iron should be titrated in 8 per cent acetic acid solution free from metaphosphoric acid. On the other hand, ferric ion interferes with the end-point in the absence of metaphosphoric acid so that the metaphosphoric-acetic acid mixture should be employed as the titration medium when testing pharmaceutical preparations containing oxidized iron.²⁶⁰

Determination of Ascorbic Acid in Plant Tissues: Modified Colorimetric Method of Roe and Kuether:²⁶¹ Principle. Ascorbic acid is oxidized to dehydroascorbic acid by shaking with norit in the presence of acetic acid, and is coupled with 2,4-dinitrophenylhydrazine.

²⁵⁸ Bessey: J. Assoc. Official Agr. Chem., 27, 537 (1944).

²⁶⁹ Dissolve 15 g. of stick metaphosphoric acid in a mixture containing 40 ml. of glacial acetic acid and 450 ml. of water. Filter, and store in the refrigerator. Discard after 10 days.

<sup>Gawron and Berg: Ind. Eng. Chem., Anal. Ed., 16, 757 (1944).
Roe and Kuether: loc. cit.; Roe and Oesterling: loc. cit.</sup>

The resulting derivative is treated with sulfuric acid to produce a red color which is measured photometrically.

Procedure: Grind 10 g. of sample in sufficient 5 per cent metaphosphoric-10 per cent acetic acid solution to produce a concentration of 5–15 γ of ascorbic acid per ml. Filter. To a 15-ml. aliquot of the clear filtrate, add 0.75 g. of acid-washed norit²⁶² and shake vigorously. Filter. To a 4-ml. aliquot of the filtrate in a test tube, add 1 drop of 10 per cent thiourea solution, and 1 ml. of 2,4-dinitrophenylhydrazine reagent.²⁶³ Place the tube in a water bath maintained at 37° for exactly 3 hours. Remove and place in an ice-water bath along with a blank tube containing 4 ml. of the norit filtrate and 1 drop of thiourea solution. To each tube in the bath add dropwise 5 ml. of 85 per cent sulfuric acid²⁶⁴ with stirring. Finally add 1 ml. of 2,4-dinitrophenylhydrazine reagent to the blank. Remove the tubes from the bath and allow to stand 30 minutes. Read the colors in a photoelectric colorimeter with a filter transmitting maximally at 540 mg, setting the instrument at 100 per cent transmittance with the blank tube.

Calculation. Prepare a calibration curve by testing 4-ml. aliquots of appropriate standards containing $0.25\text{--}15.0\,\gamma$ of ascorbic acid per ml. carried through the entire procedure. Plot photometric density against γ of ascorbic acid per ml. From the curve, estimate the ascorbic acid concentration of the norit filtrate of the unknown and multiply this by the dilution factor to obtain the ascorbic acid content of the sample.

Interpretation. The 2,4-dinitrophenylhydrazine procedure measures total ascorbic acid. This may be partitioned into the reduced and dehydro forms by including a simultaneous test in which the norit treatment is omitted. The latter procedure measures only dehydroascorbic acid. The reduced ascorbic acid content is obtained by difference. Reductones, degradation products of sugars, and diketogulonic acid (an oxidation product of vitamin C) interfere with the determination of ascorbic acid by this procedure.

Determination of Ascorbic Acid in Whole Blood, Plasma, or Urine: Method of Roe and Kuether.²⁶⁵

Procedure: Add 5 ml. of whole blood or plasma, dropwise with stirring, to 15 ml. of 6 per cent trichloroacetic acid in a 50-ml. centrifuge tube. Stir to obtain a fine suspension. Allow to stand 5 minutes, then centrifuge. Add 0.75 g. of acid-washed norit (see above) to the clear supernatant solution, and shake vigorously. Filter. Test 4-ml. aliquots by the 2,4-dinitrophenyl-hydrazine procedure as directed above.

To 2 ml. of urine, add 38 ml. of 4 per cent trichloroacetic acid solution. (A greater dilution should be made if the sample is expected to contain more than 360 mg. of ascorbic acid per liter.) Add 1.5 g. of acid-washed norit (see above), shake vigorously, and filter. Test 4-ml. aliquots by the 2,4-dinitrophenylhydrazine procedure as directed above.

Photometric Method of Hochberg, Melnick, and Oser:266 Principle. Ascorbic acid is determined in the presence of other reducing substances by photometric measurement of the rate of decolorization of the

²⁶⁵ Suspend 100 g. of norit in 500 ml. of 10 per cent hydrochloric acid. Heat to boiling, then filter with suction. Remove the cake of norit, stir it up with 500 ml. of water, and filter again. Repeat this procedure until the washings give a negative or faint test for ferric ions. Dry overnight in an oven at 110°-120°.

Dissolve 2 g. of 2.4-dinitrophenylhydrasine in 100 ml. of 9 N sulfuric acid and filter.
 To 100 ml. of distilled water, add 900 ml. of concentrated sulfuric acid, sp. gr. 1.84.

²⁴⁴ Roe and Kuether: loc. cit.

³⁴⁴ Hochberg, Melnick, and Oser: Ind. Eng. Chem., Anal. Ed., 15, 182 (1943).

dye 2,6-dichlorophenol indophenol. Dehydroascorbic acid is determined after reduction by hydrogen sulfide.

Procedure: Conduct all manipulations under an atmosphere of nitrogen and make all extractions and dilutions with solutions previously deaerated with a stream of nitrogen. Homogenize the sample with an equal weight of 6 per cent metaphosphoric acid solution. Fresh vegetables and materials containing active oxidases should first be blanched by adding the sample directly to boiling 6 per cent metaphosphoric acid. After boiling for 5 minutes, cool and homogenize.) Dilute to a convenient volume with 3 per cent metaphosphoric acid. Shake mechanically for 15 minutes, then centrifuge. To 50 ml. of the clear supernatant fluid, add 14 ml. of citrate solution. Measure reduced ascorbic acid in this aliquot as directed below.

Convert dehydroascorbic acid to the reduced form by treating the metaphosphoric-citric acid extract with a slow stream of hydrogen sulfide for 20 minutes. Allow to stand for 2 hours, then remove the hydrogen sulfide by washing with a vigorous stream of wet nitrogen (bubbled through water) for 2 hours.

Colorimetric Measurement: Determine the volume of extract necessary to decolorize 15 ml. of 2,6-dichlorophenol indophenol solution.²⁶⁹ To obtain optimal concentration for measurement in a photoelectric colorimeter, dilute this volume of extract to 30 ml. with metaphosphoric-citric acid solution.²⁷⁰

Place a colorimeter tube containing 5 ml. of standard dye solution in the instrument. Add 5 ml. of the diluted extract from a rapid delivery pipet²⁷¹ (Fig. 305) and measure the residual photometric density²⁷² 5 and 10 seconds later. Determine the blank absorption of extraneous pigments in the extract by adding a few crystals of ascorbic acid to completely decolorize the residual dye.

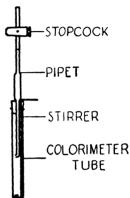

Fig. 305. Pipet used for addition of ascorbic acid extract to dye solution.

Obtain the residual photometric density at 5 and 10 seconds with standard solutions of ascorbic acid containing 1 to 6 γ per ml. in metaphosphoric-citric acid solution.

Calculation. Using ordinary graph paper, plot the photometric densities for the standard solutions on the vertical axis against time on the

267 Metaphosphoric acid changes slowly in solution to orthophosphoric acid. The extractant should be stored in the refrigerator where it is stable for several weeks.

²⁶⁸ Curate Solution: Dissolve 21 g. of citric acid in 200 ml, of 1.0 N sodium hydroxide and dilute to 250 ml.

¹⁶⁹ 2.6-Dichlorophenol Indophenol Solution: Dissolve 8.0 mg, of 2.6-dichlorophenol indophenol sodium salt in hot water and filter. Wash the filter paper several times with cold water and dilute the combined filtrate and washings with distilled water so that 5 ml, of dye plus 5 ml, of meta₁, asphoric-citric acid transmit 40 per cent of the incident light in the photoelectric colorimeter. The final volume is approximately 500 ml. Set the instrument at 100 per cent transmittance with distilled water.

²⁷⁰ Metaphosphoric-Citric Acid Solution: Add 70 ml. of citrate solution to 250 ml. of 3 per cent metaphosphoric acid solution.

²⁷¹ The pipet should deliver exactly 5 ml. of extract in a period of less than one second. To prevent formation of air bubbles, the solution should be delivered against the side of the tube.

not The photoelectric colorimeter must be of the direct reading (not null-point) type and its galvanometer must be rapid and critically damped. Set the instrument at 100 per cent transmittance with distilled water. The concentrations of ascorbic acid and dye and the volumes employed are those recommended when the Evelyn photoelectric colorimeter (Rubicon Company, Philadelphia) is employed.

horizontal axis. Extrapolate the readings linearly to zero time. This calibrates the vertical axis in terms of ascorbic acid concentration.

Calculate the ascorbic acid concentration of the unknown as follows: Subtract the photometric density of the blank from those at 5 and 10 seconds. Plot the values as above and extrapolate to zero time. Estimate the ascorbic acid concentration of the extract from the intercept on the vertical axis, calibrated as described above. Multiply by the dilution factor to obtain the ascorbic acid content of the original sample.

Interpretation. This photometric method measures both reduced and dehydroascorbic acid. Appreciable concentrations of the latter are frequently found in processed and stored foods. The method is applicable to the determination of ascorbic acid in the presence of other reducing materials, which interfere minimally in this procedure.

Biological Methods. Because of its apparent immunity to scurvy, the albino rat cannot be used in the biological assay for vitamin C. The animal employed is the guinea pig, since it is extremely sensitive to the lack of this factor in the diet. The types of quantitative technic used are based either on the determination of the minimum dose necessary for protection against or cure of gross scorbutic symptoms, ²⁷³ or on the histological examination of the incisor teeth ²⁷⁴ after a test period of 14 days. The latter method requires equipment not always available in nutrition laboratories, and while it has proved satisfactory for the determination of minimum protective dose where large enough groups are used to compensate for variation encountered, grading of vitamin C values according to the extent of dental pathology is the less commonly used biological technic. The method has the advantage, however, of a short experimental period. About twice as much vitamin C is required for protection of the teeth of guinea pigs as for prevention of gross symptoms of scurvy. ²⁷⁵

The minimum daily allowance of a food which provides a guinea pig with complete protection from scurvy is a measure of its vitamin C potency. It has been suggested by Sherman, La Mer, and Campbell that by rating the pathological effects observed in the living animal and at autopsy, the fraction of complete protection afforded by subminimal doses may be estimated. While this method allows more animals to be considered in interpreting a given experiment, it must be emphasized that experience is required in assessing the extent of the lesions, and that numerical evaluation of different lesions is purely arbitrary.

BIOLOGICAL ASSAY FOR VITAMIN C

Method of Sherman, La Mer and Campbell: Guinea pigs, six to eight weeks old and weighing from 250 to 300 g., are fed ad lib. the following scurvy-producing diet:276

²⁷³ Sherman, La Mer, and Campbell: J. Am. Chem. Soc., 44, 165 (1922); Coward and Kassner: Biochem. J., 30, 1719 (1936).

¹⁷⁴ Höjer: Brit. J. Exptl. Path., 7, 356 (1926); Goettsch: Quart. J. Pharm., 1, 168 (1928); Key and Elphick: Biochem. J., 25, 888 (1931); Fish and Harris: Proc. Roy. Soc. London, 223, 489 (1933).

²⁷⁵ Eddy: Am. J. Pub. Health, 19, 1309 (1929).

²⁷⁶ Diets containing fat must be prepared fresh weekly, as guinea pigs reject rancid food. Other scorbutigenic diets which have proved useful are the following:

Ground whole oats ²⁷⁷	59
Heated skim milk powder ²⁷⁸	30
Fresh butterfat ²⁷⁹	16
Table salt	1

This diet may be reinforced with yeast and codliver oil.

In order to provide assurance of the health of the guinea pigs and their capacity to grow, a short preliminary period may be included during which some source of vitamin C is fed, such as a leafy vegetable or orange juice. Following this period the food to be assayed is fed in graded doses as the sole source of vitamin C. 0.5 ml. of 0.1 per cent ascorbic acid or 5 ml. of orange or lemon juice may be fed as a supplement to positive control animals.

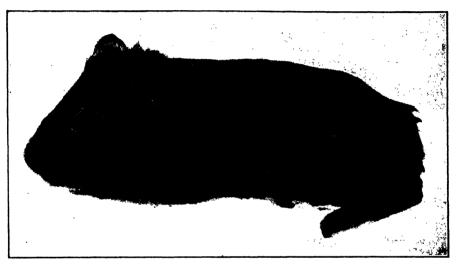

Fig. 306. Guinea pig with scurvy. Showing "scurvy position."

In the absence of antiscorbutic vitamin, growth ceases in about 2 weeks, and a rapid decline in weight is followed by death in 4 to 5 weeks. During the second or third week, the external symptoms of scurvy become evident.²⁸⁰ The joints become tender, causing the guinea pig to wince or squeal when pressure is applied to the wrists. The paws become edematous and hemor-

- (b) Demole: Z. Vitaminforsch., 3, 89 (1934). Rolled oats 2 kg., dried whole milk 1 kg. (previously dried at 120° C. for 2 hr.). Mix and make into paste with whites of 6 eggs and water. Mold into cakes 5 cm. diam. and bake 20–25 min. on a tin greased with olive oil. Supplement with 0.2 ml. of codliver oil weekly
- (c) Purina Rabbit Chow (Purina Mills, St. Louis, Mo.) is a prepared ration which produces scurvy in guinea pigs. It may be supplemented with dried yeast.
- ³⁷⁷ A mixture of equal parts of commercial rolled oats and wheat bran may be used instead of the ground whole oats.
- ²⁷⁶ Heated in shallow open pans at 110° C, until all the vitamin C is destroyed, as determined by control tests. The powder assumes a brownish color.
 - The butterfat may be replaced by vegetable oil 8 + codliver oil 2.
- ²⁸⁰ The symptomatology of scurvy in guinea pigs is fully described by Cohen and Mendel; J. Biol. Chem., 35, 425 (1918).

rhagic. The animal becomes lethargic instead of excitable, and usually assumes an unnatural position such as holding up a tender hind leg (the "scurvy position," Fig. 306) or lying with the side of its face resting on the floor (the "face-ache position," Fig. 307). The characteristic postmortem findings are apt to be more pronounced when the deficiency is not quite complete, because the lesions have time to reach an exaggerated form. These findings include hemorrhages (which may be subcutaneous, intramuscular, or intraabdominal), loosening of the teeth, fragility of the bones and teeth, and enlargement of the costochondral junctions of the ribs (beading).

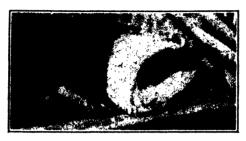

Fig. 307. Guinea pig with scurvy. Showing "face-ache position." (Special Report of British Medical Research Committee, No. 38, 1919.)

Supplying a source of vitamin C to a guinea pig in even an advanced state of scurvy usually will bring about prompt recovery, unless intercurrent disease has set in.

The unitage of vitamin C is calculated from the minimum daily allowance which affords complete protection from scurvy to a standard guinea pig, as above described. Comparison of this dose with the corresponding allowance of the crystalline l-ascorbic acid enables one to express the result of the bioassay in gravimetric units. The International standard is crystalline l-ascorbic acid, of which 0.05 mg, equals one International unit of vitamin C. About 10-12 International units are required daily for complete protection.

VITAMIN P

In 1936, Szent-György²⁸¹ prepared an extract from paprika and subsequently from citrus juice, which he claimed to have value beyond that of ascorbic acid in reducing capillary bleeding in man and in guinea pigs. The name vitamin P was applied to this factor in the belief that it was necessary for the maintenance of normal capillary permeability. Interest in various hemorrhagic conditions which do not respond to vitamin K or ascorbic acid has led to widespread investigation of concentrates high in the active permeability factor. Much of the clinical work in this field has been inadequately controlled and the results are inconclusive.

Active fractions have been obtained from lemons (citrin), from highgrade, cured tobacco (rutin), from forsythia, elder flowers, and violets.

Physiological and Clinical Aspects of Vitamin P. Scarborough²⁸² describes the characteristic type of petechial bleeding in vitamin P de-

²⁴¹ Ssent-György and Russnyák: Nature, 138, 27 (1936).

²⁵³ Scarborough, et al.: Biochem. J., 33, 1400 (1939); Lancet 2, 610 (1938); 644 (1940); Rdinburgh Med. J., 50, 85 (1943).

ficiency as accompanied by pain across the shoulders and in the legs, lassitude and undue fatigue, low capillary resistance, slightly prolonged bleeding time, and low serum calcium. Ascorbic acid is not effective in relieving this syndrome; a distinction is drawn between the spontaneous hemorrhage of scurvy and the increased capillary fragility of vitamin P deficiency. Rutin, a flavone glycoside structurally similar to hesperidin, one of the glycosides in citrin, was employed with favorable results by Griffith, Couch, and Lindauer²⁸³ in the treatment of patients with hypertension who showed increased capillary fragility.

In spite of such reports, there is conflicting evidence in the literature regarding the clinical value of these compounds which probably results from the fact that there are many factors responsible for the maintenance of normal capillary resistance. Clinical methods of measuring capillary fragility are inadequate, because of diurnal variations and differences in subcutaneous capillary beds in different areas of the body. The dosages employed clinically depend upon the purity of the extracted flavones; the crystalline glycosides have been administered in divided dosage in the order of 50 to 150 mg. per day.

Occurrence of Vitamin P. Citrin or similar glycosides having vitamin P activity have been isolated from paprika, juice or peel of citrus fruits, cured tobacco, and the leaves of a wide variety of plants and flowers.

Chemistry of Vitamin P. This vitamin occurs in nature not as a single compound but rather as mixtures of flavone glycosides. For example, citrin, from lemon peel, consists of a mixture of hesperidin and eriodictin, compounds which differ only in that the latter contains a hydroxyl group in place of the oxymethyl group shown below. (It is of interest that these compounds are closely related, structurally, to naring-in, the bitter glycoside of grapefruit rind.)

Rutin
(Rutinose is a disaccharide of rhamnose and glucose)

Determination of Vitamin P. Chemical methods have not been developed for the determination of vitamin P activity in natural sources. The biological assay for vitamin P activity is based upon the observation of petechial hemorrhages under controlled conditions similar to the procedure employed for the diagnosis of vitamin P deficiency in man. Bacharach, Coates, and Middleton²⁸⁴ have described a guinea pig assay in which crystalline hesperidin is used as the reference standard. The critical petechial pressure is determined from the negative pressure required to produce hemorrhages when a suction cup, furnished with a glass window for visibility, is applied to the prepared area of skin.

VITAMIN D

Early in the history of vitamins, antirachitic activity was regarded as a manifestation of fat-soluble vitamin A, but the work of McCollum and his collaborators²⁸⁵ established the distinction between the growth-promoting, antiophthalmic vitamin A and the antirachitic factor now known as vitamin D. The specific role of this vitamin in the prevention and cure of rickets (rachitis) is integrated with the metabolism of calcium and phosphorus; in fact, in some species, especially the rat, the absence of vitamin D from the diet does not result in rickets unless the normal dietary ratio of Ca:P is disturbed. A condition analogous to human rickets may be produced experimentally in this species by feeding a diet high in calcium, low in phosphorus, and free from vitamin D. On a low calcium-high phosphorus diet, the bones develop an osteoporotic condition resembling osteomalacia. The function of vitamin D appears to be to mobilize these calcifying elements, so as to make possible their most efficient utilization, even when the dietary supply is inadequate or disproportionate. It has been shown that even if calcium and phosphorus are fed in proper quantity and ratio, the absence of vitamin D, especially if prolonged, will result in poorer calcification of the bones than obtains under normal conditions 286

Mild cases of rickets are often unrecognized though they are quite prevalent and may not have serious consequences until later years. The work of Jeans and his associates has emphasized that the requirement of vitamin D for optimum growth exceeds the antirachitic requirement. Despite the existence of definite knowledge of its etiology, rickets in its more severe manifestations continues to be widespread especially among urban children of poor economic status. In regions where sunshine is prevalent and customs permit bodily exposure, the disease is of rare occurrence. In India rickets is less common among the poor who live an outdoor existence than among the wealthy who observe the rite of seclusion (purdah).

Physiological and Clinical Aspects of Vitamin D. Rachitic bones are characterized by a lower content of mineral matter and an apparent

²⁸⁴ Bachárach, Coates, and Middleton: *Biochem. J.*, 36, 407 (1942); See also Bourne: *Nature*, 152, 659 (1943).

²⁵⁶ McCollum, et al.: J. Biol. Chem., 50, 5 (1922); 51, 41 (1922); 53, 293 (1922).

²⁸⁶ Sherman and Stiebeling: J. Biol. Chem., 83, 497 (1929); 88, 683 (1930); Proc. Soc. Exptl. Biol. Med., 27, 663 (1930); Fairhall: Am. J. Physiol., 84, 378 (1928).

overgrowth of osteoid cartilage, in consequence of which normal rigidity is absent. The sequelae of this condition in children are misshapen bones (e.g., bowlegs), epiphyseal enlargement (e.g., knock-knees, beading of the ribs [the "rachitic rosary"]), delayed closure of the fontanelle, retarded eruption of the teeth, disturbances of respiration due to deformity of the thoracic cavity (pigeon breast), etc. In later life, difficult childbirth may be encountered because of pelvic deformities. The changes in bone composition are illustrated in the table below.

The calcium phosphate compound in all bones, normal or rachitic, appears to be Ca₃(PO₄)₂, which in the normal adult rat is accompanied by CaCO₃ to the extent of about 15 per cent of the total calcium.²⁸⁷ The ratio of tertiary phosphate to carbonate is greater in the normal than in the rachitic animal, and in the adult than in the growing animal. From evidence based partly on solubility product studies, it has been suggested that

Composition of Normal and Rachitic Bones (Schabad)²⁵⁸ (in per cent of dry fat-free matter)

	Bone	Water	Ash	Organic Matter	Calcium	Phos- phorus
Rib	Normal	14.4-32.9	40.2-16.6	26 9-39.1	15.5-18.1	5.4-8.3
	Rachitic	42.4-66.4	7 9-32.0	20.7-22.4	3.0-12 0	1.4-5.6
Occiput	Normal	13.0 16.1	47.6-51.7	32.2-36 5	18.8-19.9	7.9-9.0
	Rachitic	29.0-35.9	34 . 3-40 . 6	26.1-31 6	13.6-17.2	6.0-7.8

primary calcification differs in composition from old bone, in that it consists probably of CaHPO₄ and Ca(OH)₂. ²⁸⁹ Refractive index and x-ray studies show that the solid inorganic phase of bone consists of minute crystals of a compound $3Ca_3(PO_4)_2 \cdot CaCO_3$, similar to the apatite minerals, which are represented by $3Ca_3(PO_4)_2 \cdot CaX_2$ (where X_2 may be CO₃, Cl₂, F₂, (OH)₂, O, or SO_4 . ²⁹⁰ These crystals are normally oriented lengthwise along the bone, but in rickets the cement substance (collagen) is broken down and the x-ray diffraction pattern indicates a disoriented crystalline structure. ^{290a}

Many suggestive facts are known, but no complete explanation of the mechanism of vitamin D activity is available. The diminished retention and altered paths of elimination of calcium and phosphorus in rickets (illustrated in the table below) have provided the basis for the conception that vitamin D is concerned with the absorption of calcium and phos-

¹⁰⁷ Howland, Marriott, and Kramer: J. Biol. Chem., 68, 721 (1926).

²⁸⁸ Prepared by Orgler (Ergebnisse inn. Med. Kinderheilk., 8, 142 (1912)) from the data of Schabad (Arch. Kinderheilk., 52, 47 (1909); 53, 380 (1910); 54, 83 (1911)) and cited by Hess (see Bibliography, p. 1192).

phorus through the small intestine. Vitamin D does not appear to affect the excretion of calcium into the intestine, except indirectly. A causal relation between the intestinal pH (probably only in the cecum and colon) and the retention of the calcifying elements is suggested by the greater alkalinity (and hence the precipitation of calcium salts) in rickets, but it is not known which of these is the determining factor and, if it is the former, what ultimate mechanism is responsible for its alteration in rickets. Vitamin D is claimed to increase gastric secretion and thus facilitate calcium absorption. The sharper peaked blood sugar tolerance curve after vitamin D administration is also suggestive of an effect on intestinal absorption.

TABLE SHOWING RETENTION AND ELIMINATION OF CA AND P IN RACHITIC RATS AND DURING HEALING* (AVERAGES OF 4 RATS, EXPRESSED ON THE BASIS OF ONE RAT PER PERIOD)

Periods	Calcium				Phosphorus			
		1	. Distribution (per cent of intake)		Intake, mg.	Distribution (per cent of intake)		
1 0, 1000	Intake, mg.		Excreted				Excreted

II (Healing)	163	47.2	0.7	52.1	159	39.6	20.5	3 9.9

^{*} From unpublished data obtained in the senior author's laboratories. Similar observations are reported by Shohl, Bennett, and Weed: J. Biol. Chem., 79, 257 (1928).

Period I: A 5-day period in the fourth week of a high Ca-low P rachitogenic diet.

Period II: A 5-day period during the succeeding week, after the Ca:P ratio was diminished by substituting CaHPO42H2O for CaCO2.

A significant agent in ossification is the enzyme phosphatase²⁹¹ which occurs in various organs of the body, but especially in the bones and teeth. It is capable of precipitating calcium phosphate from soluble calcium salts of phosphate esters such as are present in blood. Its optimum range of activity lies between pH 8.4 and 9.4. The fact that phosphatase is concentrated in the ossifying centers of bone cartilage, even in rickets, would tend to indicate that in this disease the supply of substrate may be at fault. In rickets there is not only overproduction of osteoid matrix, but proliferation of cartilage cells which are an abundant source of phosphatase. The small amount of this enzyme normally found in plasma is greatly increased

²⁹¹ Robison, et al.: Biochem. J., 17, 286 (1923); 18, 740 and 1354 (1924); 19, 153 (1925); 20, 847 (1926); 23, 767 (1929); 24, 1922 and 1927 (1930); Kay: Biochem. J., 20, 791 (1926); 22, 855 (1928); J. Biol. Chem., 89, 235 and 249 (1930).

in generalized bone disorders, probably by diffusion from the osseous tissue (see p. 222) in which a compensatory stimulation of osteoblastic activity occurs. It has been suggested that two mechanisms operate in bone formation, the phosphatase mechanism which produces in the bone matrix fluid a condition of supersaturation with respect to bone phosphate, and an "inorganic" mechanism which favors deposition of this salt from supersaturated solutions.

The partition of serum calcium and phosphorus into various diffusible and nondiffusible forms indicates that these may have some relation to the etiology of rickets. Vitamin D produces an increase in adsorbable forms of these elements, particularly in a Ca-P complex which appears to be concerned with the calcification process.²⁹²

Efforts have been made to correlate the action of vitamin D with the important role played by the parathyroid hormone in the maintenance of calcium equilibrium in the serum. Hyperparathyroidism is accompanied by high serum calcium, and apparent dissolution of this element from the bones, which when prolonged may lead to osteomalacia. Parathyroid extract does not cure rickets. Though there are many similarities in the effects of vitamin D and parathyroid hormone on calcium mobilization, evidences of differences in their mode of action, e.g. in tetany or when given in overdosage, leave open to question a hormonal explanation of vitamin D activity.

The vitamin D requirement of man is influenced by age, color, pregnancy, lactation, the mineral content of the diet, and conditions which affect intestinal absorption. The vitamin D needs of adults and older children may be satisfied by sufficient exposure to solar radiation. According to the National Research Council, the recommended daily allowance of this vitamin is 400 units daily, except during pregnancy, lactation, and the first year of childhood, when it is increased to 800 units. See p. 1027. Vitamin D may be administered not only subcutaneously or intraperitoneally²⁹³ but by direct absorption through the skin²⁹⁴ although the dosage requirements under these conditions are not well defined.

Even when massive doses are given, the transfer of vitamin D to human or cow milk is limited to only a few per cent. The administration of 40,000 units per day during early lactation of mothers increased the vitamin D content from very low or zero levels to a range of 125 to 583 units per liter. Most vitamin D milk of commerce is produced by direct addition of irradiated sterols or concentrates; so-called "metabolized vitamin D milk" is obtained by controlled dosage of cows.

Some success has been claimed for the more or less empirical use of large doses of vitamin D in the treatment of arthritis but the reports in the literature are conflicting and the physiological mechanism involved is not known.

The belief that excessive doses of vitamin D were toxic owed its origin in

¹⁰¹ Benjamin and Hess: J. Biol. Chem., 160, 27 (1933); 103, 629 (1933).

²⁰³ Soames: Biochem. J., 18, 1349 (1924); Hess, Weinstock, and Helman: J. Biol. Chem., 63, 305 (1925); Kramer, et al.: J. Biol. Chem., 71, 699 (1927).

²⁰⁴ Hume, Lucas, and Smith: Biochem. J., 21, 362 (1927); Helmer and Jansen: Studies Inst. Divi Thomae, 1, 83 (1937).

part to unfortunate experiences with an early German product "Vigantol," which probably contained an excessive proportion of toxisterol (see p. 1152) due to overirradiation of the sterol. Later studies have shown that the margin between the therapeutic and the minimum toxic dose of vitamin D is very wide. Several hundred times ordinary therapeutic doses must be administered daily for several weeks before toxic effects are noted. The chief symptoms of toxicity due to overdosage of vitamin D are anorexia and polyuria. Calcification of soft tissues, and particularly of the renal arterioles and the aorta, are observed in advanced stages, although hypertension is not encountered. The toxic effects disappear upon discontinuance of the dosage.

The calcium content of the blood serum of rachitic children is normal (9-11 mg. per 100 ml.) or only slightly lower, but the inorganic phosphorus content may be reduced to half the normal values of 4-5 mg., or even lower in severe cases. There are seasonal variations in the blood phosphate values, the minimum occurring in late winter and early spring, and the maximum in midsummer. These changes run parallel to the seasonal variation in solar ultraviolet radiation and coincide with the variations in the incidence of clinical rickets. They may also account for the spontaneous healing often observed in summer.

These observations as well as the well-known geographical distribution of rickets, have been attributed to the effect of exposure to sunlight. The therapeutic value of the sun's rays in rickets was noted by Huldschinsky who also studied the use of artificial sources of ultraviolet radiation. It is now known that certain of these rays cause a synthesis of vitamin D from a precursor in the skin, and that a similar synthesis can be produced in vegetable oils and other foods containing the inert provitamin.

For further discussion of the clinical aspects of vitamin D, see the American Medical Association syllabus, p. 1186.

Ultraviolet Radiation. The visible region of the spectrum comprises only a small portion of the entire scale of radiant energy. The various colors in the visible spectrum (see Frontispiece) result from differences in the frequency, or inversely, the wavelength, of the radiations. In the invisible regions of electromagnetic vibrations, there are the longer radiations (infrared or heat rays, Hertzian, and radio waves) and the shorter radiations (ultraviolet rays, gamma rays, x-rays, etc.). The relation between these forms of radiant energy is illustrated in Fig. 308.

It will be noted that the antirachitic region of the spectrum extends from about 256 m μ to about 313 m μ , whereas the shortest solar radiation is about 290 m μ . It is only when the atmosphere is free from smoke, fog, dust, clouds, etc., that solar energy of wavelength shorter than 300 m μ reaches the earth, and even then its intensity is very slight. On a clear day at sea level the energy distribution is approximately 1 to 2 per cent ultraviolet, 42 to 53 per cent visible and 57 to 63 per cent infrared. The limited antirachitic protection offered from this source helps explain the frequency of rickets and the need for dietary sources of vitamin D. Ultraviolet radiation exerts its maximum activating power at the wavelength of maximum absorption by the provitamin, e.g., at 281 m μ (range = 275 to 300 m μ)

in the case of ergosterol. The energy required for activation is 7.5×10^{13} quanta per unit of vitamin D.

Ultraviolet energy emanates from incandescent solids. The distribution and intensity of this energy depends on the nature of the incandescent source. The most widely used sources of ultraviolet radiation in experimental or therapeutic work are the carbon are and the quartz mercury arc. Carbon are lamps are provided with carbons containing metallic cores of definite composition. The quartz mercury vapor lamp consists of a quartz chamber in which an arc discharge takes place between electrodes

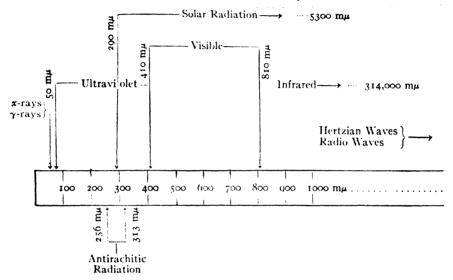

Fig. 308. Chart showing distribution of radiant energy. (The figures indicate the wavelengths, expressed in millimierons.²⁹⁵)

of mercury or of mercury and tungsten. The ultraviolet component of these lamps depends on the energy input, and in the case of the mercury vapor arc, diminishes with the age of the lamp.

Ordinary window glass is opaque to ultraviolet radiation but quartz is transparent. Various makes of glass of special composition permit the transmission of antirachitic radiation and are used in schools, hospitals, solaria, etc. Certain cellulose compounds (e.g., Celoglass) are also transparent to the antirachitically active rays, and these have been used for windows of poultry houses.

The variation in distribution and intensity of ultraviolet radiation from the sun or from artificial sources makes necessary some means of measurement. No satisfactory method has been developed for analyzing the antirachitic region alone, and of the biological and photochemical methods it may be said that no two of them measure exactly the same region and none of them gives an index of the distribution of energy. The only ac-

One micron (μ) = 0.001 mm.
 One millimicron (mμ) = 0.001 μ.
 One Ângström unit (Å) = 0.1 mμ.

curate methods are those based on a physical measurement of the energy, such as those employing a thermopile and galvanometer. Radiation of any region of wavelength, selected by optical filters or a quartz monochromator, may be absorbed by a thermocouple, causing a flow of current which can be measured by a galvanometer previously standardized against radiation of known intensity. Such a method, while nonselective and reliable, is beyond the scope of most biological laboratories.

Of the photochemical methods²⁹⁶ there may be mentioned (1) Clark's, in which the number of minutes required for a paste of lithopone, or preferably pure zinc sulfide, to darken to a definite shade, is taken as the index and expressed as lithopone or ZnS units of ultraviolet energy; (2) Pohle's, in which the index is the time required for the ultraviolet energy to produce a blue color in a solution containing potassium iodide, sodium thiosulfate, and starch; (3) Webster, Hill, and Eidinow's in which the fading of the blue color in an acetone-methylene blue solution is measured by comparison with known standards; and finally (4) the method of Anderson and Robinson, given below.

Photochemical Method for Measuring Ultraviolet Intensity: **Principle.** In the presence of a uranium salt which acts as a catalyst, a solution of oxalic acid is decomposed by ultraviolet, but not by visible, light. The degree of decomposition is determined by titration with potassium permanganate.

Procedure: A solution containing exactly 6.3 g. of c.p. oxalic acid (H₂C₂O₄,-2H₂O) and 4.27 g. of uranyl sulfate (UO₂SO₄.3H₂O) per liter of distilled water is prepared and kept protected from the light, 25 ml. of this solution are placed in a fused quartz cell 3.35×10 cm. in area and 1.65 cm. thick.²⁹⁷ The unshielded area of the cell is exposed directly to the source of ultraviolet energy for a definite period. In the case of solar measurements a one-hour exposure is used, the angle of the cell being changed every 5 minutes to keep the rays perpendicular to the surface.

After the exposure the contents of the cell are rinsed into a flask with 50 ml. of distilled water, and 2 ml. of concentrated sulfuric acid are added. The solution is then boiled and titrated while hot with a solution of potassium permanganate standardized to be equivalent to the oxalic acid solution (theoretically 3.16 g. of KMnO, per liter).

Calculation. (25 - ml. of KMnO₄ used)0.63 = mg, of oxalic acid decomposed. Duplicate determinations should agree within 0.06 mg. The maximum value found by Tonney for sunlight at Chicago was 7.12 mg. per hour. Sunburn of untanned skin (the "erythema reaction") was observed whenever the intensity exceeded half this maximum value.

²⁹⁴ Clark: Am. J. Physiol., 69, 200 (1924); Science, 68, 165 (1928); Pohle: J. Am. Med. Assoc., 86, 318 (1926); Webster, Hill, and Eidinow: Lancet, 1, 745 (1924); Hill: Lancet, 2, 299 (1924). A set of standard blue gauges, quartz tubes, and solution for use in this test is marketed by Siebe, Gorman and Co., Ltd., London, S.E. 1, England. Anderson and Robinson: J. Am. Chem. Soc., 47, 718 (1925); Tonney: J. Prevent. Med., 2, 493 (1928),

The photochemical methods have been calibrated against the radiometric method and critically reviewed by Mayerson (Am. J. Hygiene, 22, 106 (1935)) with the conclusion that the oxalic acid-uranyl sulfate method is reliable and most convenient.

297 Obtainable from the Hanovia Chemical and Manufacturing Co., Newark, N. J. The cell walls are covered with opaque paper except for a 10 sq. cm. area on the face to be exposed to the light source.

Storage of Vitamin D. The animal body is able to maintain a reserve of vitamin D, the amount depending on the dietary supply and on the extent of exposure to the synthesizing influence of ultraviolet radiations. The rate of depletion of the bodily store of vitamin D, when a supply of this factor is lacking, is affected by the ratio of calcium to phosphorus in the diet, which under normal conditions should be between 1:1 and 2:1.

Young animals acquire some degree of antirachitic protection by virtue of the transfer of vitamin D into the mother's milk, although the efficiency of this transfer is very low (about 1 to 2 per cent). By feeding codliver oil or irradiating the mother during the periods of gestation and lactation, the vitamin D potency of the milk can be increased somewhat, but ordinarily both cow and human milk are poor sources of the antirachitic vitamin. The fortification of cow milk with vitamin D is discussed on p. 1156.

Chemistry of Vitamin D. Five years after Huldschinsky's 298 demonstration of the therapeutic value of ultraviolet irradiation on rickets, Hess²⁹⁹ and Steenbock³⁰⁰ independently and almost simultaneously (1924) revealed the startling discovery that antirachitic activity could be induced in foods by exposure to ultraviolet radiation. It was soon demonstrated that, like codliver oil, activated oils contained the antirachitic factor in their nonsaponifiable fraction. Interest then centered on the activability of phytosterol and cholesterol, the important unsaponifiable lipids of plant and animal tissue, respectively. That cholesterol itself was activated appeared to be indicated by the failure of repeated recrystallizations to diminish its capacity to acquire antirachitic potency upon irradiation. Later work disclosed, however, that pure cholesterol, obtained by reconversion from the dibromide, could not be activated. The search for the "impurity" that behaved as a precursor of the antirachitic factor was greatly aided by the long experience of Windaus in sterol chemistry. for he suggested that this "impurity" might be ergosterol, the sterol found in ergot, the fungus of rve, as well as in other fungi and in yeast. Subsequent investigations of a large number of sterols and their derivatives pointed to ergosterol as the specific "provitamin," but later evidence showed that this is limited to plant sources and that at least one other provitamin occurs in animal sources.

The synthesis of vitamin D from ergosterol is independent of the wavelength of the ultraviolet radiation over the range of selective absorption (about 256 to 313 m μ), but is a function only of the absorbed energy.³⁰¹ It is therefore possible to activate ergosterol by exposure to the unobstructed rays of the sun in spite of the fact that radiation of such short wavelength, even under ideal conditions, hardly ever exceeds 0.1 per cent of the total solar energy.³⁰² The efficiency of solar irradiation may be

affected by a relative preponderance of inactive decomposition products produced by the longer waves. 303

In the ultraviolet activation of ergosterol a series of products is formed depending on the wavelength of the radiation, the duration of exposure, overheating, the nature of the solvent, the presence of oxygen, etc. The changes induced in the absorption spectrum of ergosterol by irradiation

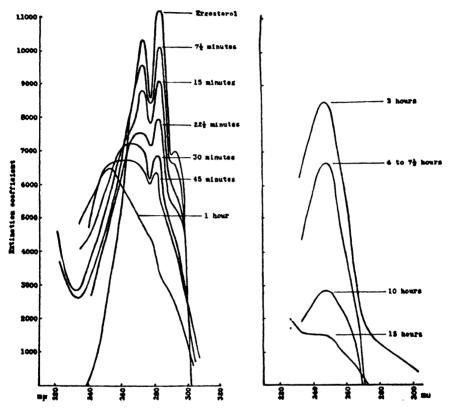

Fig. 309. Effect of prolonged irradiation on the ultraviolet absorption spectrum of ergosterol. (Courtesy, Bills, Honeywell, and Cox: J. Biol. Chem., 80, 557 (1928).)

are shown in Fig. 309. The following scheme summarizes the sequence in which the isomeric products of irradiation appear:

Ergosterol
$$\rightarrow$$
 Lumisterol \rightarrow Tachysterol \rightarrow Calciferol (*Provitamin D*₁) Suprasterols (*I and 11*)

The designation vitamin D₁ was applied to what later was found to be an equimolecular addition compound of lumisterol and calciferol; calciferol itself has been called vitamin D₂. Of these irradiation products only

J. Am. Med. Assoc., 88, 390 (1927); Greider and Downes: Trans. Illum. Eng. Soc., 25, 378 (1930); Forsythe and Christison: J. Optical Soc. Am., 29, 396 (1930).
 Lahousse and Gonnard: Cited by Bills: Physiol. Rev., 15, 1 (1936).

calciferol is antirachitic. Toxisterol, as its name implies, has pronounced toxic-calcifying properties. The isomeric conversion of ergosterol to calciferol is now believed to be characterized by the opening of the B ring at C₉₋₁₀, resulting in a fourth unsaturated linkage.

The properties of ergosterol, 7-dehydrocholesterol and their respective activation products are shown in the following table:

	Ergosterol	Vitamin D ₂ (Calciferol)	}-Dehydrochol- esterol	Vitamin D ₃	
Formula	СаНаОН	C ₂₅ H ₄₅ OH	C ₂₇ H ₄₃ OH	C ₂₇ H ₄₂ OH

Antirachitic activity for rats. Antirachitic activity for chicks	None None	40,000,000 u./g. 400,000 u./g.		45,000,000 u./g. 45,000,000 u./g	

The demonstration³⁰⁴ that activated ergosterol when fed on an equivalent rat-unit basis is only about one-hundredth as effective as codliver oil for chicks, paved the way for studies proving that calciferol is not identical with naturally occurring vitamin D. Furthermore, by means of the comparative chick vs. rat assays, Waddell³⁰⁵ obtained convincing evidence that the provitamin in impure cholesterol is not, as was formerly believed, ergosterol, since the relative species effectiveness of irradiated cholesterol is similar to that of the natural vitamin. Numerous investigations in this field of organic chemistry have resulted in a long list of sterol derivatives which acquire antirachitic potency upon irradiation³⁰⁶ including, in addition to the natural precursors ergosterol and 7-dehydrocholesterol, 22dihydroergosterol, 7-hydroxycholesterol, heated cholesterol which may contain the latter, and 7-dehydrositosterol. There is also evidence for the chemical activation of cholesterol (by forming cholesterylene sulfonic acid) and of ergosterol (by treatment with nitrite). The products of irradiation of 7-dehydrocholesterol are analogous to those of ergosterol, the antirachitic substance being identical with the naturally occurring vitamin (D₂) in fish liver oils. 7-Dehydrocholesterol differs from ergosterol only in the side chain at position 17 of the D ring which in this case is C_8H_{17} as shown in the formula for vitamin D₃ below. The initial ultraviolet absorption curves and the transitional changes during irradiation of ergosterol

and 7-dehydrocholesterol are identical. The pharmaceutical preparation of irradiated ergosterol is known as *viosterol*; the corresponding product of 7-dehydrocholesterol is manufactured under the name of Delsterol, and, because of its relatively greater potency for chicks, is used principally for poultry feeding. The principal natural sources of provitamin D are mussels, shrimp waste, and various species of worms and molluscs. 7-Dehydrocholesterol is also synthesized commercially from cholesterol.

From an extensive series of comparative rat-chick assays of the liver oils of many species of fish, Bills demonstrated the existence of more than one form of natural vitamin D. For example, the liver oil of blue-fin tuna was found to be only about one-sixth as effective antirachitically for the chick as for the rat, whereas that of white sea bass was two or three times

as effective, rat unit for rat unit. For the vitamin content of various fish liver oils, see the table on p. 1036.

Dihydrotachysterol (AT 10 or Antitetany compound No. 10), a drug used for raising serum calcium in hypoparathyroid conditions, has little antirachitic potency for rats but is about six times as effective for chicks as determined by bone ash studies.

The resistance of vitamin D to oxidation is shown by the failure of aeration of hot codliver oil or of treatment with hydrogen peroxide for 18 days to effect appreciable loss of antirachitic potency. The vitamin is not readily destroyed by gentle hydrogenation, ²⁰⁷ or by the action of such reducing agents as hydrogen sulfide, sulfur dioxide, or formaldehyde; on the other hand, nitrous fumes cause destruction. ²⁰⁸

Vitamin D is thermostable in approximately neutral medium, as is indicated by its ability to withstand the direct steaming process used in rendering cod livers. Ninety minutes' exposure in an autoclave at 130° C. caused practically no destruction; at 140° to 145° C. the loss was slight, while at 165° to 170° C. destruction was complete. ³⁰⁸ In acid medium, however, gradual destruction of the vitamin takes place, the rate depending on the reaction and the temperature. ³⁰⁹ Vitamin D can withstand treatment with strong alkali even at elevated temperatures.

Distribution of Vitamin D. The most abundant natural source of vitamin D is codliver oil. Nevertheless, whereas ordinary codliver oil possesses a vitamin D activity of approximately 100 to 200 U.S.P. units per gram, the liver oils of certain other species of fish may be many times more potent. To Some liver oils which are blended for medicinal use are high in vitamin D, e.g., from various species of tuna. Among these oils the swordfish and halibut are also high in vitamin A. On the other hand, certain fish liver oils such as sturgeon, shark, catfish, and Japanese cod are very low in vitamin D. (See table, p. 1036.) The vitamin potency of fish liver oils is affected by spawning (and hence the season of the catch and the oil content of the livers) and by the age of the fish. Varying amounts of vitamin D are also found in the body oils of many marine animals, among them being salmon, herring, sardine, shrimp, oysters, etc. The state of the season of the catch and the oil content of the livers of the body oils of many marine animals, among them being salmon, herring, sardine, shrimp, oysters, etc.

Whether the cod is able to synthesize the vitamin, as would seem to be indicated by the experiments of Bills,³¹⁰ or whether it acquires its supply from the caplin and other forms of food it consumes, is not definitely settled. There is evidence³¹² that the vitamins of codliver oil are derived indirectly from unicellular marine organisms, via copepods, larval

decapods, and mollusca which are present in marine plankton, which in turn are consumed by the cod. However, Leigh-Clare³¹³ failed to demonstrate the presence of vitamin D in these diatomaceous organisms, although other investigators report the presence of the vitamin in marine plankton³¹⁴ especially during the summer months when they are abundant near the surface of the water.

When the livers of cod are in the process of becoming spent, the vitamin D potency of the oil bears an inverse relation to the oil content.³¹⁵ This has been attributed to the relatively rapid depletion of the glycerides during the starvation period, leaving behind the more resistant antirachitic factor. In a large-scale experiment conducted at the Norwegian fishing grounds, however, the senior author found that at the spawning season, when the livers were rich in oil, there was no demonstrable difference in antirachitic potency between the oil of male and female cod. The livers of the females had a somewhat lower oil content but were larger than those of the males.³¹⁶

No increase in the vitamin D content of codliver oil is observed after ultraviolet irradiation, excess exposure being destructive not only of vitamin A but of vitamin D as well.

Vitamin D has a very limited distribution among the common food-stuffs. Of these, egg yolk probably takes first rank, although this source is quite variable, depending upon the hen's ration and upon the amount of exposure to ultraviolet radiation. The vitamin D content of butterfat is relatively low, in contrast to its vitamin A content, but is likewise somewhat higher in summer than in winter. Human milk is an even poorer source of the antirachitic vitamin than cow milk. The calcifying power of milk may be increased by the administration of vitamin D or by ultraviolet irradiation, but these processes are very inefficient. More reliable prophylaxis against rickets can be assured by adding the vitamin directly to the milk or by administration of codliver oil or viosterol.

Several processes are used for increasing the antirachitic potency of whole or evaporated cow milk. These include: (a) feeding activated yeast or sterols to cows, a small fraction of the vitamin D (i.e., calciferol) being transmitted to the milk; (b) ultraviolet irradiation of the milk; (c) fortification of the milk with irradiated ergosterol or vitamin D concentrates obtained from fish liver oils. Vitamin D milk produced by direct fortification is standardized to contain 400 U.S.P. units per quart (whole milk), and provides adequate safeguard against rickets. Infants fed irradiated milk containing only 135 units per quart should be supplied additional vitamin D;²¹⁷ however, higher potencies are attainable nowadays by irradiation.

³¹⁶ Hawk: Reported before the American Chemical Society, Minneapolis Meeting, 1929. Of 1779 livers examined, those from female cod (58.6 per cent of the total) averaged about 288 cc. in size and contained 37.1 per cent oil, while those from the male averaged 163 cc. and contained 43.3 per cent oil.

²¹⁷ The Present Status of Vitamin D Milk: Rept. of Council on Foods, J. Am. Med. Assoc., 106, 206 (1937). See also Jeans: J. Am. Med. Assoc., 106, 2066 (1936).

Plant foods and vegetable oils are notoriously deficient in vitamin D. Excellent sources of vitamin A though they are, the green leafy vegetables lack the antirachitic factor in significant amounts even when grown in the summer months. Sun-drying of hay or alfalfa results in a considerable increase in antirachitic potency. Some activation occurs during fermentation of cocoa due to the exposure of the sterols, present in contaminating fungi, to solar rays.

There appears to be in certain cereals, notably oatmeal, a factor which actively inhibits calcification.³¹⁸ It is claimed however, that this is due to the phosphorus being present largely in a nonassimilable form; i.e., as inositol hexaphosphoric acid or phytin.³¹⁹

Antirachitic activation of foods by ultraviolet irradiation is dependent upon the presence of the provitamin. Hence certain food products—e.g., milk, egg yolk, yeast, etc.—are capable of much greater activation than others, like cornstarch, egg white, or certain cereals. Careful control is required in irradiation processes to avoid the development of rancidity or disagreeable odors, and to guard against destruction of vitamin A, riboflavin, pyridoxine, and (by overirradiation) of the vitamin D which is formed.

"Viosterol" is the designation assigned by the Council on Pharmacy and Chemistry of the American Medical Association to ergosterol activated by ultraviolet irradiation or other physicochemical processes (e.g., cathode rays). It is not the name of a single compound nor is it synonymous with vitamin D. Clinical and laboratory studies indicate that the efficacy of the vitamin (D_2) in viosterol in man and in rats is somewhat less than that of natural vitamin D_3 , but the evidence is not conclusive on this point.

Determination of Vitamin D: Chemical Methods. The determination of vitamin D by physical and chemical methods is complicated by the multiplicity of forms in which it may occur and by the interference of inactive sterols and of vitamin A in the color reactions. Several colorimetric methods have been proposed and discarded for lack of specificity. By selective chromatographic adsorption the active vitamin may be separated from interfering compounds. Vitamin D and its provitamins react with antimony trichloride to produce colors which are read photometrically. This reaction permits the differentiation between ergosterol and 7-dehydrocholesterol which are indistinguishable spectrophotometrically. The antimony trichloride reaction, with or without chromatography, has been employed with success by some for assay purposes but erratic results have been obtained in the hands of others.³²¹

Spectrophotometric absorption methods, though of extreme importance in the study of the effects of irradiation on purified sterols, are of limited value in the quantitative estimation of vitamin D as it occurs in natural foods and fish liver oils.

BIOLOGICAL METHODS. The quantitative study of vitamin D activity is based on the determination of the comparative amounts of test materials and of standard vitamin D preparations necessary to induce healing of rickets in rats or to maintain bone ash levels in chicks. The production of experimental rickets of a moderate but uniform degree of severity within a definite period of time is the primary requisite for reproducibility of results. The various methods differ in respect to the composition of the rachitogenic diet, the criterion for the establishment of the presence of rickets, or the basis for judging the degree of healing. The rat curative assay (U.S.P.) is employed for the evaluation of the vitamin in foods or pharmaceutical products intended for human (or other mammalian) use; because of the relative insensitivity of fowl to vitamin D₂, the chick method (A.O.A.C.) is employed in the assay of vitamin D intended for feeding poultry.

Ordinarily diets used for the production of experimental vitamin deficiency diseases are characterized by being complete in all respects (i.e., as regards proteins, calories, minerals, and vitamins) except only for the absence of the vitamin in question. This, however, is not so in the case of the vitamin D assay with rats because, as has been previously pointed out, marked decalcification does not occur readily in the absence of vitamin D unless the normal calcium: phosphorus ratio is disturbed. 322 The analog of clinical rickets may be produced experimentally in rats by feeding a vitamin D-free diet possessing a Ca:P ratio of about 4.5:1 instead of the normal 1.2:1.

After 18 to 21 days on a standard rachitogenic diet, the animals develop a decalcified zone in the epiphyseal region of the long bones (the so-called "rachitic metaphysis") which may be readily demonstrated roentgenographically (see Fig. 310). At this time gross symptoms of rickets, such as shambling gait or enlargement of the knee joint, are not yet apparent. Hence it is desirable in order to establish the presence of the rachitic lesions that the animals be x-rayed or fluoroscoped or that some of them be sacrificed and their leg bones examined histologically or chemically according to the methods to be described.

After three weeks the bone ash values, expressed on a dry fat-free basis, drop from 35 to 45 per cent, the value at the time the rats are placed on the rachitogenic diet, to 25 to 35 per cent. At this age the normal ash content should be about 50 to 60 per cent. Similarly, the inorganic phosphorus content of the blood decreases from the normal level (for rats) of 8 to 10 mg. per 100 ml. of serum, to about 2 to 3 mg. ²²³ During this period the

*** Bethke, Nelson, and Steenbock: J. Biol. Chem., 58, 71 (1923); Dutcher, Creighton, and Rothrock: J. Biol. Chem., 66, 401 (1925); Hammett: J. Biol. Chem., 64, 409 (1925).

series and Stiebeling (J. Biol. Chem., 83, 497 (1929); 88, 683 (1930)) describe a preventive technique based on feeding a diet adequate in other respects but deficient only in vitamin D. Their diet consists of extracted casein 18, cornstarch 66, dried brewers' yeast 10, dried powdered spinach 1, sodium chloride 1, Osborne-Mendel salt mixture 4. Rats 21-28 days old are placed on this diet plus graded allowances of supplement. The criterion for equivalent vitamin D content is the amount of material required to produce an ash or Ca value in the fresh femur at 56 days, midway between the values of the negative and positive controls. The latter receive an abundance of vitamin D; e.g., irradiated ergosterol or ultraviolet irradiation.

animals continue to grow, but at a somewhat subnormal rate, the more rapidly growing animals exhibiting rickets of greater severity.

Following the preparatory period, the animals are fed the same diet plus the material to be assayed, which may be incorporated in the diet or preferably fed as a supplement. Negative controls are allowed to continue on the basal diet without antirachitic supplements, while positive controls receive a daily dose of a standard source of vitamin D; e.g., the International Standard (calciferol) or the U.S. Pharmacopoeia Reference Cod Liver Oil. It is important that food materials fed as supplements do not appreciably alter the Ca:P ratio of the diet. In the event of this possi-

bility, the supplement may be fed in the form of its ether extract, or the effect of this factor may be controlled by including the ash of the test material in the diet of the negative controls.

Rats which lose weight or which fail to consume sufficient food must be discarded, because starvation is attended by a remobilization of tissue phosphate and spontaneous healing of rickets. The animals must be shielded against exposure to sunlight or even against undue exposure to filtered daylight.

The duration of the test period depends upon the criterion employed for healing. If the roentgenographic method is adopted, a six-day period may be used, *24 or pictures may be taken at weekly intervals for 2 to 5 weeks.

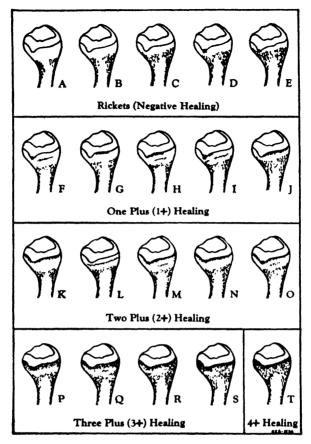

Fig. 312. Chart for Interpretation of Line Test of Tibia.

A, B, C, D, and E are examples of rickets. A, extremely severe rickets; B, severe rickets; C, moderately severe rickets; D, moderately severe rickets with a spot of old calcium evident in the principal tongue of cartilage; E, the poorest type of rickets that can be accepted in controls. F, G, H, I, and J are examples of 1+ healing. F, very slight healing evidenced by a metaphyseal line; G, very slight healing evidenced by a trace of calcium at the distal edge of the cartilage; H and I, slight healing; J, strongest 1+ healing. K, L, M, N, and O are examples of 2+ healing. K, moderate epiphyseal healing; L, moderate metaphyseal healing; M and N, stronger healing; O, strongest 2+ healing. P, Q, R, and S are examples of 3+ healing, in order of increasing calcification. T shows 4+, or complete healing. (Courtesy, Bills, Honeywell, Wirick, and Nussmeier: J. Biol. Chem., 90, 619 (1931).)

(See Figs. 310 and 311.) This method has the advantage of permitting each animal to serve as its own control, and very conveniently may be combined with the histological technique as prescribed by the U.S. Pharmacopoeia. The histological examination of stained sections of the leg bones ("Line Test," see Fig. 312) is conducted at the end of the seven-day assay period.

The feces of rats on a rachitogenic diet tend to become alkaline, but return to the normal slightly acid condition during the process of healing. 326 Efforts to adapt this to the quantitative estimation of vitamin D326 have failed owing to lack of uniformity in response and the variable effect of extraneous factors.

Fish liver oils and vitamin D concentrates are important constituents of poultry rations. Since the rat assay is an inadequate measure of the vitamin D value of certain fish oils and sterols for avian species, a quantitative method of vitamin D assav employing chicks has been adopted by the Association of Official Agricultural Chemists. 327 This is a preventive technique based on a comparison of the average bone ash content of the assay group with that of reference groups receiving graded doses of the U.S.P. Reference Cod Liver Oil. One A.O.A.C. chick unit of vitamin D is equal in biological activity for the chick to one unit of vitamin D in the U.S.P. Reference Cod Liver Oil.

BIOLOGICAL ASSAYS FOR VITAMINS A AND D

Methods of the U.S. Pharmacopoeia XIII. 328,32°

Definitions. As used herein, unless the context otherwise indicates, the term assayer means the individual immediately responsible for the interpretation of the assay; the term assay group means a group of rats to which the assay oil shall be administered during the assay period; the term assay oil means the oil under examination for its vitamin potency; the term assay period for the Vitamin A assay means the interval in the life of a rat between the last day of the depletion period and the twenty-ninth day thereafter or between the last day of the depletion period and the death of the rat; the term assay period for the Vitamin D assay means the interval in the life of a rat between the last day of the depletion period and the eighth day thereafter; the term assemble means the procedure by which rats are selected and assigned to groups for the purpose of feeding, care, and observation; the term control group means a group of rats receiving no assay oil during he assay period; the term daily, for the Vitamin A assay, means 6 days of each week of the assay period; the term daily, for the Vitamin D assay, means each of the first 6 days of the assay period; the term declining weight means the condition of a rat when the body weight of the rat on any given day is equal to or less than the body weight of the rat on the seventh day prior to the given day; 330 the term depletion period means the interval

Assoc. Official Agr. Chem., 19, 628, 637 and 647 (1936); Lachat: Ibid., 20, 450 (1937); Griem: Ibid., 20, 438 (1937).

328 For a critique of the 1934 Interim Revision of these methods see Oser: Ind. Eng.

Chem., 27, 230 (1935).

329 Grateful acknowledgment for permission to reproduce these methods is made to Prof. E. Fullerton Cook and the Board of Trustees of the U.S. Pharmacopoeial Convention. 230 In this connection it is well to remember that rats manifest a diurnal variation in body weight averaging about 2 g. Because of the severity of avitaminosis and the high mortality

in the life of a rat between the last day of the preliminary period and the first day of the assay period; the term dose means the quantity of the Reference Oil or of the assay oil to be fed daily to a rat during the assay period; the term fed means made readily available to the rat or administered to the rat by mouth; the term ground gluten means the clean, sound product made from wheat flour by the almost complete removal of starch, and contains not more than 10 per cent of moisture, and, calculated on the water-free basis, not less than 14.2 per cent of nitrogen, not less than 15 per cent of nitrogen-free extract (using the protein factor 5.7), and not more than 5.5 per cent of starch (as determined by the diastase method 331); the term group for the Vitamin A assay means six or more rats maintained on the same required dietary regimen during the assay period; the term group for the Vitamin D assay means seven or more rats maintained on the same required dietary regimen during the assay period: the term ophthalmia means a pathological state of the eye and/or the conjunctiva and/or the tissues anatomically related to the eye, readily discernible macroscopically and usually associated with Vitamin A deficiency; the term preliminary period means the interval in the life of a rat between the seventh day after birth and the first day of the depletion period; the term rachitogenic diet means a uniform mixture of the food materials, and in the proportions named, in either of the following formulas:

Rachitogenic Diet No. 1	Rachitogenic Diet No. 2
Whole Yellow Maize, ground 33 per cent	Whole Yellow Maize, ground 76 per cent
Whole Wheat, ground 33 per cent	Ground Gluten 20 per cent
Ground Gluten 15 per cent	Calcium Carbonate (U.S.P.) 3 per cent
Gelatin 15 per cent	Sodium Chloride (U.S.P.) 1 per cent
Calcium Carbonate (U.S.P.). 3 per cent	
Sodium Chloride (U.S.P.) 1 per cent	

The term Vitamin A test diet means a food material consisting of the following proportions of the named ingredients of the quality specified:

Vitamin	A Test Diet	
Casein		18 per cent
Salt Mixture (see p. 1163)		4 per cent
Yeast, dried		8 per cent
Starch		
Vegetable Oil		
Vitamin D. a sufficient amount		•

Not less than 3 U.S.P. Units of Vitamin D shall be provided in each gram of diet and this vitamin shall be carried by the yeast or the vegetable oil. The ingredients of the Vitamin A test diet shall be free from Vitamin A or shall have been treated so as to reduce the Vitamin A content to such a degree that when the Vitamin A test diet is fed to the control group two-thirds or more of the rats shall manifest, prior to the eleventh day of the assay period, symptoms of Vitamin A deficiency characterized by both declining weight and ophthalmia. The dried yeast shall carry the Vitamin B complex in such concentration that a daily dose of 0.15 g. shall permit an average gain in weight of at least 3 g. per week in rats during an interval of 4 weeks between the twenty-fifth and sixtieth days of age, at which time the rats are provided ad libitum with a ration which is adequate for optimal growth, except that the ration shall be devoid of the Vitamin B complex.

³³¹ "Official and Tentative Methods of Analysis, Association of Official Agricultural Chemists," 6th ed., 1945, p. 410, method II.

that often results when rats remain too long on the depletion diet, many workers prefer to reduce the period of "declining weight" to four or five days. Differences in pathological symptoms which arise at the end of the depletion period are responsible for much of the variation encountered in biological assays for vitamin A. It has therefore been suggested that preventive, rather than curative, technique might yield more uniform results.

Salt Mixture No. 1332 Magnesium Carbonate (U.S.P.).... Sodium Carbonate, anhydrous (U.S.P. Reagent).... g. g. g. Sulfurie Acid (U.S.P., 96 per cent)..... g. g. Ferric Citrate (U.S.P. Reagent).... 7.44 g. Potassium Iodide (U.S.P.).... 0.020 g. 0.117 g. Sodium Fluoride (U.S.P. Reagent)... 0.062 g. Potassium Alum (U.S.P.).... $0.044 \, g$.

SALT MIXTURES

For preparing the salt mixtures the available form of each chemical is taken to furnish the stipulated equivalent of each chemical.

Dissolve the citric acid in a sufficient quantity of hot distilled water and add the solution to the mixed carbonates. Then add the potassium iodide, manganese sulfate, sodium fluoride, and potassium alum, previously dissolved in distilled water. Then add the ferric citrate dissolved in the hydrochloric acid. Dilute the sulfuric acid with distilled water, add the phosphoric acid, and add this acid mixture to the mixture previously prepared and stir until effervescence ceases. Evaporate the final mixture to dryness, in a current of air at from 90° to 100°, and reduce the resulting product to a fine powder.

Note: A salt mixture may also be prepared by combining suitable quantities of chemical compounds of such degree of purity as to produce a mixture having essentially the same proportions of the same elements as Salt Mixture No. 1.³³²

Salt Mixture No. 2	
Sodium Chloride (U.S.P.)	1.73 g.
Magnesium Sulfate (U.S.P.)	5.45 g.
Sodium Biphosphate (U.S.P.)	3.47 g.
Potassium Phosphate (U.S.P. Reagent)	9.54 g.
Calcium Biphosphate (U.S.P. Reagent)	5.40 g.
Ferric Citrate (U.S.P. Reagent)	1.18 g.
Calcium Lactate (U.S.P.)	13 g.

Mix the finely powdered salts uniformly.

The assay of an oil for Vitamin A and Vitamin D potency shall be by comparison with the U.S.P. Vitamin A Reference Standard and U.S.P. Vitamin D Reference Standard, respectively, by assay procedures conforming in all respects to the following specifications:

METHOD OF ASSAY FOR VITAMIN A

The Vitamin A assay, comprising the recording of observations of groups of rats throughout specified periods of their lives, while being maintained on specified dietary regimens, and the interpretation of such data, are as follows:

Preliminary Period. Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the supply of Vitamin A, or precursors of Vitamin A, shall be limited to such a degree that rats weighing between 40 and 50 g. and not exceeding 28 days of age and sub-

²¹¹ This is the Osborne-Mendel salt mixture (*J. Biol. Chem.*, 15, 317 (1913)). A more easily prepared, and stoichiometrically equivalent, mixture which eliminates the need for dehydration, is described on p. 1273.

sisting on a suitable Vitamin A deficient ration and water for an interval not exceeding 45 days shall manifest symptoms characteristic of Vitamin A deficiency.

Depletion Period. A rat shall be suitable for the depletion period when the age of the rat does not exceed 28 days, and if the body weight of the rat shall exceed 39 g., and does not exceed 50 g., and if the animal manifests no evidence of injury, or disease, or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the Vitamin A test diet and water (U.S.P.), ad libitum, and during this period no other dietary supplement shall be available to the animal.

Assembling Rats into Groups for the Assay Period. Rats which are suitable for the assay period shall be assembled into groups. For each assay oil there shall be one or more assay groups. In the assay of one assay oil there shall be provided at least one control group and at least one reference group, but one control group and one reference group may be used for the concurrent assay of more than one assay oil. The interval of assembling rats into groups shall not exceed 60 days. On any one day during the interval of assembling rats into groups, the total number of rats that shall have been assigned to make up any one group shall not exceed by more than two the number of rats that shall have been assigned to make up any other group. When the assembling of all groups shall have been completed, the total number of rats in each group shall be the same, and the number of rats of one sex in each group shall be the same. Not more than three rats from one litter shall be assigned to one group. When the assembling of all groups shall have been completed, the average weight of the rats in any one group on the day beginning the assay period shall not exceed by more than 10 g, the average weight of the rats in any other group on the day beginning the assay period.

Assay Period. A rat shall be suitable for the assay period, provided that the depletion period shall have exceeded 20 days and shall not have exceeded 45 days, and provided that a rat shall manifest evidence of Vitamin A deficiency characterized by declining weight and/or ophthalmia. Throughout the assay period each rat of the control, reference, and assay groups shall be kept in an individual eage and shall be provided with the Vitamin A test diet and water (U.S.P.), ad libitum. Throughout the assay period each rat in any assay group shall be fed daily a dose of the assay oil, and throughout the assay period each rat in any one reference group shall be fed daily a dose of the reference oil. The reference oil and 'or the assay oil may be diluted before feeding with an edible vegetable oil free from Vitamin A. Diluted oil shall be stored in the dark at a temperature not exceeding 10° C. (50° F.). The period of storage shall not exceed 7 days. Not more than 0.1 ml. of the diluted oil shall be fed as a daily dose. During the assay period all conditions of environment shall be maintained as uniformly as possible with respect to the assay, reference, and control groups.

Recording of Data. On the day beginning the depletion period and at intervals of not more than 7 days for the first 21 days of that period, there shall be a record made of the body weight of each rat. From the twenty-first day of the depletion period until the end of the assay period a record shall be made of the body weight and eye condition of each rat at intervals not exceeding 5 days. The eye condition shall be designated as normal, watery, sensitive to light, swollen, bloody exudate, purulent, opacity of cornea, or any combination of these terms. A record shall be made of the failure of a rat to consume the prescribed daily dose of reference or assay oil.

Vitamin A Potency of the Assay Oil. In determining the Vitamin A potency of the assay oil, the performance of the rats of the assay and reference groups shall be calculated for each group on the basis of the difference between the average weight of the surviving rats and the average weight of the same rats on the day beginning the assay period. The data from the reference group shall be considered valid for establishing the Vitamin A potency of the assay oil only when two-thirds or more of the total number of animals comprising a reference group shall have made individually between the beginning day of the assay period and the twenty-eighth day thereafter an increase in body weight which shall equal or exceed 12 g. and shall not exceed 60 g., and the data from an assay or reference group shall be considered valid for establishing the Vitamin A potency of the assay oil only when two-thirds or

more, but not less than 6, of the rats of an assay or reference group have survived 28 days of the assay period. The data from an assay group shall be considered valid for establishing the Vitamin A potency of an assay oil only when two-thirds or more, but not less than 6 rats, shall have made individually between the beginning day of the assay period and the twenty-eighth day thereafter an increase in body weight which shall equal or exceed 12 g. The data from a rat shall be considered valid for establishing the average performance of a reference or assay group only on the condition that the rat has consumed the prescribed dose of oil for at least 22 days of the assay period. A Vitamin A assay shall not be considered valid unless two-thirds or more of the total number of animals comprising the control group shall, prior to the eleventh day of the assay period, manifest symptoms of Vitamin A deficiency characterized by both declining weight and ophthalmia.

Calculation of Vitamin A Potency

Minimum Standard.

Let R equal the daily dose in milligrams of the reference oil necessary to produce in a reference group an average gain in weight, G, of not less than 12 g. and not more than 60 g.

Let A equal the daily dose in milligrams of the assay oil that will produce in an assay group an average gain in weight equal to or greater than G.

If the product of $\left(\frac{R}{A}\right)$ × (units per g. of Vitamin A contained in the reference oil)

is equal to or greater than the minimum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the minimum standard for Vitamin A potency.

Maximum Standard.

Let R equal the daily dose in milligrams of the reference oil necessary to produce in a reference group an average gain in weight, G, of not less than 12 g, and not more than 60 g.

Let A equal the daily dose in milligrams of the assay oil that will produce in an assay group an average gain in weight equal to or greater than G.

If the product of $\binom{R}{A} imes$ (units per g. of Vitamin A contained in the reference oil)

is equal to or less than the maximum standard in the U.S.P. units per g, for the oil assayed, then the assay oil meets the maximum standard for Vitamin Λ potency.

METHOD OF ASSAY FOR VITAMIN D

The Vitamin D assay, comprising the recording of observations of groups of rats, throughout specified periods of their lives, while being maintained on specified dietary regimens, and the interpretation of such data, is as follows:

Preliminary Period. Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the supply of Vitamin D shall be limited to such a degree that rats, weighing between 40 and 60 g. at an age of 21 to 30 days, and subsisting for an interval of 3 weeks on a suitable rachitogenic diet, shall manifest evidence of severe rickets.

Depletion Period. A rat shall be suitable for the depletion period when the age of the rat does not exceed 30 days, and if the body weight of the rat shall exceed 44 g., and does not exceed 60 g., and if the animal manifests no evidence of injury, or disease, or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the rachitogenic diet and water (U.S.P.), ad libitum, and during this period no other dietary supplement shall be available to the animal.

Assembling Rats into Groups for the Assay Period. Rats which are suitable for the assay period shall be assembled into groups. For each assay oil there shall be one or more assay groups. In the assay of one assay oil there shall be provided at least one reference group, but one reference group may be used for the concurrent assay of more than one assay oil. The interval of assembling rats into groups shall not

exceed 60 days. On any one day during the interval of assembling rats into groups, the total number of rats that shall have been assigned to make up any one group shall not exceed by more than two the number of rats that shall have been assigned to make up any other group. When the assembling of all groups shall have been completed, the total number of rats in each group shall be the same. Not more than three rats from one litter shall be assigned to the assay group unless an equal number of rats from the same litter are assigned to the reference group. When the assembling of all groups shall have been completed, the average weight of the rats in any one group of the day beginning the assay period shall not exceed by more than 8 g. the average weight of the rats in any other group on the day beginning the assay period.

Assay Period. A rat shall be suitable for the assay period, provided that the depletion period shall have exceeded 18 days and shall not have exceeded 25 days, and provided that a rat shall manifest evidence of rickets characterized by a distinetive, wabbly, rachitic gait and by enlarged joints. The presence of rickets may also be established by examination of a leg bone of one member of a litter by the "line test" described below. Each rat shall be kept in an individual cage and shall be provided with the rachitogenic diet and water (U.S.P.), ad libitum. On any calendar day of the assay period the assay and reference groups shall receive a rachitogenic diet compounded from the same lots of ingredients. Throughout the first 6 days of the assay period each rat in any one assay group shall be fed daily a dose of the assay oil, and throughout the first 6 days of the assay period each rat in any one reference group shall be fed daily a dose of the reference oil, except that the following deviation from the daily feeding shall be permissible; that the daily dose may be doubled on the day preceding a one-day holiday falling within the first 6 days of the assay period. During the remainder of the assay period neither the assay oil nor the reference oils shall be fed. At the termination of the assay period, each rat shall be killed and one or more leg bones examined for healing of the rachitic metaphysis according to the "line test" described below. The reference oil and or the assay oil may be diluted before feeding with an edible vegetable oil free from Vitamins A and D. The diluted oil shall be stored in the dark at a temperature not exceeding 10° (50° F.), the storage period not to exceed 30 days. Not more than 0.1 ml. of the diluted oil shall be fed as a daily dose. During the assay period all conditions of environment (particularly with reference to physiologically active radiations) shall be maintained as uniformly as possible with respect to the assay and reference groups.

Line Test. The line test shall be made on the proximal end of a tibia or distal end of a radius or ulna.333 The end of the desired bone is removed from the animal and cleaned of adhering tissue. A longitudinal median section shall be made through the end of the bone with a clean, sharp blade to expose a plane surface through the junction of the epiphysis and diaphysis. In any one assay the same bone of all the animals must be used and sectioned through the same plane. Both sections of the bone shall be rinsed in distilled water and shall then immediately be immersed in a 2 per cent aqueous solution of silver nitrate for 1 minute. 334 The sections shall then be rinsed in distilled water and the sectioned surfaces of the bone shall be exposed in water to daylight or other source of actinic light until the calcified areas have developed a clearly defined stain without marked discoloration of the uncalcified areas.

Records shall be made immediately of the extent and degree of calcification of the rachitic metaphysis of every section. 335 It shall be permissible to use modifications of the described procedure for staining, provided that such modified procedures clearly differentiate between calcified and uncalcified areas.

Recording of Data. On the day beginning the assay period and on the seventh day thereafter, a record shall be made of the body weight of each rat. A record shall be made of the quantity of rachitogenic diet consumed per rat during the assay period. Numerical values shall be assigned to the extent and degree of calcification of the rachitic metaphysis of the bones examined by the line test so that it will be possible to average the performance of each group.

²²³ Calcification is bilaterally symmetrical.

Better stains for photographic purposes are obtained by allowing the bones to stand overnight in acetone or alcohol, before washing, dissecting, and exposing in silver nitrate. 325 See Bills' scale, Fig. 312, p. 1160.

Vitamin D Potency of the Assay Oil. In determining the Vitamin D potency of the assay oil, the average performance of groups with respect to healing of the rachitic metaphysis shall be considered, provided that the average performance of a reference group with respect to calcification of the rachitic metaphysis shall be determined by the data from rats which individually show an extent and degree of calcification in a condition described as positive macroscopic evidence of calcification, but less than an extent and degree of calcification described as complete healing. The data from a reference group shall be considered valid for establishing the Vitamin D potency of the assay oil only when two-thirds or more, but not less than seven rats, show individually an extent and degree of calcification of the rachitic metaphysis equal to or greater than a condition described as positive macroscopic evidence of calcification, but less than an extent and degree of calcification described as complete healing. The data from an assay group shall be considered valid for establishing the Vitamin D potency of an assay oil only when two-thirds or more, but not less than seven rats. show individually an extent and degree of calcification of the rachitic metaphysis equal to or greater than a condition described as positive macroscopic evidence of calcification. The data from a rat shall be considered valid for establishing the average performance of a group only on the condition that the weight of the rat at the termination of the assay period shall equal or exceed the weight of the rat on the beginning day of the assay period and that the rat has consumed 28 g, or more of the rachitogenic diet during the assay period and on the condition that the rat has consumed each prescribed dose of assay oil within 24 hours from the time it was fed. 336

Calculation of Vitamin D Potency

Minimum Standard.

Let R equal the daily dose in milligrams of the reference oil necessary to produce in a reference group an average extent and degree of calcification C not less than a condition described as positive macroscopic evidence of calcification but less than an extent and degree of calcification described as complete healing.

Let A equal the daily dose in milligrams of the assay oil that will produce in an assay group an average extent and degree of calcification equal to or greater than C.

If the product of $\left(\frac{R}{A}\right)$ × (units per g. of Vitamin D contained in the reference oil)

is equal to or greater than the minimum standard in U.S.P. units per g. for the oil assay, then the assay oil meets the minimum standard for Vitamin D potency.

Maximum Standard.

Let R equal the daily dose in milligrams of the reference oil necessary to produce in a reference group an average extent and degree of calcification C not less than a condition described as positive macroscopic evidence of calcification but less than an extent and degree of calcification described as complete healing.

Let A equal the daily dose in milligrams of the assay oil that will produce in an assay group an average extent and degree of calcification equal to or greater than C.

If the product of $\left(\frac{k}{A}\right)$ × (units per g. of Vitamin D contained in the reference oil)

is equal to or less than the maximum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the maximum standard for Vitamin D potency.

VITAMIN E (TOCOPHEROLS)

In 1922 Evans and Bishop³³⁷ showed that a purified diet complete from the standpoint of its ability to support normal growth is conducive to

²³⁶ Correlation between growth and food consumption is so close that it seems sufficient to regard the weight alone as a criterion of starvation. A net loss of 1 or 2 g. can be disregarded, unless it is the result of a substantial terminal loss. With experience one can distinguish the appearance of calcification due to starvation from that due to vitamin D.

337 Evans and Bishop: Science, 55, 650 (1922); J. Metabolic Research, 3, 233 (1923).

impairment of the reproductive process in rats unless it includes a fertility factor, which they called factor X, present in certain natural foods. This ingredient has since been assigned the name vitamin E, or the antisterility, reproductive, or fertility vitamin. These terms attach unwarranted nutritional importance to the vitamin, since its role in the reproductive processes of man and many other animals is doubtful and, at any rate, not exclusive. In fact, the most common symptom of vitamin E deficiency is muscular dystrophy³³⁸ which has been noted in rats, rabbits, guinea pigs, and other species. One form of vitamin E, α-tocopherol, was isolated in 1936, by Evans, Emerson and Emerson, and the structure elucidated in 1938 by Fernholz. In the same year the vitamin was synthesized by Karrer, Fritzsche, Ringier, and Salomon and by Smith, Ungnade, and Prichard. Though vitamin E has been studied extensively for a quarter of a century, its role and importance in human nutrition have not yet been established.

Physiological and Clinical Aspects of Vitamin E. Vitamin E is essential for normal reproduction in rats, the two sexes being affected differently. In the male, the germinal epithelium of the testes is destroyed at the onset of sexual maturity, causing irreversible loss of reproductive power. In the female, normal ovulation and fertilization take place, but fetal development is retarded at about the eighth day, and death and resorption of the fetuses occur between the twelfth and twentieth days of gestation. The capacity for normal reproduction in females can be restored, however, by correcting the vitamin E deficiency in the diet, even if this is done as late as the tenth day of pregnancy.

An excess of vitamin E in the diet does not improve fertility beyond normal limits. The vitamin is essential for normal reproduction in certain other species. Testicular degeneration occurs in the chick subsisting on diets treated with ferric chloride to destroy the vitamin E. Similar observations have been made in the male guppy fish and in the guinea pig. However, therapeutic use of the vitamin in habitual and threatened abortion in humans has produced little evidence of the efficacy of the treatment. The vitamin is so widely distributed in foods that dietary deficiency is very unlikely, except possibly in cases where there is impaired absorption. The early enthusiastic therapeutic use of vitamin E in treating sterility and abortion in veterinary and clinical medicine has diminished considerably.

The most common lesion of vitamin E deficiency is the necrosis of striated musculature noted in many vertebrates. In many species it is the only lesion demonstrated, although various species differ in the ease of production of the lesion in the absence of vitamin E and in their response to treatment with the vitamin. The syndrome consists of a hyaline degeneration characterized by disappearance of striation, multiplication and irregular distribution of sarcolemma nuclei, and swelling of the sarcoplasm. The lesion occurs in irregularly scattered fibers. It may be attended by edema and inflammation of interstitial connective tissues and calcification

²²⁸ Evans and Burr: J. Biol. Chem., 76, 273 (1928); Goettsch and Pappenheimer: J. Exptl. Med., 54, 145 (1931).

of necrotic muscle fibers. Atrophy and replacement by connective tissue occur as well as repair from unaffected parts of the sarcolemma.

Whereas vitamin E deficiency results in irreversible structural changes in many animal tissues, administration of the vitamin may restore their function. In some species smooth muscles are affected, e.g., by necrosis of the uterus and seminal vesicles in the adult rat and of the gizzard of the gosling. Lesions of the vascular system have also been observed, including hemorrhage in the rat fetus and chick embryo, and edema, exudative diathesis, and encephalomalacia in the chick. Exudative diathesis is characterized by localized areas of plasmalike fluid in the subcutaneous, muscle, adipose, and connective tissues. Symptoms of encephalomalacia are ataxia, head retraction, prostration, local edema, small hemorrhages, capillary thrombosis, necrosis of neural elements, and degeneration of the cerebellum. Where muscle damage occurs in vitamin E deficiency, the course of the disease and the effect of vitamin E therapy may be studied by measurement of the urinary excretion of creatine. Creatinuria occurs as a sign of muscle damage. Vitamin E is important in the oxidative processes in muscle cells.

There is evidence that vitamin E possesses a form of growth accelerating activity which becomes evident after the attainment of maturity, when the rate of growth is usually very slow. 339 Other dietary factors, especially fats, affect the occurrence of vitamin E deficiency symptoms. In the chick, exudative diathesis and encephalomalacia occur only when the vitamin E-deficient diet includes fats containing highly unsaturated fatty acids. Vitamin E is related to the mobilization of body fats. In the rat a deficiency of tocopherols results in an increase in brain and muscle cholesterol. When vitamin E or lipocaic is included in the diet of vitamin E-deficient chicks, the concentration of phospholipids in the blood increases. It is inferred that the deficient chick lacks an active principle of lipocaic and requires vitamin E for its formation.

Numerous early reports relating vitamin E to the proper function of endocrine glands and to the prevention of nerve lesions have been largely disproved. The clinical use of the vitamin for treating amyotrophic lateral sclerosis and other chronic degenerations of the nervous system in man has been unsuccessful. Some favorable results have been claimed for vitamin E in preventing sterility or abortion in humans. These experiments, however, have been meager or uncontrolled. Human muscular dystrophy and creatinuria are not influenced by tocopherol therapy. Only one disease in man, primary fibrositis, responds to treatment with vitamin E. The symptoms are aching limbs, fibrillar nodules on the arms and legs in the region of the joints, and frequently creatinuria. The deficiency has been treated successfully with many different vitamin E preparations. For this syndrome, γ -tocopherol is as effective as α -tocopherol.

Because of the presence of a phenolic hydroxyl group in the molecule, vitamin E is a powerful antioxidant for fats. This stabilization may be increased many fold by the simultaneous presence of other compounds, most of them also antioxidants. Ascorbic, phosphoric or pyruvic acid,

^{***} Evans: J. Nutrition, 1, 23 (1928); Emerson and Evans, J. Nutrition, 14, 169 (1937)

phospholipids, and phenols like tannin or gallic acid are synergistic with vitamin E. The antioxidant properties of the vitamin are probably responsible for its sparing action on vitamin A and carotene. The latter have a greater effect in curing their deficiency symptoms in rats when tocopherol is fed simultaneously. This effect is most pronounced at low levels of vitamin A dosage. High doses of ascorbic acid, another antioxidant, also enhance the biological activity of vitamin A. These effects are probably due to the stabilization of the vitamin during its passage through the gastrointestinal tract rather than after absorption. The relationship of vitamin E to the endocrine system, if any, may be due to a hormone-sparing action of the antioxidant.

The antisterility potency of vitamin E in rats varies with the different forms of the vitamin. α -Tocopherol is twice as effective as β -, and four times as effective as the γ -form. These relationships, however, do not hold with respect to their relative potencies for preventing other symptoms, and their efficiency in other species. The relative biological potency of the d- and l-forms has not been established. Reports of the greater biological potency of the esters are probably due to their greater stability in the gastrointestinal tract.

Certain synthetic molecules have been prepared which are only slightly related to the tocopherols but have vitamin E activity. The biological activity of α -tocopherol is reduced by shortening the side-chain, by altering the number and position of the methyl groups in the aromatic ring, by substitution of ethyl for methyl in that ring, by removal of the phenolic hydroxyl group, or by masking the latter as the ether or allophanate. However, conversion of the hydroxyl to an amino group or coupling it in other ester linkages has no effect on the biological potency. α -Tocopheryl quinone, produced by mild oxidation of α -tocopherol, has no biological activity in rats and guinea pigs. This finding is contrary to the hypothesis that vitamin E acts biologically by participation in some oxidative enzyme system by virtue of an oxidation-reduction equilibrium between the quinone and tocopherol forms.

The administration of vitamin E in large doses to man results in an increase in the concentration of the vitamin in the serum where approximately one-half is found as the quinone. When rats are fed tocopherol they excrete much in the feces and none in the urine.

Storage of Vitamin E. When rats, reared on a normal diet, are deprived of vitamin E, three or four months elapse before they become sterile. The tissues of newborn rats possess antisterility properties, thus indicating that the vitamin may be transferred from the mother to the fetus. In the rat, vitamin E is stored chiefly in the heart, lungs, muscles, or fatty tissues under normal conditions. At very high levels of intake, the vitamin is stored chiefly in the liver.

Distribution of Vitamin E. The widespread distribution of vitamin E in nature provides adequate assurance against the possibility of a deficiency of this vitamin in the human dietary. As far as is known, the richest

²⁴⁰ Mattill, Carman, and Clayton: J. Biol. Chem., 16, 729 (1924); Evans: Proc. Natl. Acad. Sci., 11, 334 (1925); Mason: Proc. Natl. Acad. Sci., 11, 377 (1925).

natural source of this vitamin is wheat germ oil. Cereal grains, green leaves, legumes, and nuts are good plant sources of vitamin E. It occurs also in most organs of the animal body in greater or less degree though, quite remarkably, it is less abundant in most visceral organs than in muscular and adipose tissue. The testes do not contain appreciable amounts in spite of the need for vitamin E in spermatogenesis. Vitamin E is present in cottonseed, soybean, and corn oils, but is absent from coconut, sesame, olive, and linseed oils. It is also absent from orange juice, yeast, and most samples of codliver oil, though it is found in tuna and shark liver oils. That milk is not a good source of vitamin E is shown by the fact that 9 per cent of butterfat added to a vitamin E-free diet failed to prevent sterility. Milk from cows on fresh alfalfa pasturage contains a slightly higher vitamin E content.

In seed oils vitamin E occurs in the free form, not as esters. The proportions of the α -, β -, and γ - forms vary with different plants. Lettuce contains only α -tocopherol. California wheat germ oil contains twice as much α as β and only traces of γ -tocopherol, whereas the European oil contains much more of the β form. Cottonseed and corn oils contain γ -tocopherol almost exclusively.

Chemistry of Vitamin E. Vitamin E is classified among the fatsoluble vitamins, since it is soluble in ethyl and methyl alcohol, acetone and the usual fat solvents and insoluble in water. The vitamin occurs in nature in three forms, α -, β -, and γ -tocopherol. α -Tocopherol is $C_{29}H_{50}O_2$, having the structural formula shown below. The β and γ forms differ from

 α -tocopherol in that they lack one methyl group in the aromatic nucleus, in the 7 and 5 positions, respectively. The three forms have been isolated from plant material by procedures which include extraction with fat solvents, saponification, solvent partition, precipitation of sterols with digitonin, chromatographic separation, high vacuum distillation, and isolation of ester derivatives. High vacuum distillation is now used in the large-scale isolation of vitamin E from natural sources. Most preparations of the free alcohols are viscous oils, though α - and γ -tocopherols have been obtained as crystals. The three forms may be separated by fractional crystallization of the esters or by differential adsorption.

 α -, β -, and γ -tocopherols exhibit characteristic absorption spectra in the ultraviolet region, having absorption maxima at 292, 297, and 300 m μ respectively. The $E_{1cm}^{1\%}$ values at these wavelengths are 74.7, 85.1, and 89.2, respectively. The esters, too, show characteristic absorption curves, those of the acetate being shifted approximately 10 m μ lower in the spectrum. The extinction coefficients of the esters are considerably lower

than those of the free alcohols. Though fairly stable to visible light, the tocopherols are sensitive to ultraviolet light. Exposure of wheat germ oil to a quartz mercury lamp for 45 minutes produces partial destruction of the vitamin E content. In the absence of oxygen, the tocopherols are stable at 200° C. They may be heated to 100° C. in strong sulfuric acid or hydrochloric acid. They are destroyed very slowly by alkalis, so that care must be exercised during the saponification steps in the chemical analysis for vitamin E. The tocopherols are easily oxidized to tocopheryl-quinones which lack biological activity.

The tocopherols are powerful antioxidants and behave as natural stabilizers of vegetable fats. They are also effective stabilizers when added to animal fats or unsaturated fatty acids. The development of rancidity in fats which is an index of oxidation is accompanied by a considerable loss of vitamin E content. The tocopherols are decreasingly effective as antioxidants in the order γ , β , α ; their vitamin E activity for many species, however, is in the decreasing order α , β , γ .

Determination of Vitamin E. Chemical methods for the determination of the tocopherols are based upon the oxidation of the vitamin. In general, these methods suffer from several defects. They cannot distinguish between the α -, β -, and γ -forms which have different biological activity, but their greatest drawback is that they lack specificity. Tocopherylquinone, and compounds unrelated to vitamin E, such as the carotenoids or other reducing agents, frequently interfere. Most of the tests require high concentrations of the vitamin so that large amounts of interfering materials may be present in the final test extracts.

Vitamin E may be determined spectroscopically in pure systems by measurement of the extinction coefficients at the absorption maxima in the ultraviolet region of the spectrum. In natural materials, carotenoids and other absorbing materials interfere. Another method involves spectroscopic measurement of the products formed after oxidation with alcoholic silver nitrate. Colorimetric measurement of the red pigment formed by oxidation with alcoholic nitric acid has been employed, though tocopherylquinone gives the same reaction. One method involves measurement of the red color produced when ferrous ion reacts with α, α' -dipyridy], the former being obtained in the quantitative oxidation of tocopherol by ferric chloride. Many reducing compounds interfere with this test. Greater specificity may be obtained by conducting the determination on the unsaponifiable fraction of the sample, or by destroying interfering materials with 85 per cent sulfuric acid, or by removing them by adsorption on activated clay. Correction for the blank reduction can be made by subtracting the red color produced after acetylation of the extract. One oxidation-reduction method which distinguishes between the tocopherols and their quinone derivatives involves the reaction with 2,6-dichlorophenol indophenol in an organic solvent. The quinone forms may be determined by this procedure by preliminary reduction with hydrogen in the presence of a Raney nickel catalyst. Another chemical method for the determination of vitamin E involves electrometric titration with gold chloride. Reducing substances and carotenoids interfere with this test.

In general, the analytical methods are not applicable to foods and show variable specificity even when applied to concentrates.

A satisfactory biological assay for the determination of vitamin E is based on measurement of the prevention of fetal resorption in female rats.

Chemical Determination of Vitamin E: Modified Colorimetric Method of Emmerie and Engel:³⁴¹ Principle. Tocopherol is isolated from natural materials by saponification followed by ether extraction. The vitamin is then allowed to reduce ferric chloride and the reduction product, ferrous ion, is determined colorimetrically after reaction with α, α' -dipyridyl.

Procedure: Saponify a sample containing not more than 200 y of tocopherol by refluxing with 2 N methanolic potassium hydroxide on a boiling water bath for 30 minutes under an atmosphere of nitrogen. Use 10 ml. of potassium hydroxide solution for each gram of sample, but never less than 20 ml. Transfer the mixture to a separatory funnel. Add 2.5 ml. of 95 per cent ethyl alcohol to each 10 ml. of methanol, plus a volume of water equal to that of the methanol. Extract the mixture four times with 50-ml. portions of freshly distilled ether. (If a large weight of solid material has been saponified, decant the methanolic potassium hydroxide into the separatory funnel, and wash the residue in the flask several times with ether, using these ether washings for the first extraction.) Wash the combined ether extracts with 50-ml. portions of water until the last washing gives no color with phenolphthalein. Dry the ether solution with anhydrous sodium sulfate and evaporate to dryness on a steam bath under nitrogen. Dissolve the residue in 1 ml. of a 0.2 per cent solution of ferric chloride in ethyl alcohol. Then add 1 ml. of a 0.5 per cent solution of α, α' -dipyridyl in ethyl alcohol. Dilute the reaction mixture with 10 ml. of ethanol and 10 ml. of benzene. Measure the red color in a photoelectric colorimeter with a 520-mu filter exactly 2 minutes after adding the ferric chloride solution to the sample. Prepare a calibration curve by conducting the entire test on standard solutions of dl-α-tocopherol acetate in the following quantities: 0, 25, 50, 75, 100, 150, and 200 y. Plot the photometric densities as the ordinates, and amounts of di-a-tocopherol acetate as the abscissae on ordinary graph paper.

Calculation. Calculate the vitamin E content of the sample using the formula

$$\frac{C}{G} \times 0.911 = \gamma$$
 of tocopherol per gram of sample,

where C is the amount of tocopherol (expressed as the acetate) in the extract as estimated from the standard curve, G is the weight of the sample taken, expressed in grams, and 0.911 is the factor for converting the acetate to the free phenol.

Since tocopherol is not stable when heated in alkali and is readily susceptible to oxidation, the saponification should be conducted exactly as described, since under these conditions no loss of vitamin E occurs. Water-soluble reducing materials which would interfere with the colorimetric reaction are discarded during the ether extraction. However, carotenoids, if present in the original sample, appear in the final extract

³⁴¹ Emmerie and Engel: Rec. trav. chim., 57, 1351 (1938); Z. f. Vitaminforsch., 13, 259 (1943). Grandel and Heumann, Z. Untersuch. Lebensm., 79, 57 (1940).

and reduce ferric chloride. These may be removed from the extract by adsorption on a column of an activated clay.

BIOLOGICAL ASSAY FOR VITAMIN E

Introduction. Since methods for the chemical determination of vitamin E are not sufficiently specific to be applicable generally to a wide variety of natural materials, biological procedures based on the prevention of resorption gestation continue to fulfill a useful function. The basic principle employed in most bioassays for this vitamin involves the determination of the doses of test material and of a tocopherol standard required to insure fertility in female rats reared on a vitamin E-deficient ration. Numerous refinements and modifications of the procedure have been proposed with the view toward increasing its precision and accuracy. For example, in order to reduce the incidence of "first litter fertility," due to storage of vitamin E during the lactation or pre-depletion period, Mason and Bryan³⁴² recommend replacing the breeder ration of the mother rat with the vitamin E-free diet during the latter stages of lactation, thus limiting storage in the sucklings to that resulting from placental and mammary transfer.

The time and duration of dosage in relation to the gestation period, the advantages as test animals of virgin rats as compared with rats in which resorption gestation has been established, and the criteria for measuring the response are among the many factors that have been investigated in the vitamin E assay. Some investigators have recommended the presence of rancid fat or ferric chloride in the basal diet to insure the destruction of traces of vitamin E. This can be avoided, however, if proper precautions are taken.

The availability of the International (U.S.P.) reference standard of dl- α -tocopheryl acetate makes it possible not only to use this material as the control but to express the results of bioassays in gravimetric units.

Bioassay of Vitamin E: Method of Emerson and Evans³⁴³ (Modified): Principle. The reproductive response of female rats reared on a vitamin E-free diet, to graded doses of test material is compared with that of control litter mates receiving graded doses of the reference standard tocopherol.

Procedure: In order to deprive the litters of access to a source of vitamin E, the normal ration in the breeder cages is replaced by the following vitamin E-deficient diet when the litters are 16 days of age:

Extracted casein	24
Sucrose	62
Brewers' yeast	10
Salt mixture	4

Litter mate sisters are segregated at weaning and continue to receive this diet ad libitum plus the following daily supplement:

β-Carotene	80 γ
Calciferol	0.3γ
Peanut oil	250 v

Mason and Bryan: Biochem. J., 32, 1785 (1935); J. Nutrition, 20, 501 (1940).
 Emerson and Evans: J. Nutrition, 27, 469 (1944).

Virgin rats and rats of proved sterility (having gone through a resorption gestation) serve equally well as test animals, but the latter are preferable because they serve as their own controls. Inasmuch as the specific type of sterility resulting from deficit of vitamin E is characterized by successful copulation and fertilization, it is desirable to confirm the occurrence of these events. Vaginal smears may be examined beginning at 60 days and at the next pro-estrus period the females on the deficient diet are mated with normal, healthy males of known fertility. The stages of the estrus cycle of the rat may be recognized by the following vaginal changes (Long and Evans).³⁴⁴

Stage	age Duration Vaginal Changes		Remarks	
I	12 hrs.	Mucosa slightly dry. Lips a little swollen.	No heat toward end. Copulation may occur	
II	12 hrs.	Smear: Epithelial cells only Mucosa dry and lusterless. Lips swollen.	In heat. Copulation may occur	
111	15-18 hrs.	Smear: Cornified cells only As in Stage II. Cornified material abundant (cheesy)	Not in heat. Ovulation.	
IV	6 hrs.	Mucosa slightly moist. Swelling of lips gone. Smear: Cornified cells and leukocytes	Copulation uncommon	
V	57 hrs.	Mucosa moist, glistening. Smear: Leukocytes and epithelial cells. Mucus		

(It is of interest to note that when fed a vitamin E-deficient diet, male rats develop a gradually decreasing sex interest, the spermatozoa lose their motility, and testicular degeneration is evident at autopsy. While the gross weight of the testes is not an infallible index of fertility, it has been shown that 70 per cent of the normal represents a fair minimum weight compatible with normal function.³⁴⁵)

Impregnation is indicated by the presence of spermatozoa in the smear and the appearance of the vaginal plug (bouchon vaginale), and pregnancy may be definitely diagnosed by the placental or erythrocyte sign—i.e., the appearance of erythrocytes in the vaginal canal on the twelfth to fourteenth day after impregnation. Daily records of body weight are kept throughout the gestation period. The first, or preliminary gestation, which culminates in a typical resorption, is followed by a rest period until the estrus cycle returns.

Mating is then repeated, and on the first day of the next gestation or test period the pregnant females are assigned to groups of eight or more. The doses of assay material and standard dl- α -tocopheryl acetate are fed orally on the first five days of the gestation period. The standard is dissolved in vitamin E-free olive oil so that the daily dose is contained in 0.1 ml. The minimum dose of α -tocopheryl acetate required to insure fertility lies between 1.8 and 2.7 mg.; 1.0 mg. will prevent resorption in about half of a group of reasonable size.

³⁴⁴ Long and Evans: The estrus cycle in the rat and its associated phenomena, Memoirs of the Univ. of Calif., 6 (1922).

weight of the testis at different ages is given by Donaldson: "The Rat," 2d ed., Philadelphia. Wistar Institute of Anatomy and Biology, 1924.

The record of observations should include the number of rats per group, the number of implantations, the number of resorptions, the per cent of implantations resulting in litters (i.e., the per cent fertility), the number of litters with living young at birth, the number of litters with dead young, and the average number of living young per litter and their average weight.

It is important to inspect the uterus during or immediately after an assay pregnancy in order not to misinterpret as a negative response to dose the not infrequent instances of pseudopregnancy with uterine bleeding which can be confused with resorption. The changes in body weight during gestation should also be noted as an index of resorption gestation.

Calculation. The relation between total (five day) dose at each level of the standard and the per cent fertility can be plotted as a reference curve from which the vitamin E potency of the assay doses may be interpolated. Bacharach³⁴⁶ has reported an equation calculated for the regression line representing the dose-response curve for tocopherol as observed in his own laboratory.

VITAMIN K

In the late 1920's, Dam³⁴⁷ observed a hemorrhagic syndrome in chicks, raised on a diet low in lipids, which failed to respond to rich sources of the known vitamins. The disease is associated with a reduction in clotting power of the blood, hemorrhages occurring especially in regions exposed to trauma. In 1935, Dam advanced the claim that this syndrome was due to deficiency of a new fat-soluble vitamin in green leaves, which he called vitamin K (for Koagulations). Almquist and Stokstad³⁴⁸ independently announced a similar claim for a factor present in putrefied fish meal. In 1939, the pure vitamin was isolated from alfalfa by Dam and others³⁴⁹ and from both alfalfa and putrefied fish by MacCorquodale, Binkley, McKee, Thayer and Doisy. 350 Physical and chemical differences in the vitamins thus isolated led to the designation K₁ for the vitamin from green leaves and K₂ for that formed by bacterial putrefaction. Investigation of the vitamin K molecule has revealed the presence of a quinoid ring structure, 2-methyl-1,4-naphthoquinone, which alone or substituted in various ways possesses all or part of the physiological activity of the vitamin; thus vitamin K has various natural and synthetic vitamers.

Physiological and Clinical Aspects of Vitamin K. The specific type of hemorrhagic diathesis observed in vitamin K deficiency is due to a lowering of the prothrombin level of the plasma. (For the role of prothrombin in the coagulation of blood, see p. 430.) Hypoprothrombinemia may, however, result from other causes such as cirrhosis, chloroform poisoning, or Banti's disease, where liver tissue is damaged. Vitamin K is without value in hemophilia, a condition due to a deficiency of thromboplastin, hence failure of conversion of prothrombin to thrombin. Vitamin K does not alter the clotting time of hypoprothrombinemic blood

when added in vitro; its probable function in the body is to facilitate the synthesis of prothrombin through some intracellular enzyme system, possibly in the liver.

Chicks, ducklings, and other birds fed a vitamin K-deficient diet develop severe hemorrhagic lesions both internally and subcutaneously, especially under the wings, on the legs, breast, abdomen, neck, and in the intestinal tract. The concomitant anemia terminates in death. In the rat, bacterial synthesis of vitamin K_2 in the intestine, especially when coprophagy is possible, often prevents the characteristic sequelae of a vitamin K-free diet.

Simple dietary deficiency of vitamin K is rare, not merely because of the presence of the vitamin in foods, but because intestinal microörganisms, especially of the *coli* group, synthesize the vitamin which is released upon putrefactive disintegration of the bacterial cells. K-avitaminosis in humans is more often associated with impaired absorption of fat (and concomitantly of vitamin K) such as is seen in obstructive jaundice and biliary fistulas as well as in intestinal disorders like celiac disease and ulcerative colitis. In these conditions, or after removal of biliary obstructions, vitamin K is administered parenterally or orally to prevent or relieve the bleeding tendency. When the flow of bile is obstructed, oral dosage of vitamin K must be accompanied by bile salts to insure its absorption; this may be avoided by the use of water-soluble derivatives of the vitamin.

The most common form of vitamin K deficiency is seen in newborn infants, so-called hemorrhagica neonatorum. The blood prothrombin level is low at birth; it decreases further during the first few days, rises sharply and then gradually until a normal level is reached between one and two months of age. Whether the initial hypoprothrombinemia is due to poor placental transfer has not been established. It is significant that milk, both human and cow, is a very poor source of vitamin K. The rise in prothrombin after birth is attributed to bacterial decomposition in the intestine. Administration of vitamin K to the mother before parturition results in slightly higher blood prothrombin levels at birth, but direct dosage of the infant with as little as one microgram of the vitamin has been claimed to be effective.

The minimum daily requirement of vitamin K has not been established. The extremely low prophylactic dose for the infant, and subsequent synthesis in the intestine, indicate that the dietary requirement, if any, is small. One to 2 mg. of the vitamin is capable of correcting most deficiencies, although the therapeutic dose may vary with the severity of the hepatic or intestinal condition. For further discussion of clinical aspects, see p. 1186.

Storage and Distribution of Vitamin K. With the possible exception of the liver, the organs and tissues of the body do not store vitamin K to any significant degree. In the hen, even when the ration is rich in this vitamin, only small concentrations are found in the various organs. Vitamin K is not found in the urine; the high concentration in the feces is due largely to intestinal synthesis.

Occurrence of Vitamin K. The principal natural source of vitamin K is the green leaf or other chlorophyll-containing portions of plants; this form of the vitamin (K₁) has therefore been named *phylloquinone*. The vitamin is present in high concentration in spinach and alfalfa, while cabbage, cauliflower, seaweed and carrot-tops are good sources. Most seeds, fruits, and roots (including cereals, beans, potatoes, peas) contain little, if any, vitamin K, although soybean oil, tomatoes, orange peel, and hemp seed are good sources. Milk and eggs are poor sources of vitamin K even when the ration of the cow or hen contains a high level of the vitamin.

Chemistry of Vitamin K. Recognition of the quinoid structure of vitamins K_1 and K_2 was due to the work of McKee, et al. ³⁵¹ at Washington University, St. Louis, and of Karrer and Geiger. ³⁵² The former group established that these vitamins were derivatives of 2-methyl-1, 4-naphthoquinone with substituent groups in the 3-position, K_1 containing the phytyl group and K_2 a similar but longer side chain.

Vitamin K_1 is a light yellow, viscid oil, whereas K_2 is a yellow crystalline solid (melting point 54°). Both are soluble in oil and various fat solvents. The vitamins are sensitive to light and, as would be expected from their quinoid structure, are destroyed by saponification. Vitamins K_1 and K_2 are characterized by ultraviolet absorption maxima at wavelengths of 243, 248, 261, 270, and 328 m μ . The quinoid ring common to these compounds is responsible for their physiological activity. This is shown by the fact that the synthetic compound 2-methyl-1,4-naphthoquinone, to which the name menadione has been given, is equally active on a molar basis as the natural vitamers. Menadione has a molecular weight of 172

McKee, Binkley, MacCorquodale, Thayer, and Doisy: J. Am. Chem. Soc., 61, 1295 (1939).
 Karrer and Geiger: Helv. Chim. Acta, 22, 945 (1939).

Menadione (C₁₁H₈O₂) 2-methyl-1,4-naphthoquinone

whereas the molecular weights of K₁ and K₂ are 450 and 580 respectively. Menadione is a yellow, crystalline compound (melting point 106°), slightly soluble in water and soluble in alcohol, ether, acetone, and glacial acetic acid and in vegetable oils. It is light-sensitive and, in common with other quinones, has a burning taste and is irritating to mucous membranes. The long substituent side chains of the natural vitamins diminish their solubility in water and, at the same time, their taste.

Many active derivatives and homologs of menadione or the natural vitamins have been prepared but always with a diminution or loss of biological potency. Phthiocol (2-methyl-3-hydroxy-1,4-naphthoquinone), a constituent of the tubercle bacillus, was early recognized to have slight vitamin K activity. Substitution of the 2-methyl group by hydrogen or various alkyl radicals results in marked loss of activity. Substitution in the 3 position does not cause a serious drop in potency, although a double bond in the position shown for the phytyl group in vitamin K_1 and a long branched side chain are essential.

The hydroquinones of vitamins K_1 and K_2 or of menadione may be converted into diacetates, diphosphates, disulfates, etc., which possess lower activity than the corresponding quinones but are less irritating to the mucosa of the mouth and gastrointestinal tract. Nevertheless, certain of these derivatives which, unlike natural vitamin K, are water-soluble and more stable to light and air, have been employed clinically. Important among these is menadione sodium bisulfite, a white crystalline powder containing 49 per cent menadione.

Determination of Vitamin K. Physical or chemical procedures for the estimation of vitamin K activity are complicated by the presence of interfering substances (including vitamins A and E), the different forms in which vitamin K occurs in nature, and their susceptibility to destruction by light, heat, and air, especially during the saponification and extraction steps. The method of Scudi and Buhs³⁵³ involving reduction of the quinones by catalytic hydrogenation, and subsequent reaction of the hydroquinones with 2,6-dichlorophenol indophenol, appears to offer the best approach to the determination of vitamin K in extracts of natural materials. The extent of the reaction is measured in a photoelectric colorimeter. The use of hydrosulfite has been recommended to avoid destruction of the vitamin during saponification.

BIOLOGICAL ASSAY FOR VITAMIN K

Method of Almquist:³⁵⁴ Principle. The assay is based on the relative doses of assay material and of standard menadione required to restore the prothrombin clotting time of the blood of vitamin K-depleted chicks.

Procedure: One- or two-day-old chicks are placed in heated (90° to 95° F.) battery brooders with wire-mesh floors. To prevent consumption of vitamin K from bacterial synthesis, food and water should be provided through apertures outside the cage, and moist or soiled food should be discarded. The following ration is fed ad libitum:

Sardine meal (ether extracted)	17.5
Dried brewers' yeast (ether extracted)	7.5
Ground polished rice	72.5
Codliver oil	1.0
Calcium carbonate	0.5
Manganous sulfate	0.005

After 10 to 14 days, when the clotting time of the blood of 5 per cent of the chicks is 15 minutes or more, divide them into groups of 12. (Determine clotting time as follows: Withdraw a few drops of blood from clean cut of exposed wing vein. Place in small vials and shake in water bath at 38.5° to 39° C. Time from withdrawal of blood to formation of a firm clot.)

Maintain one group on basal ration as negative controls, at least two groups on different dosages of U.S.P. menadione, and at least one on each product to be assayed. Administer doses orally in 0.1 ml. of water or ethyl laurate, depending on solubility. Open mouth of chick by applying pressure at the corners so that the dose may be given with a tuberculin syringe (fitted with a blunt-edged needle) well down in the throat. Do not permit access to food or water for one-half hour after dosage. Repeat dosage for four days at 24-hour intervals.

Determine prothrombin clotting time on all chicks 24 hours after administration of last dose, as follows: Place 0.2 ml. of 0.1 M sodium oxalate in short, narrow tubes graduated at 2 ml. Introduce 2 ml. of blood from each chick into a tube. (Blood may be obtained by decapitation with scissors and directing flow into tube with fingers.) Shake thoroughly. Pipet 0.1-ml. portions into small flat-bottomed vials (15 \times 50 mm.). Add 0.2 ml. of clotting agent 356 and start timing with stopwatch. Place vials in thermostatically controlled water bath at 38.5° to 39° C. so that they are tilted at an angle of 45° in a device to permit moving them to a vertical position once per second. When gelatinous film (clot) covers bottom of vial, stop watch and record "prothrombin time." Duplicate test on each blood sample until results agree within 2 seconds.

Calculation. Plot the mean prothrombin time (M.P.T.) against log micrograms of menadione for reference groups and draw best-fitting straight line. Interpolate equivalent dosage of assay material. (One γ menadione = 1 A.O.A.C. unit of vitamin K activity.)

³⁶⁴ Almquist: J. Assoc. Off. Agr. ('hem., 24, 405 (1941); also "Methods of Analysis of the A.O.A.C.," 6th ed., Washington, D.C., 1945.

²⁶⁶ Preparation of Clotting Agent: Maintain 4 or 5 chicks on a practical ration containing at least 5 per cent dried alfalfa. (Avoid contamination of vitamin K-deficient ration.) Kill one bird by bleeding. Excise 10 g. of breast muscle and grind with sand and 10 ml. of 0.85 per cent NaCl. Centrifuge and filter through coarse paper. Store in refrigerator no more than a few days. Dilute to 200 ml. with 0.85 per cent NaCl and mix with 200 ml. of 0.025 M CaCl₂. This clotting agent should clot blood of normal chicks in 20 to 30 seconds. If it does not, modify concentration until prothrombin time falls within this range.

THE PHYSIOLOGICAL AVAILABILITY OF THE VITAMINS

The vitamin content of a food, or of the diet as a whole, as determined by chemical or microbiological assay, may not constitute a reliable indication of the actual amount of utilizable vitamin consumed. Failure of foods to be completely disintegrated, digested, and absorbed from the intestinal tract. in vivo destruction due to oxidation or incompatibilities among the dietary constituents, abnormal pH conditions due to gastric hypoacidity or the use of antacids, are among the many factors which influence the potential vitamin content which is physiologically available for absorption. Vitamins often exist in nature in firm union with protein or other compounds, necessitating hydrolysis prior to chemical or microbiological assay which may be of a nature not duplicated in the gastrointestinal tract. Animal assays are a better measure of physiologically available vitamins, although they do not always duplicate conditions in man. For example, assay materials sometimes have to be subdivided or dissolved in order to feed the small doses required by animals; moreover, the purified basal rations deviate considerably from the diet of man.

These factors emphasize the desirability of a human assay technique for determining physiologically available vitamins in foods and other sources and for determining the effect of various conditions which influence their availability. A highly reproducible procedure developed by Melnick. Hochberg, and Oser, 356 is based on the fact that normal human subjects subsisting on a complete diet excrete the water-soluble vitamins in the urine in direct proportion to the quantity consumed above the adequate basal level. These vitamins may be excreted either unchanged or as derivatives. The linear relationship of excretion to dosage is established for a group of experimental subjects by feeding the vitamins in pure solution, the form in which they are most completely available. Fig. 313 illustrates a series of such urinary excretion studies for thiamine, riboflavin, niacinamide, and ascorbic acid. To determine the physiologically available vitamin content of an unknown material, the experiment is repeated, feeding an amount of the test food furnishing (according to chemical or microbiological analysis) a critical dose of the vitamin in question. The relation between the extra urinary excretion of the vitamin in the test dose and in the pure solution constitutes the index of physiological availability. For example if, under the test conditions, threequarters as much extra thiamine (i.e., above the basal excretion level) is found in the 24-hour urine following the ingestion of a given food as was excreted following the ingestion of an equivalent amount of thiamine in the form of the pure solution, the physiological availability of the thiamine in the test food is said to be 75 per cent.

The illustrations of the application of this technique which follow are taken from the work of Melnick, Hochberg, and Oser. 366 The method may be applied only to those vitamins normally excreted via the urinary tract which, of course, excludes the fat-soluble vitamins.

Any suitable method may be employed for the analysis of the urine sam-

⁸⁸⁶ Melnick, Hochberg, and Oser: J. Nutrition, 30, 67 (1945).

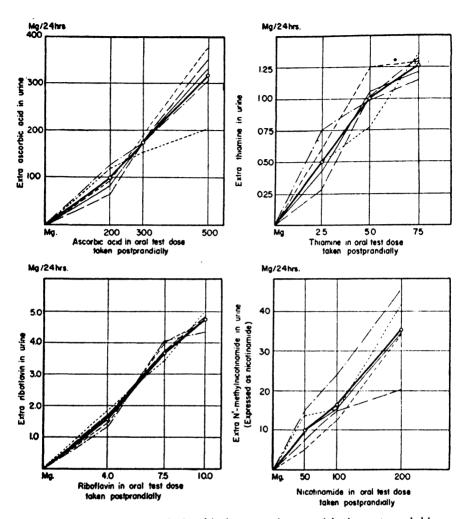

Fig. 313. The linear relationship between dosage with the water-soluble vitamins ascorbic acid, thiamine, riboflavin, and nicotinamide, and the extra urinary excretion of the vitamins (or derivative). The test doses in aqueous solution (pH 3.0) were taken orally immediately after dinner. The fine lines represent the responses of the individual subjects whereas the heavy line indicates the average responses.

ples. It is worth noting that thiamine is excreted in the urine as the free, unphosphorylated vitamin; ascorbic acid is largely, but not entirely, in the reduced state so that reduction of the dehydro form is necessary; nicotinic acid is excreted principally as the metabolite N¹-methylnicotinamide.

Determinations of the physiological availability of the vitamins employing this procedure have been reported for pharmaceutical tablets in which the vitamin ingredients are protectively coated to insure their

stability; for the thiamine in live yeast cells; for ascorbic acid as influenced by the presence of copper or ascorbic acid oxidase; for thiamine as influenced by the presence of the antithiamine factor in raw fish such as clams; and for the B vitamins in the presence of adsorbing agents.

Determination of the Physiological Availability of Thiamine in Live Yeast Cakes: Principle. Unless yeast cells are destroyed by autolysis or heat, they give up only a small proportion of their total natural thiamine content in the human gastrointestinal tract. A group of subjects in whom nutritional equilibrium has been established receive, on a control day, 6 mg. of thiamine in pure solution and in divided doses after each meal. After an intervening period has elapsed, the same subjects receive 6 mg. of thiamine (determined by chemical analysis) in the form of live yeast cakes, similarly divided, after meals. The ratio of extra thiamine excretion in the test and control days is the measure of physiological availability of thiamine in the yeast product.

Procedure: A group of five subjects in good nutritional status, but not unduly saturated with respect to thiamine, is assigned for four days to a complete diet (as illustrated in the table above). The dietary schedule is as follows: a basal day followed immediately by a control (standard

¹⁶⁷ Expressed in terms of total food consumed in the three meals.

dose) day; then, after an interval of one to two weeks another basal day followed immediately by a test (assay dose) day. Just before the largest (noonday) meal of each basal day, the urine is voided and discarded. The urine collection is then begun (in a 2-liter brown glass bottle containing 20 ml. of 10 per cent sulfuric acid as a preservative) this marking the beginning of the control (or test) period. On the control day, 2 mg. of thiamine, dissolved in water or milk, are taken after each meal. The 24-hour urine is collected as described above. At least one week (preferably two) should elapse to provide for complete flushing of this control dose, during which no remaining collections are made and the subjects are free to eat adequate diets of their own selection. 358 The basal diet is then resumed and the urine collected for a 24-hour period. On the succeeding (test) day the same diet is consumed, but in place of the thiamine supplement of the control period each meal is supplemented with a suspension of yeast cake in milk or water furnishing the equivalent of 2 mg. of thiamine. (It is necessary, of course, to establish the thiamine content of the yeast under test by actual analysis rather than to assume the quantity stated to be present

Analyses of the 24-hour urine collections made on the basal, control, and test days are performed according to the colorimetric method described on p. 1066.

Calculation. From the thiamine excretion of both the control and test days, subtract that of the preceding basal days. If the absolute increment of thiamine intake is not identical on the control and test days, express the increment in thiamine excretion as percentages of the respective supplementary doses. The extra excretion of thiamine following yeast dosage divided by that following dosage in the form of pure solution, multiplied by 100, gives the percentage physiological availability of the thiamine contained in the yeast.

The experiment may be so extended that each test period is allowed to run for 48 instead of 24 hours. In experiments reported by the authors of this method, 359 this was done in order to eliminate the possibility of a delayed rate of absorption of thiamine from live yeast cells as compared with pure solutions. That this does not occur is illustrated by the data in the table on p. 1185.

Effect of Dietary Thiaminase in Fish Products. 360 ('hastek paralysis, an acute dietary disease of foxes, is caused by including 10 per cent or more of certain species of uncooked fish in the diet and may be cured or prevented by giving adequate amounts of thiamine. 361 Thiamine deficiency has been observed in cats fed a diet consisting exclusively of saltwater herring.362 The enzymic nature of the anti-thiamine factor was suggested by the fact that concentrates possessed protein characteristics and reacted like a typical enzyme toward inhibitor substances. 363 The over-all reaction has been demonstrated to be the hydrolytic cleavage of the vitamin between the pyrimidine and thiazole rings. 364

The anti-thiamine factor has been found in 15 out of 31 species of

<sup>Pork meats and pharmaceutical vitamin preparations especially should be avoided.

 per cent availability (as measured by first 24 hrs.' excretion). $\frac{(0.47+0.31)-2(0.24)}{(1.63+0.56)-2(0.21)} \times 100 = 17.0$ per cent availability (as measured by 48 hrs.' excretion).

fresh-water fish tested,³⁶⁷ in clams,³⁶⁸ in the Atlantic herring, in whiting, and in the Pacific mackerel; oysters are among the fish not containing this factor. In many parts of the world, fish are eaten raw or only slightly heated (e.g., smoked). The following experiment demonstrates the effect of the thiaminase in raw clams in subjects receiving thiamine as a dietary supplement, and the inhibition of this effect by heat-inactivation of the destructive enzyme. This experiment may be performed with certain other edible raw or lightly smoked fish.

Procedure: Whip 100 g, of raw clams in 400 ml, of water in a Waring Blendor. Adjust 100 ml, of this suspension to plł 4.5, and boil under reflux for 20 minutes. Cool and readjust to original pH. Prepare an aqueous thiamine solution containing 250 γ per ml. Set up three 100-ml, centrifuge tubes as follows: (1) 50 ml, of water plus 1 ml, of thiamine solution, (2) 50 ml, of unheated clam suspension plus 1 ml, of thiamine solution, (3) 50 ml, of heated clam suspension plus 1 ml, of thiamine solution.

Store the suspensions for 6 hours at 37° C. with frequent agitation. Centrifuge. To 10 ml. of the clear supernatants, add 10 ml. of phenolalcohol reagent and complete the colorimetric test for thiamine described on p. 1067.

For the *in vivo* availability study, choose five normal subjects with good dietary histories. Feed the basal diet shown on p. 1183, starting at noon, and

³⁰⁵ Taken as three 1.92-mg. doses of thiamine in milk, one after each meal.

³⁶⁶Containing 5.75 mg. of thiamine. Two cakes, containing 1.92 mg., suspended in milk and taken after each meal.

¹⁴⁷ Deutsch and Hasler: Proc. Soc. Exptl. Biol. Med, 53, 63 (1943).

³⁶⁸ Woolley: Personal communication (1943).

collect 24-hour urine samples in 2-liter bottles containing 20 ml. of 10 per cent sulfuric acid. On the second day, just after the midday meal, feed 5 mg. of thiamine in 30 ml. of aqueous solution and collect the second 24-hour samples.

Before starting the test period, allow two weeks to intervene during which the subjects return to their usual, adequate diets. The test period comprises four days. On the first three, feed the subjects the basal diet, but at the end of each meal, add a fresh, raw clam weighing approximately 35 g. (without the shell) which may be swallowed whole. At the beginning of the fourth day (after the midday meal) the subjects ingest 5 mg. of thiamine in 39 ml. of water followed by a clam. Continue the experiment till the end of the fourth day, feeding a clam with each meal as before. Collect 24-hour urine samples on all four days.

Analyze the urine samples for thiamine as described on p. 1066. Note the prompt and marked decrease in basal urinary excretion values when clams are ingested. Note also the effect of the clams on the test dose of the vitamin.

CLINICAL VITAMIN DEFICIENCIES

SYLLABUS OF "STIGMAS, SYMPTOMS AND THERAPY" OF THE COUNCIL ON FOODS AND NUTRITION OF THE AMERICAN MEDICAL ASSOCIATION 369

The stigmas and symptoms associated with deficiency of vitamin A, thiamine, riboflavin, niacin, ascorbic acid, vitamin D and vitamin K are listed in this syllabus together with a statement concerning treatment of each deficiency. Deficiencies of several vitamins, notably biotin, pyridoxine, pantothenic acid, and vitamin E, are not accompanied by stigmas which can be recognized at present.³⁷⁰ The subject is in a stage of fluidity and development which probably will necessitate early revision or amplification. Particularly is this true of the diagnosis and treatment of deficiency of folic acid. This vitamin has been prepared in isolated form so recently that its consideration here is omitted. Not many of the stigmas listed are diagnostic of a vitamin deficiency in themselves, but the occurrence of several of these stigmas in association is at least presumptive evidence of some nutritional failure. Vitamin deficiencies commonly encountered in clinical practice are multiple. Scrutiny of the dietary history is indicated in cases in which several of the stigmas listed are present. Due attention should be paid to the well known fact that stresses such as pregnancy, exposure or disease may occasion the development of deficiency states when the diet otherwise might be considered adequate.

Treatment for a deficiency involves administration orally or, if need be, parenterally of large enough doses of the vitamin to be of therapeutic value and continuation of this treatment for long enough periods to assure a satisfactory therapeutic trial. However, since the diagnosis is necessarily presumptive in many instances, exclusive dependence on specific therapy is justified only infrequently, and basic to good treatment in all cases is a diet planned to be adequate nutritionally and assurance that the diet is eaten. 371 The diet is important for the education of the patient and as a means of dispensing factors heretofore not isolated which will be contained in the foods of such a diet. Likewise helpful in treatment because of its content of factors not as yet identified is some good source of the vitamin B complex as a whole. Products such as brewers' yeast or an extract of such yeast, wheat germ, extracts of cereal grasses or of rice bran, crude extract of liver or desiccated liver represent such sources. For a patient who cannot take foods or drugs orally or in whom absorption is poor, crude liver extract may be given intramuscularly or even on occasion it may be diluted with sterile isotonic solution of sodium chloride or dextrose and administered by vein.

Stigmas Suggesting Deficiency of Vitamin A

Xerosis of the conjunctiva:

Thickening with loss of transparency, so that only the more superficial vessels of the bulbar conjunctiva are clearly seen, associated with more or less yellow pigmentation, especially along the horizontal meridian of the eveball; infrequently associated with small foamlike plaques called Bitot's spots.

Papular cruptions of pilosebaceous follicles:

A grater-like feel, which in arly stages resembles gooseflesh but, when more fully developed, presents the picture of keratosis pilaris. The extensor surfaces of the arms and thighs and the flexor surfaces of the legs are primarily affected.

Xerosis or asteatosis of the skin:

Dryness, scaliness and crinkling, in extreme cases resembling alligator skin. In early stages the condition is associated with keratosis pilaris but it persists and extends after follicles have disappeared, the body hairs being broken and later lost. All parts of the body are involved, but the skin of the extremities, particularly of the legs, is more severely affected than the skin of the head and the trunk.

Follicular conjunctivitis:

Hypertrophy of the follieles, particularly of the lower eyelids.

Night blindness:

Conspicuous only in cases of advanced, severe deficiency.

Keratomalacia:

Thickening with subsequent ulceration and necrosis of the cornea; present only in most severe and advanced forms of deficiency.

Stigmas Suggesting Deficiency of Thiamine

Loss of strength of the quadriceps: disproportionate to loss of general strength, evidenced by difficulty in rising from the squatting position.

Loss of vibration sense: first of the toes and later of the mallcoli and tibias.

Tenderness of the calves and hypercethesia of the feet:

Diminution and loss of the achilles tendon and patellar reflexes first. Other tendon reflexes are lost in the later stages of the polyneuritis of "dry beriberi."

Edema of the shins, ankles and knee joints: found in "wet beriberi."

Enlarged heart with dependent edema and elevated venous pressure: Poor response to rest and administration of digitalis unless thiamine is given. This is a late manifestation of severe deficiency (beriberi heart).

Treatment of Vitamin A Deficiency

Early deficiency state:

25,000 U.S.P. units of vitamin A twice daily for two months or longer.

More chronic states:

25,000 U.S.P. units of vitamin A two to three times daily for a prolonged period.

Treatment of Thiamine Deficiency

Acute deficiency state:

10 to 20 mg, or more of thiamine twice daily until relief of symptoms, this may be days or weeks.

Chronic deficiency state:

5 to 10 mg, or more of thiamine twice daily for a prolonged period.

Papillary edema with retinal hemorrhages: associated with ophthalmoplegia and polyneuritis. The condition is a late manifestation of severe deficiency.

Stigmas Suggesting Deficiency of Riboflavin

Congestion of the limbic plexus:

Visible with a small hand lens or the +20 lens of the ophthalmoscope; invasion of the cornea by capillaries arising from this plexus (vascularization) requires a biomicroscope and slit lamp for detection.

Cheilosis:

Represented in chronic deficiency by excessive and irregular wrinkling, in acute deficiency by swelling and erasure of the normal wrinkling of the lips. Reddening, thinning, scaling, chapping of epithelium are associated.

Angular stomatitis:

Various combinations of ervthema and open fissuring in the angles of the mouth with or without a white, moist maceration (perlèche); scars of healed fissures.

Dussebacia:

An erythema overlaid with somewhat greasy, flaky accumulations resembling hoar frost, noted mostly in the alae nasi, canthi, pinnae, and other folds of the skin, accompanied in some cases by coarsening and elevation of the sebaceous follicles of the nose and cheeks, the latter also seen with deficiency of vitamin A.

Magenta tonque:

A purplish red coloring with moderate edema and flattening of filiform papillae; observed in more advanced deficiency.

Stigmas Suggesting Deficiency of Niacin

Edema of the tonaue:

Shown by dental indentations.

Increased redness of the tongue:

Beefy red in chronic states; scarlet red in severe acute deficiency.

Congestion and hypertrophy of the papillae of the tongue, followed by fusion and atrophy:

In early stages the fungiform papillae are congested and hypertrophied. This is followed by hypertrophy of the filiform papillae and later by their flattening. As they atrophy they fuse or mat together with multiple fissuring to give a cobblestone appearance and finally baldness. Vincent's infection of tongue and fauces, ulceration and pseudomembrane formation may or may not accompany these changes in the more advanced stages of this deficiency.

Dermatitis:

Erythema, rough scaling, with ulceration and formation of bullae, affecting primarily areas of

Treatment of Riboflavin Deficiency

Acute deficiency state:

5 mg, of riboflavin three times daily for weeks.

Chronic deficiency state:

3 to 5 mg, of riboflavin three times daily for a prolonged period.

Treatment of Niacin Deficiency

Acute deficiency state:

100 mg, or more of niacinamide twice daily for weeks:

Chronic state:

100 mg. of niacinamide twice daily over a prolonged period. the skin exposed to light; namely, wrists, ankles, neck, and face; observed only in severe deficiency (pellagra) and then frequently associated with diarrhea and dementia.

Encephalopathy:

Clouding of consciousness, cogwheel rigidity, and grasping, sucking reflexes observed in acute, severe deficiency.

Stigmas Suggesting Deficiency of Ascorbic Acid

Redness, edema, tenderness, and bleeding on pressure of the gums:

Observed in acute or subacute deficiency of moderate severity, sometimes with, but usually without, other signs of ascorbic acid deficiency.

Thickening and increased firmness of the gums:

With recession and exposure of the base of the teeth, including recession of interdental papillae; observed in chronic deficiency.

Retraction of the gums:

Leaving pockets between gum and tooth, secondary infection and resulting pyorrhea; observed in chronic deficiency.

Loosening and shedding of the teeth.

Increased capillary fragility:

Manifested by petechial hemorrhages of the skin, especially in the tourniquet test; observed in more severe acute and subacute deficiency. Easy bruising, spontaneous ecchymosis of the skin, idiopathic hemorrhage into joints and slow healing of wounds, observed in severe acute and subacute deficiency.

Stigmas Suggesting Deficiency of Vitamin D

Deformities of the skeleton:

Bowed legs, malformation of the chest (funnel breast) and defects of the teeth may be residues of early rickets which is usually no longer active or susceptible to treatment; enlargement of the wrists, elbows, knees, ankles and costochondral junctions (beading, rachitic rosary) and bulging forehead (cranial bosses) which respond to treatment are found in infancy and in the rare example of late rickets.

Stigmas Suggesting Deficiency of Vitamin K

A tendency to bleeding:

Particularly from minor wounds, related to abnormal lengthening of the prothrombin time, developing spontaneously in newborn infants; observed in adults after treatment with dicoumarol or large doses of salicylates; in advanced disease of the liver with poor excretion of bile, and in disease of the intestine, such as sprue in which vitamin absorption is disturbed.

Treatment of Ascorbic Acid Deficiency

Acute or subacute deficiency state:

100 mg. or more of ascorbic acid daily for weeks.

Chronic deficiency state:

100 mg, of ascorbic acid three times daily over a prolonged period.

Treatment of Vitamin D Deficiency

In infants:

1,500 to 2,500 U.S.P. units of vitamin 1) daily, continued for several months (double this amount for premature infants).

Treatment of Vitamin K Deficiency

In adults:

1 mg. of vitamin K two to three times daily with or without bile (1 g. of desiccated bile or bile salts).

In newborn babies:

1 mg. of synthetic vitamin K intramuscularly daily in oil solution for several days.

Deficiency Symptoms

A diagnosis of vitamin deficiency only rarely can be based on symptoms or less significant abnormalities than those which have been listed thus far. However, such symptoms and abnormalities frequently accompany the more specific lesions of deficiency.

Symptoms commonly observed with deficiency of thiamine, also less conspicuously in deficiency of other vitamins, include apathy, lethargy, increased emotional irritability, hypersensitivity to noise and painful stimuli, headache, vague fears, confusion of thought, uncertainty of memory, asthenia, loss of manual dexterity, insomnia, heart consciousness, paresthesia, anorexia, nausea, flatulence, epigastric pain, constipation.

Photophobia, burning of the eyes, lacrimation and eyestrain not relieved by

glasses are encountered in deficiency of riboflavin.

Other abnormalities unrelated to deficiency of any single vitamin but commonly observed in persons who are malnourished are dry, brittle, lack-luster, rebellious, so-called staring head hair, a loss of sleekness analogous to the rough coat of malnourished animals, blepharitis, spider-like telangiectasis of the face, seborrhea of the face, patchy pigmentation of the face, especially suborbital and circumoral, sinus arrhythmia, bradycardia, tachycardia, low blood pressure, loss of tone of muscles and anemia.

Antibiotics: Metabolic Antagonists

ANTIBIOTICS

It has long been known that certain microörganisms produce substances during their growth in culture media which may inhibit the growth or activity of other unrelated species of microörganisms. Thus well before the year 1900 it was found that old cultures of *Pseudomonas aeruginosa* (at that time called *Bacillus pyocyaneus*) were inhibitory to the growth of many other bacteria. This action was attributed to the presence of a substance called pyocyanase, to which enzyme-like properties were ascribed. More recent studies have shown that the antibacterial activity is due largely (but not entirely) to the blue pigment pyocyanine produced by the organism. Pyocyanine itself was first isolated in crystalline form in 1860. It has the following structure:

Pyocyanine

Pyocyanine behaves as an acid-base indicator and likewise undergoes reversible oxidation and reduction; it is possible that this latter property is related to its antibacterial action. It is quite toxic to animal tissues; the reason is not known. The antibacterial activity of pyocyanine (and of certain other substances with similar activity produced by other bacteria) attracted little attention because of the high toxicity to animals as well, and such substances were regarded largely as curiosities. It was not until 1939, when the striking results of Dubos on the isolation and use of the antibacterial substance tyrothricin (subsequently shown to be a mixture of two compounds, see p. 1203) were published, that interest in the possible clinical and experimental application of these substances became accentuated, and this may be said to mark the beginning of the present phase of this subject.

Antibacterial substances as a class are now known as antibiotics. An antibiotic has been defined as a soluble organic compound produced by the metabolic processes of one species of microörganism which is inhibitory to the growth or activity of another species of microörganism. Thus far only bacteria, yeasts, molds, and actinomycetes have been shown to produce antibiotics, but the possibility that other forms of life may likewise be found to do so cannot be excluded.

The definition of antibiotics as given is clearly subject to future revision. It excludes synthetic compounds such as the sulfonamides whose mode of action in many ways resembles that of the naturally occurring antibiotics, and it likewise excludes synthetic derivatives of the antibiotics such as alkylated, halogenated, and diazo modifications, many of which have been prepared in the laboratory and some of which show promise as antibacterial agents. It appears likely that a more adequate definition of antibiotics ultimately will be based upon a general mode of action rather than on the more limited basis of natural occurrence.

The reason for the production of an antibacterial substance by a microorganism is not clear. It is doubtful that the production by one species of microorganism of a substance toxic to a second species is designed to enhance chances of survival of the former in the presence of the latter, since instances are known where the antibiotic is effective against organisms not apt to be encountered under natural conditions. Penicillin, for example, is believed to be the result of growth under the artificial conditions of a culture medium, and not to be a normal product in a natural environment. Furthermore, the same organism or strain may produce more than one antibiotic, of quite different characteristics (see the table on p. 1206), or may produce one antibiotic under one set of conditions and a different one under another set of conditions. An analogous instance of apparent lack of purpose is found, for example, in the production by Cl. tetani of tetanus toxin, which has a powerful effect on animals but which has no recognized value to the organism producing it. Until further knowledge is gained, no satisfactory theory concerning the cause of antibiotic production can be advanced.

The nature of antibiotic action must also await further knowledge concerning bacterial metabolism. Unlike the common disinfectants and antiseptics, which are general protoplasmic poisons and which usually act by irreversibly denaturing or precipitating protein, or by inactivating functional groups (sulfhydryl, iron, etc.) within the cell, the action of antibiotics must be much more subtle, since they are apparently harmless in the protoplasm of the organisms which produce them but inhibitory or toxic in the protoplasm of the susceptible organism. Most antibiotics are primarily bacteriostatic in their action; that is, they do not appear to inhibit the metabolic processes of treated microörganisms except where subdivision and growth are concerned. In some instances, however, substrate utilization may be affected. Some antibiotics are bactericidal, irreversibly destroying the metabolic processes of the susceptible cell. In some cases, concentration may determine whether the action is bacteriostatic or bactericidal. It appears reasonable to postulate that antibiotics may act in general by inhibition or inactivation of certain specific enzyme systems of importance to the susceptible cell; precise evidence on this point, however, is lacking. It is interesting to note that at low concentrations certain antibiotics stimulate growth rather than inhibit it.

Antibiotics differ considerably in their relative effectiveness against various species of microorganisms, and even against different strains of the same species. In some instances susceptibility to an antibiotic may be considerably modified by variations in the conditions of culture. Most antibiotics are active against Gram-positive bacteria only, with only limited activity against Gram-negative organisms; the reason for this is not known. Streptomycin is an example of an antibiotic which gives promise of successful use against Gram-negative organisms. Some antibiotics are fungicidal as well as bactericidal.

The differential susceptibility of various species of microörganisms to a given antibiotic permits the construction of a bacterial "spectrum" for the antibiotic, in which the relative effectiveness is determined for a standardized series of test organisms. Such a spectrum may be useful in comparing two supposedly identical or dissimilar antibiotics, and in comparing synthetic compounds or derivatives with the naturally occurring antibiotic.

Antibiotics also differ considerably in their relative toxicity to animals, and in their effectiveness in vivo as compared with in vitro. In the latter instance, effectiveness may be modified by the presence in the host of means for metabolizing or destroying the antibiotic. For example, certain bacteria (and apparently human blood serum as well) contain an enzyme called penicillinase which is capable of destroying penicillin. Of all known antibiotics, the combination of high potency, low toxicity, and resistance to inactivation is found only in the penicillins and in streptomycin, and these are the only antibiotics which have as yet found extensive clinical application.

The Penicillins. In 1929 Fleming reported that a certain species of mold, later recognized to be a strain of *Penicillium notatum*, and first encountered as an accidental contaminant of bacteriological plate cultures, produced a soluble diffusible substance which inhibited the growth of the common *Staphylococcus aureus* and certain (but not all) other microörganisms in culture media. Fleming was able to concentrate this substance from cultures of the mold, and called the material penicillin. It is now known that the original penicillin was a mixture of several similar substances which are called as a class the penicillins.

Fleming showed that his penicillin preparation could be used for the differential separation of resistant and nonresistant species of microorganisms in culture media, and that it was nontoxic to animals. He suggested its possible use in the treatment of infections due to penicillinsensitive organisms.

These observations however attracted little further attention until about 10 years later. In 1939 Dubos² published his striking results on the antibacterial properties of tyrothricin (see p. 1203); it is probable that these results contributed significantly to a reawakening of interest in the antibacterial possibilities of penicillin. In 1940 Chain, Florey, et al.,³ reported the preparation of penicillin in impure form, with some studies on its toxicity to animals and therapeutic value in experimental infections in mice. This was followed by a more extensive study on the methods for large-scale production, partial purification, assay, and further studies

1196

on toxicity and therapeutic value in animals and man. Similar studies on the chemotherapeutic value of penicillin were reported by Dawson, Hobby, Meyer, and Chaffee at about the same time. Developments since then have made penicillin by far the most widely used and important of all the antibiotics thus far known, even outranking the sulfonamides in therapeutic importance.

Of the various known penicillins, the most important at the present time is the one known as G-penicillin (called penicillin-II in Britain).

The probable structure of G-penicillin is as follows:

Evidence upon which this structure is based has been obtained by a variety of methods, including those of synthetic and degradative organic chemistry, electrometric titration, x-ray crystallography, and infrared spectrometry. Conclusive proof of this structure by unequivocal methods of synthesis is as yet lacking. It is to be noted that other structures have been proposed; the one presented here is believed to be the most satisfactory explanation of the known data.5

As a class, the penicillins all have the composition represented by R-CO-NH-C₇H₉OSN-COOH, where R varies. In G-penicillin, for example. R = C₆H₅CH₂— (the benzyl group); the relationship between the various known penicillins is indicated in the following table. The variation between penicillins already known makes it appear likely that still others remain to be discovered.

THE PENICILLINS

Name	Type Structure: R—CO—NII—C7H4OSNCOOH			
Nume	R	Name of R		
F-penicillin Dihydro-F-penicillin G-penicillin K-penicillin X-penicillin	CH ₃ ·CH ₂ ·	Δ²-pentenyl n-amyl benzyl n-heptyl p-hydroxybenzyl		

It has been suggested that the various penicillins be designated by names which include the name of the major differentiating group (the R group in the above table). According to this suggestion, G-penicillin becomes benzylpenicillin, X-penicillin is p-hydroxybenzylpenicillin, etc.

As a class the penicillins are moderately strong monobasic organic

⁴ Dawson, Hobby, Meyer, and Chaffee: J. Clin. Invest., 20, 434 (1941).

For a summary of the chemistry of the penicillins, see Science, 102, 627 (1945).

acids, soluble in water and in organic solvents such as alcohol, ether, amyl acetate, etc. In aqueous solution the free acids are quite unstable; neutralized solutions, or solutions of the salts, are more stable. The sodium salt, which is quite soluble in water and alcohol, is the usual commercial form. The stability of dry sodium G-penicillin is greatest at low temperatures: the crystalline salt has been shown to be more stable than the amorphous preparation. Neutral aqueous solutions of the sodium salt will retain their activity for several days if stored in the cold; acid or alkaline solutions rapidly become inactive. Alcoholic solutions readily become inactivated, probably because of the formation of an ester of penicilloic acid, as described below. Inactivation by water has been shown to be due to the formation of penicilloic acid, which contains two carboxyl groups and which is biologically inactive. This process is hastened by alkali, but occurs to a measurable extent in neutral solution. where it can be followed manometrically in terms of the CO₂ liberated from a bicarbonate-containing solution by the neutralization of the newly formed carboxyl group. In methyl alcohol, an inactive methyl ester of the new carboxyl group is formed.

Treatment of the inactive penicilloic acid by hot dilute acid liberates carbon dioxide from the carboxyl group not originally present in the penicillin molecule, and yields among other products (which differ with the different penicillins) an amino acid known as penicillamine. Penicillamine is d- β , β -dimethylevsteine. It has been shown that the precursor of the carbon dioxide, and hence the other half of the G-penicillin molecule, is a substance known as G-penaldic acid, C_6H_5 ·CH₂·CO·NH·CH·CHO,

COOH

which loses carbon dioxide from the earboxyl group on treatment with acid.

The facts which have just been presented with regard to certain of the primary degradation products of G-penicillin may be summarized as follows:

It is to be noted here that the other penicillins thus far investigated behave chemically in a similar manner, with modifications associated with variations in the side-chain (R group) of the molecule. Various other chemically recognized degradation products of penicillin are known and have had their structures confirmed by synthesis, but a detailed consideration appears unprofitable at this point. It is interesting to note that penicillamine has the d configuration around the α -carbon. If the sulfur is split off by suitable means, the amino acid d-valine may be obtained.

From the point of view of the organic chemist, the penicillin molecule is an extremely reactive one, and this has made more difficult the establishment of its structure by degradation or synthesis. It likewise prevents the drawing of any conclusions at the present time with regard to the group or groups in the molecule responsible for biological activity. At the same time, it permits the preparation of synthetic derivatives which may ultimately give a clue to the nature of such active groups. Thus the presence of the hydroxyphenyl group in X-penicillin makes possible the synthetic preparation of various diazo derivatives, studies of which may furnish a clue to the nature of the action of penicillin, or even lead to the production of substances more satisfactory than the naturally occurring compounds.

All of the penicillin available commercially is obtained from natural sources, i.e., from cultures of mold, of which special strains of P. notatum and P. chrysogenum have been most commonly employed. The enormity of the task of producing penicillin in commercial quantities can be readily imagined, particularly in view of the chemical lability and variation in the penicillin molecule which has already been pointed out, when it is realized that the production of penicillin is now in terms of billions of units, and the original yield of penicillin was but a few units per ml. of culture medium. That this task was successfully accomplished to produce a therapeutically useful product represents a triumph of technical and laboratory skill. Many factors had to be carefully investigated, including the most satisfactory type of mold, the conditions of growth and maximal vield of penicillin, and the processing of the material to yield a final product of commercial value. Under the stimulus of wartime necessity, many groups and organizations engaged in a joint and cooperative study on the chemistry, manufacture, and clinical use of penicillin, and all share in the credit of a job well done.

One of the results of this study was the unequivocal synthesis of G-penicillin (benzylpenicillin), based on work done in the Merck, Oxford, Cornell, and Upjohn laboratories. The synthetic material was shown to be identical with the naturally occurring compound in chemical and physical properties, and in antibiotic potency. While the yield reported was low, and the synthesis as yet does not lead to absolute proof of structure, the successful synthesis of benzylpenicillin should open the way to the synthesis of new and different penicillins which might possess desirable therapeutic possibilities.

Penicillins as a class are apparently nontoxic to animal tissues in any Du Vigneaud, Carpenter, Holley, Livermore, and Rachele: Science, 104, 431 (1946).

except very large doses; for example, in ordinary concentrations they have no demonstrable effect on the metabolic characteristics of those isolated animal tissues which have been thus far investigated. They differ among themselves, however, in their action on microörganisms; G-penicillin, for example, is most effective clinically, while K-penicillin is much less useful. Lack of recognition of this fact led to some confusion concerning the therapeutic effectiveness of commercial penicillin preparations during the early stages of their clinical application. A wide variety of organisms, mostly Gram-positive but including some Gram-negative forms, are susceptible to the action of penicillin; included in this list, which may be lengthened by further study, are organisms which are refractory to the action of the sulfonamides. The mode of action of penicillin is not known, but its effects appear to be bacteriostatic rather than bactericidal.

Penicillin is usually determined in terms of its inhibitory effect on the growth of certain test microörganisms, i.e., by microbiological assay. A detailed description of procedures based upon this principle, together with a definition of assay units, will be found on pp. 1200 to 1203. Methods involving the production of a color,⁷ or the measurement of selective absorption in the ultraviolet region of the spectrum,⁸ have also been described; doubtless other procedures will be developed in due course.

Penicillin is administered intravenously, intramuscularly, or orally. Intravenous administration has the disadvantage that the substance is rapidly excreted in the urine; intramuscular injection delays absorption into the blood and subsequent excretion therefrom, and a desired concentration level may be maintained for a longer time, particularly by repeated administration. It has been shown that admixture of penicillin with peanut oil containing beeswax prolongs the effectiveness of intramuscular injection, possibly by de aying absorption. Oral administration has obvious clinical advantages over any other method; despite earlier beliefs to the contrary, orally administered penicillin is as effective in maintaining a desired concentration in the body fluids as any other method, provided a higher (about five-fold) dose is used. Penicillin is inactivated to a certain extent by high gastric acidity, and various means of overcoming this have been proposed, such as the administration of antacids, the use of capsules resistant to gastric digestion, etc. The value of such measures as these is questionable, however, since it has been found that inactivation by gastric acid plays at the most only a minor part in the problem of oral administration of penicillin. Curiously enough, some penicillin appears to be absorbed from the stomach.

DETERMINATION OF PENICILLIN

1. Method of Vincent and Vincent:10 Principle. A disk of filter paper is saturated with the solution to be analyzed, which has been di-

⁶ For a list of susceptible and insusceptible organisms, see Herrell, Nichols, and Heilman: J. Am. Med. Assoc., 125, 1003 (1944).

⁷ Scudi: J. Biol. Chem., 164, 183 (1946); Scudi and Jelinek: J. Biol. Chem., 164, 195 (1946).

^{*} Herriott: J. Biol. Chem., 164, 725 (1946).

[•] McDermott, Bunn, Benoit, DuBois, and Haynes: Science, 101, 228 (1945).

¹⁰ Vincent and Vincent: Proc. Soc. Exptl. Biol. Med., 55, 162 (1944). Similar methods

luted if necessary so as to contain approximately 1 unit per ml. The disk is placed on a nutrient agar culture plate impregnated with the test organisms and incubated at 37°. If the solution contains penicillin, after incubation a clear zone of inhibition of colony formation surrounds the disk. The diameter of this zone is measured and the penicillin content determined by reference to a calibration curve showing the relation between inhibition zone diameters and known amounts of penicillin.

Procedure: The test organism (Staphylococcus aureus H is recommended)¹¹ is transferred from an agar slant twice through peptone broth for 24-hour periods at 37°. The second transfer is held at 5° for 16 to 18 hours.

Pipet 10 ml. of nutrient agar into uniform flat-bottomed petri dishes and incubate at 37° for 16 to 18 hours. Transfer to a refrigerator for at least one hour. When the plates are ready, flood each one with 1 ml. of the refrigerated culture of test organisms. Remove the excess with a capillary pipet. Place the plates at 37° for one hour to dry. At this point it is necessary to use wooden racks which support the top half of the petri dish above the bottom half so that there is about ½ inch clearance. When the plates are dry, store in an inverted position in the refrigerator for at least one hour.

Sterilize the filter paper disks¹² by dry heat and immerse them for 30 seconds in the solution to be tested. Remove each disk from the fluid with sterile forceps, shake off excess fluid, and place flat on the seeded agar plate. Three disks, evenly spaced, may be placed on a plate, and it is suggested that the plates be run in triplicate for greater accuracy. One of the disks on a plate may serve as a standard penicillin control.

Incubate the prepared plates (not inverted) at 37° for 14 hours. The plates should be placed on a wooden block in the incubator to prevent excess condensation. After the incubation period, measure to the nearest mm. the diameter of the zone of inhibition around each disk.¹³ Average

the results for each unknown.

Calculation. The penicillin content of the sample is equal to that of a standard solution of penicillin which gives the same diameter of inhibition zone under comparable conditions. This is best established by reference to a previously prepared calibration curve relating known amounts of penicillin to zone diameters. To prepare such a curve, set up a series of solutions of penicillin in amounts ranging from 4 to 0.1 units per ml., and carry out the procedure as described for the unknown on each of these solutions. Plot a curve with zone diameters in mm. on the y axis against units of penicillin per ml. on the x axis. A curve similar to that shown in Fig. 314 should be obtained. It is advisable to check this curve at intervals with standard penicillin solutions, and to reconstruct it if necessary.

were described almost simultaneously by Epstein, Foley, Perrine and Lee: J. Lab. Clin. Med., 29, 319 (1944), and by Sherwood, Falco, and de Beer: Science, 99, 247 (1944).

12 Schleicher and Schüll No. 470, ½ inch in diameter. Obtainable from the Schleicher

and Schüll Company, New York.

¹¹ Foster and Woodruff: J. Biol. Chem., 148, 723 (1943), describe a procedure similar to that given here, using B. subtilis as the test organism. The agar plates are seeded before pouring with a standardized suspension of B. subtilis spores, which is stable indefinitely in the refrigerator. It is claimed that with B. subtilis the edge of the zone of inhibition is invariably quite sharp.

¹³ A bacteriological "colony counter," equipped with a magnifying glass and a built-in millimeter scale, is very satisfactory for this measurement. Such a "penicillin reader" may be obtained from Eimer and Amend, New York, and the Fisher Scientific Corp., Pittsburgh.

Interpretation. This method is a slight modification of the original method of Chain, Florey, et al., (loc. cit.) developed at Oxford in England and called the "Oxford cup" method, in which the solution to be tested is placed in small glass cylinders partially immersed in the seeded agar; this solution then diffuses out beneath the cup rim into the agar to produce a zone of inhibition similar to that described here. A unit of penicillin (formerly called the Oxford unit and now known as the Florey unit) was defined as that amount which produced a zone of inhibition 24 mm. across under the conditions of the cup assay. Such a unit is clearly subject to variation from laboratory to laboratory and even in the same laboratory unless assay procedures are rigorously controlled. With the availability of pure crystalline sodium G-penicillin, it is possible to define a penicillin unit in terms of this substance. The Federal Food and

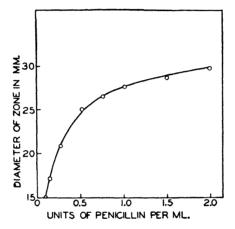

Fig. 314. Type of calibration curve obtained in penicillin determination by method of Vincent and Vincent.

Drug Administration of the United States has adopted the following relationship: 1 mg. of pure sodium G-penicillin is equivalent to 1667 units of penicillin. Thus I unit equals $0.6~\gamma$ of the sodium salt.

The disk method described here has been found to give satisfactory results on blood serum, spinal fluid, urine, and other solutions whose penicillin activity is to be established. For greatest accuracy the solution to be tested should contain between 0.1 and 4 units per ml. For further aspects of interpretation, see the following method.

2. Method of Rammelkamp: ¹⁴ Principle. The fluid to be analyzed is incubated at various dilutions with a standard inoculum of hemolytic streptococci in the presence of erythrocytes. Dilutions of a standard penicillin solution are treated in the same way. From the relative dilutions of sample and standard required to inhibit the hemolytic action of the test organisms under test conditions, the penicillin content of the sample is obtained.

¹⁴ Rammelkamp: Proc. Soc. Exptl. Biol. Med., 51, 95 (1942).

Procedure: Set up two series of 12 or more small sterile culture tubes each, one series for the solution to be tested and one for the standards. Leave the first tube in each series empty. In the second and succeeding tubes of each series place 0.2 ml. of sterile veal infusion broth. Now to each of the first two tubes of one series add 0.2 ml. of the solution to be tested. Leave the first tube as it is. Mix the contents of the second tube, withdraw a 0.2-ml. portion, and transfer to the third tube. Mix the contents of this tube, withdraw 0.2 ml., and transfer to the fourth tube. Continue with this serial dilution of the sample in the remaining tubes of the series, discarding the final 0.2-ml. portion. Each tube will now contain 0.2 ml., with dilutions of the unknown as follows: 0, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, etc.

Prepare the standard series in the same way. In the first two tubes of the standard series, place 0.2 ml. of the standard penicillin solution, containing 20 units per ml. Serially dilute the standard, beginning with the second tube in the series, as described for the unknown.

When the two series are ready, to each add 0.5 ml. of the diluted suspension of test organisms¹⁵ in veal infusion broth containing 1 per cent of erythrocytes. Incubate the tubes for 18 hours and then examine for evidence of hemolysis. At the time of the examination, as a check on sterility, streak a 3-mm. loop of the cultures near the end-point on blood-agar plates. The end-point tube is the one containing the highest dilution at which hemolysis is still zero.

Calculation. The calculation is as follows:

$$\frac{4}{\begin{array}{c} \hline \text{Dilution of unknown} \\ \hline \text{Dilution of standard} \\ \text{at end-point} \end{array}} \times \frac{\text{at end-point}}{0.2} - \frac{\text{units of penicillin}}{\text{per ml. of unknown}}$$

where 4 equals the number of units of penicillin in the portion of standard (0.2 ml.) taken for serial dilution, and 0.2 is the volume of unknown similarly taken. Thus if the end-point in the standard series is at a dilution of 1024, and for the unknown at a dilution of 64, the calculation is as follows:

$$\frac{4}{1024} \times \frac{64}{0.2} = 1.25$$
 units of penicillin per ml.

Interpretation. This method, although not so accurate as the preceding one, is recommended for routine clinical purposes. It has given satisfactory results on unknown penicillin solutions, whole blood, erythrocytes, urine, spinal fluid, exudates, and joint fluid. The solutions to be analyzed should be stored at 5° until the time of testing, to preserve penicillin activity. This is also true of the standard penicillin solutions. Urine has been kept for two weeks without losing activity. If the sample is contaminated with bacteria, it should be sterilized by passing through a Berkefeld or Seitz filter; this does not lead to appreciable loss of penicillin.

The level of penicillin obtained in the blood after dosage depends upon

¹⁵ The test organism used by Rammelkamp was a group A strain of hemolytic streptococcus, isolated from the blood stream of a patient with erysipelas. The 12-hour broth culture of the organisms was diluted in the erythrocyte-containing veal broth so that the final diluted suspension as used contained between 1,000 and 10,000 organisms per ml.

the size of the dose, the method of administration, and the time after dosage. Intravenous administration of 5,000 units may produce a maximum blood level of approximately 0.15 units per ml. of serum within 10 minutes; this falls rapidly to zero within 1 hour. If 20,000 units are given intravenously, the blood serum level may reach a value of approximately 1.25 units per ml. in a short time, and the time required for complete disappearance is lengthened to about three hours. Intramuscular administration produces a lower serum level which is, however, maintained approximately constant for several hours. This is the preferred method of administration, the dose being repeated every three hours to give a total of approximately 150,000 units per day. If given at longer intervals, the dosage must be greater. Subcutaneous injection gives still lower serum levels, maintained for much longer periods of time.

Penicillin is excreted fairly rapidly from the blood, in large part by the kidneys. In average normal individuals somewhat over half the amount administered intravenously may be found in the urine, although there is considerable variation in this respect. Some of the penicillin is destroyed within the body, possibly by a penicillinase present in the blood.

Gramicidin and Tyrocidine. The antibiotic preparation obtained by Dubos from cultures of B. brevis and called tyrothricin proved on further study to consist of two separate compounds, called gramicidin and tyrocidine respectively. 16 They may be separated from tyrothricin by treatment with acctone-ether mixture, in which gramicidin is soluble but tyrocidine is insoluble. Gramicidin may be recrystallized from acetone, and tyrocidine hydrochloride from acidified alcohol. Both of these substances are polypeptides, of fairly low molecular weight but as yet unknown structure. They are resistant to the action of proteolytic enzymes. On hydrolysis they yield mixtures of amino acids, all of which have presumably been identified (see below). It is interesting to note that certain of these amino-acid hydrolytic products are of the d configuration, which as yet has not been found among the hydrolytic products of animal proteins, where the l configuration prevails (see discussion on p. 112). The relationship, if any, of these stereochemical findings to the antibiotic activity remains to be established.

Gramicidin crystallizes in colorless platelets (m.p. 230°) from acetone. It is insoluble in water, slightly soluble in ether, and readily soluble in acetone and alcohol. Its alcoholic solution is dextrorotatory. Estimates of its molecular weight vary; on the basis of the amino acid composition a value of approximately 2800 has been proposed, and this is in agreement with certain of the results obtained by physical methods. On hydrolysis, gramicidin yields five known amino acids and the basic compound ethanolamine. These components of the gramicidin molecule, and their estimated molecular ratios, are as follows: d-leucine, 6; l-tryptophane, 6; dl-valine, 5; l-alanine, 3; glycine, 2; ethanolamine, 2; making a minimum of 24 residues present. The valine was probably racemized during the hydrolysis; if it were all present in the d form, the leucine and

¹⁶ Hotchkiss and Dubos: J. Biol. Chem., 141, 155 (1941).

valine would account for the approximately 45 per cent of d amino acids found present in gramicidin by the use of the enzyme d-deaminase (d-amino acid oxidase). There are no free carboxyl or amino groups, so that a cyclic structure is probable.

Gramicidin is inhibitory to all Gram-positive organisms except acidfast bacilli, but is entirely inactive against Gram-negative bacilli. It does not destroy the respiration of susceptible cells; in particular instances it may be highly bacteriostatic but not at all bactericidal, thus indicating that it acts rather as a metabolic inhibitor than as a protoplasmic poison. The therapeutic value of gramicidin is limited by its relative toxicity to animals and its low solubility in water, penicillin for example being much superior in both respects. It has, however, found some application in the topical treatment of infected wounds.

Tyrocidine is a polypeptide containing free amino groups (probably the δ-amino group of the ornithine present, see below) and forms a crystalline hydrochloride. Tyrocidine hydrochloride is insoluble in water, acetone, and ether, but soluble in alcohol, from which it may be crystallized as colorless needles, m.p. 240° with decomposition. On hydrolysis it yields the amino acids phenylalanine, leucine, proline, valine, tyrosine, ornithine, glutamic acid, aspartic acid, and tryptophane. Of these, the phenylalanine has the d configuration while all the rest (with the possible exception of tryptophane) have the common l configuration. It is interesting to note that the amino acid valine occurs in one configuration in tyrocidine and in the opposite configuration in gramicidin. The proof of the existence of ornithine in the tyrocidine molecule is probably the first instance of the discovery of this amino acid as a primary constituent of polypeptide chains in nature. The molecular weight and amino acid distribution of tyrocidine have not been accurately established because of technical difficulties, among which is the inability to determine accurately the tryptophane content.

Tyrocidine is strongly bactericidal for all Gram-positive and Gramnegative organisms thus far investigated, with the exception of the tubercle bacillus. It destroys immediately and irreversibly the metabolic activities of susceptible organisms. Its toxicity for animals is about the same as that of gramicidin. It has had no therapeutic application.

Streptomycin. This antibiotic was first characterized by Schatz, Bugie and Waksman¹⁸ in 1944, being obtained from cultures of a strain of Actinomyces griseus. Its discovery was the result of a systematic study of organisms which were antagonistic to Gram-negative bacteria. Several years earlier the same laboratory reported the existence of an antibiotic called streptothricin, obtained from Actinomyces lavendulae. Both streptothricin and streptomycin are somewhat similar in their antibacterial properties (and probably in chemical nature as well), but streptomycin has attracted the greater attention because of its relatively lower toxicity to animals and greater antibiotic activity against both Grampositive and Gram-negative organisms.

 ¹⁷ Lipmann, Dubos, and Hotchkiss: J. Biol. Chem., 141, 163 (1941).
 ¹⁸ Schatz, Bugie, and Waksman: Proc. Soc. Exptl. Biol. Med., 55, 66 (1944).

Streptomycin is an organic nitrogenous base, soluble in water, and has been obtained in crystalline form. Various crystalline chemical derivatives have been isolated but the actual chemical nature of the streptomycin molecule has not as yet been completely elucidated. The empirical formula is $C_{21}H_{39}N_7O_{12}$. On hydrolysis, streptomycin yields a basic compound called streptidine and a disaccharidelike portion known as streptobiosamine, these two substances apparently being joined together in a glycoside linkage to form streptomycin. The structure of streptidine is known (see below); streptobiosamine consists of two components, one of which is N-methyl-l-glacosamine, and the other is of as yet unknown chemical nature but has the empirical formula $C_6H_{10}O_5$.

Streptomycin has had considerable clinical trial, and appears to be of value, particularly for infections by organisms which are resistant to treatment with penicillin. Of special interest is the sensitivity of the tubercle bacillus and related organisms to streptomycin. This sensivity varies from species to species and even from strain to strain; for example, the human type of tubercle bacillus is more sensitive to streptomycin than the avian type; but experimental study in vitro and with animals infected with tuberculosis gives some promise that streptomycin may be of value in the treatment of this disease. The streptomycin content of biological fluids is determined by methods quite similar to those used for penicillin.

Other Antibiotics. A variety of antibiotic substances other than those just discussed have been recognized, some of which have been sufficiently well-characterized to indicate their chemical nature, either partially or completely. A summary of the known facts regarding some of these, adapted from the reviews by Waksman and by Oxford (see Bibliography at end of chapter) is presented in the table on page 1206. This table is presented not because of the relative present or possible future importance of the substances listed, but to illustrate the variety of chemical structures at present known to be associated with antibiotic action. Although there is in some instances a structural similarity between an antibiotic and a known constituent of protoplasm—fumigatin and vitamin K, for example, are both 2-methyl-1,4-quinones—it is clear

OTHER ANTIBIOTICS

Name	Empirical Formula	Origin	Structure	Toxicity to Animals	Effectiveness Against Gram- positive(+) or Gram- negative(-) Organisms
Aspergillic acid	C12H20O2N2	A. flavus	CH ₃ HC N C ₂ H ₄ C ₂ H ₅	++	+
Citrinin	C13H14O5	P. citrinum, A. candidus	ОН ОС.СООН	?	+
Clavacin (Patulin, etc.).	C2H8O4	A. clavatus, P. claviforme, others	$H_{2}C \stackrel{C}{\leftarrow} H \stackrel{O}{\rightarrow} C$ $H_{2}C \stackrel{C}{\leftarrow} CH \stackrel{O}{\rightarrow} C$	+++	+-

that knowledge or even a theory concerning antibiotic action must await further study.

In addition to antibiotics of known chemical composition, more complex substances with antibacterial activity have been obtained from cultures of microörganisms from time to time. In some instances these appear to be proteins, sometimes with enzymatic activity. For example, notatin, a substance obtained from *Penicillium notatum*, has been shown to be a glucose oxidase, producing hydrogen peroxide in the presence of glucose and oxygen, the antibacterial activity being due to the production of the hydrogen peroxide. A detailed consideration of these substances does not appear profitable at the present time.

METABOLIC ANTAGONISTS

The relation between the chemical structure of molecules and their biological action has attracted the attention of both chemists and biologists for a long time. The subject has obvious importance in connection with such aspects of protoplasmic behavior as the action of enzymes and coenzymes, the availability of substrates, the action of drugs, the action of antibiotics and related compounds, the effect of chemotherapeutic agents, etc. It is not our purpose to discuss these various phases of this subject in great detail. There is one aspect of the relation between structure and biological action, however, which is attracting considerable attention and which promises to play an increasingly important part in the future. This is the realization that it is possible to alter certain natural activities of protoplasm by introducing into the system compounds which are structural analogs of those known to be normally concerned in such activities. For want of a better term, such analogs are known as metabolic antagonists, since their action in general is one of inhibiting normal metabolic manifestations.

Perhaps the simplest example of inhibition related to structural analogy is found in the case of the enzyme succinic dehydrogenase. This enzyme catalyzes the oxidation of succinic acid to fumaric acid in the presence of a hydrogen acceptor (see p. 276). The action of succinic dehydrogenase on succinic acid is almost completely inhibited by the presence of malonic acid.¹⁹ The relation between these two compounds is evident from a comparison of their structures:

The inhibition by malonic acid is reversible, that is, it may be overcome by the addition of a sufficient amount of succinic acid, in which case the enzyme behaves as though no inhibitor were present. This reversible relation between succinic and malonic acids, together with the obvious fact that these two substances cannot react with each other, implies that both types of molecule are competing for a reactive group

¹⁹ Quastel and Wooldridge: Biochem. J., 21, 1224 (1927).

on the enzyme molecule itself. This is therefore known as "competitive inhibition" and is believed to be a prototype of metabolic antagonists in general, although the evidence in most other instances is by no means as definite as for succinic dehydrogenase and the succinate-malonate system.

Another example of what is believed by many to be an instance of competitive inhibition is found in the action of the sulfonamides on bacteria. In studying the action of sulfanilamide on certain bacteria, Woods²⁰ found that the growth-inhibiting effect of this compound could be reversed by a substance present in yeast extracts. This substance was believed to be structurally similar to sulfanilamide, so a number of structural analogs were tested for their antisulfanilamide activity. Of these, p-aminobenzoic acid ("PABA") proved to be remarkably effective; the structural similarity of this compound to sulfanilamide is evident from a comparison of their structures:

On the basis of his results, Woods suggested that p-aminobenzoic acid should prove to be an essential growth factor for bacteria, and this was later shown to be the case. Whatever merits or demerits the concept of structural analogy in its relation to cell metabolism may have, in this instance at least it led directly to two outstanding contributions to scientific knowledge.

Titration with suitable bacteria has shown that it requires about 23,000 molecules of sulfanilamide to inhibit the effect of 1 molecule of PABA; thus the so-called "molar inhibition ratio" is 23,000 in this instance. Within certain limits, this ratio is independent of the actual amounts of the two substances present, and this is one of the characteristics of true competitive inhibition. As in the case of succinic and malonic acids mentioned previously, sulfanilamide and PABA cannot possibly react with each other, i.e. undergo mutual inactivation. Therefore inhibition must ultimately be in terms of a third reacting molecule or cell component. The high molar inhibition ratio has led some to doubt that a simple competition with a third type of molecule is the explanation for the antagonistic effects of sulfanilamide and PABA, and it must be admitted that there are many difficulties in the way of accepting such a simple theory as a general explanation for metabolic antagonism, as the subsequent discussion will demonstrate. It appears likely, however, that when more knowledge is gained concerning cell permeability, adsorption at surfaces and other factors determining local concentration, interrelated protoplasmic reactions, and other aspects of biological behavior, these difficulties may prove to be more quantitative than qualitative.

²⁰ Woods: Brit. J. Exptl. Path., 21, 74 (1940).

There is another type of inhibition of biological systems and its reversal which has not always been recognized as being somewhat different from the type described here. This is the condition in which an inhibition of enzymatic or cellular activity by one substance is reversed, i.e., the activity is restored, by the addition of a second substance which is capable of reacting directly with the inhibitor. For example, many compounds are known which react with the sulfhydryl group (-SH). Certain of these compounds will inactivate biological systems, and the activity may be regenerated by adding an excess of a second substance which contains sulfhydryl groups, such as cysteine or mercaptoacetic acid. It is to be noted, however, that the substance which overcomes the inhibition is not necessarily a constituent of the biological system being acted upon by the inhibitor, and the reversal of inhibition is essentially one of neutralizing the activity of the inhibitor by reacting directly with it. While this type of study may suggest the kind of compounds or active groups which function in biological systems, it is clearly different from metabolic antagonism as described here.

In the following pages examples are given of what appears to be metabolic antagonism between structurally related compounds. It must be recognized that in practically all instances the precise mode of action of even the normal metabolite is relatively unknown; the action of the antagonist, therefore, can only be a subject for speculation. There is, nevertheless, a fundamental similarity in action between all of the substances to be described, in that their inclusion in a normally functioning biological system leads to signs of a deficiency which resembles that produced by a lack of the normal metabolite concerned, and which can be overcome by the presence of sufficient amount of the latter. The substances to be discussed include structural analogs of the naturally occurring amino acids, vitamins, and hormones.

ANALOGS OF AMINO ACIDS

Methionine and Ethionine. In 1938 Dyer²¹ reported from du Vigneaud's laboratory that the S-ethyl analog of methionine, called ethionine, appeared to be toxic to rats on a low-cystine low-methionine diet, whereas in the presence of sufficient methionine loss of growth and death did not occur.

²¹ Dyer: J. Biol. Chem., 124, 519 (1938).

ANALOGS OF VITAMINS

Thiamine and Pyrithiamine. Pyrithiamine is the pyridine analog of thiamine, obtained by replacing the —S— group in the thiazole ring of thiamine (see p. 1062 for structure) by —CH—CH—; the structural relationship is thus similar to that between thienylalanine and phenylalanine (p. 1210).

$$\begin{array}{c|ccccc} & CH_3 \\ N=CNH_2 & C=C-CH_2\cdot CH_2OH \\ & & CH \\ H_3CC & C-CH_2-N & CH \\ & & N-CH & HC-CH \end{array}$$

Pyrithiamine

Pyrithiamine was found by Robbins²⁸ to be inhibitory to the growth of certain microörganisms which required an exogenous supply of thiamine for growth, and Woolley and White²⁹ showed that the feeding of pyrithiamine to mice produced a severe deficiency which resembled that of thiamine deficiency and which could be overcome by the administration of thiamine; one molecule of thiamine was required for approximately 40 molecules of pyrithiamine. This is one of the earliest instances of a deficiency disease produced in animals by the administration of a structural analog of a vitamin.

Studies on the inhibition of growth of microörganisms by pyrithiamine have revealed that the substance is inhibitory only in those instances where the organism requires an external supply of thiamine. If the organism is capable of synthesizing thiamine from the constituents of the medium, pyrithiamine is not inhibitory to growth. This emphasizes the point already made (p. 1211) that structural analogy per se is not necessarily the sole factor in determining whether or not competitive inhibition will occur, particularly in the complex metabolic processes of living protoplasm. One interesting example has been presented of a strain of yeast which became resistant to the inhibitory effect of pyrithiamine apparently by the development of a system which permitted liberation of the pyrimidine portion of the molecule and its subsequent utilization in the synthesis of thiamine itself.³⁰

Certain other structural analogs of thiamine have likewise been shown to be antagonistic to thiamine; for example, oxythiamine, in which the NH₂ of thiamine is replaced by OH. The thiamine molecule is particularly susceptible to such chemical modification, consisting as it does of two reactive portions, the pyrimidine moiety and the thiazole portion.

Pantothenic Acid and Pantoyltaurine. The substitution of the carboxyl group of pantothenic acid (see p. 1107 for structure) by the sulfonic acid group³¹ produces a substance known as pantoyltaurine (or thiopanic acid):

²⁸ Robbins: Proc. Nat. Acad. Sci., 27, 419 (1941).

²⁹ Woolley and White: J. Biol. Chem., 149, 285 (1943).

²⁰ Woolley: Proc. Soc. Exptl. Biol. Med., 55, 179 (1944).

³¹ Snell: J. Biol. Chem., 139, 975 (1944).

$$\begin{array}{c} \mathrm{CH_3} \\ \downarrow \\ \mathrm{HOCH_2-C-CHOH-CO-NH-CH_2-CH_2-SO_3H} \\ \downarrow \\ \mathrm{CH_3} \end{array}$$

Pantoyltaurine

This substance and related compounds, e.g. the amide, have been shown to be antagonistic to pantothenic acid for a variety of microörganisms; growth inhibition caused by pantoyltaurine can be overcome in most instances by pantothenic acid, and the inhibition appears to be truly competitive in nature. As with thiamine and pyrithiamine, pantoyltaurine is not inhibitory to the growth of those microörganisms which can synthesize the pantothenic acid they need.

Pantoyltaurine has not as yet been shown to produce unequivocal signs of a pantothenic acid deficiency in animals, probably because of the relatively large amounts which would be required to compete successfully with the pantothenic acid present in animal tissues. Some success has been obtained in the use of pantoyltaurine as a chemotherapeutic agent in rats infected with an organism susceptible to inhibition by pantoyltaurine, but here again the doses required were so large as to indicate little practical application of this fact. The possibility remains open, however, that further studies along these lines may produce more effective substances. As with thiamine, the presence of two chemically distinct portions in the pantothenic acid molecule has permitted the synthesis of a variety of structural analogs other than pantoyltaurine, and certain of these appear to be effective in inhibiting the growth of microörganisms in a manner similar to that described for pantoyltaurine.

Riboflavin and Analogs. Various structural analogs of riboflavin have been synthesized which appear to be metabolic antagonists of the naturally occurring vitamin. One of these is isoriboflavin, in which the two methyl groups are in the 5,6 positions instead of in the 6,7 positions as in the naturally occurring vitamin:

5,6-dimethyl-9-(d-1'-ribityl)-isoalloxazine (Isoriboflavin)

Isoriboflavin was shown by Emerson and Tishler³² to inhibit the growth of rats on a diet containing a suboptimal intake of riboflavin, and this growth inhibition was overcome by the feeding of an adequate level of riboflavin. Previously, Kuhn, Weyand, and Möller³³ had shown that another analog of riboflavin, containing chlorine in the 6,7 positions instead of methyl, competed with riboflavin in the metabolism of certain bacteria. Woollev³⁴ has shown that if the riboflavin molecule is modified by substituting a 2,4 diaminobenzene ring for the pyrimidine portion of the vitamin, a compound is obtained which causes typical riboflavin deficiency in mice, the effect being overcome by the presence of sufficient riboflavin in the diet.

Nicotinic Acid and Analogs. Analogs of nicotinic acid which appear to act as competitive antagonists of the latter have been obtained by replacing the carboxyl group of nicotinic acid with either the sulfonic acid group or the acetyl group:

The analogous amides have also been studied. The sulfonic acid analog produces inhibition of growth of certain microörganisms which can be overcome by nicotinic acid,35 but is apparently without effect on animals.36 As with certain other inhibitors already discussed, pyridine sulfonic acid is without effect on those species of microorganisms which can synthesize nicotinic acid, again suggesting that cell penetration or local concentration may be as important as simple structural analogy in explaining the action of metabolic antagonists. The acetylpyridine analog of nicotinic acid brings about reversible signs of nicotinic acid deficiency in mice and dogs, but is without effect on those microorganisms which have been studied.37

Ascorbic Acid and Glucoascorbic Acid. It was shown by Woolley and Krampitz³⁸ in 1943 that a synthetic compound called glucoascorbic acid produced scurvy-like symptoms when fed to mice. These symptoms could not be cured when ascorbic acid was also included in the diet, but disappeared when the glucoascorbic acid was omitted. It will be recalled that mice do not require ascorbic acid in the diet, apparently being capable of synthesizing the amount they need. In the case of the guinea pig, however, which develops scurvy on diets free from ascorbic acid, Woolley has reported that typical symptoms of scurvy are produced on diets containing glucoascorbic acid, and ascorbic acid counteracts this effect.

³² Emerson and Tishler: Proc. Soc. Exptl. Biol. Med., 55, 184 (1944).

²³ Kuhn, Weyand, and Möller: Ber., 76, 1044 (1943).

²⁴ Woolley: J. Biol. Chem., 154, 31 (1944). ²⁵ McIlwain: Brit. J. Exptl. Path., 21, 136 (1940).

³⁴ Woolley and White: Proc. Soc. Exptl. Biol. Med., 52, 106 (1943).

²⁷ Woolley: J. Biol. Chem., 157, 455 (1945).

³⁸ Woolley and Krampitz: J. Exptl. Med., 78, 333 (1943).

The structural relationship between ascorbic acid and glucoascorbic acid is evident from the following:

It appears likely that the relation between ascorbic acid and glucoascorbic acid is one of metabolic antagonism, although the evidence is more limited than for most other examples of this phenomenon. It is of interest to note that glucoascorbic acid appears to present an almost unique example of a synthetic compound used for the development of a nutritional deficiency in a species of animal where such deficiency had not previously been shown to occur.

Vitamin K and Analogs. Two examples of what appears to be competition between vitamin K and structural analogs are found in the cases of dicoumarol and α -tocopheryl quinone; the relation between the structures of these compounds and that of vitamin K is as follows:

The structural relationship between vitamin K and α -tocopheryl quinone is more apparent than that between the former and dicoumarol; on inspection, however, it may be seen that this latter involves primarily a substitution of a carbon atom in one of the ring systems of vitamin K

by an oxygen atom. It is to be noted that this structural analogy did not become apparent until in retrospect it was realized that the administration of dicoumarol to animals produced symptoms of a vitamin-K deficiency. Thus Overman, Field, Baumann, and Link³⁹ showed that rats fed dicoumarol developed a hypoprothrombinemia, as in vitamin-K deficiency, and that this effect was greatest on diets low in vitamin K. Administration of vitamin K in any of its various forms overcame the deficiency. While the quantitative relationship between vitamin K and dicoumarol is not so satisfactory from the point of view of competitive inhibition as in other instances, it appears likely that these two compounds are antagonistic to each other. The difficulties in this connection are more readily appreciated when it is recalled that practically nothing is known concerning the mode of action of vitamin K on prothrombin formation or activity.

A possible antagonism between vitamin K and α -tocopheryl quinone was discovered by Woolley⁴⁰ in an attempt to produce tocopherol deficiency by the use of the quinone analog. Although typical signs of tocopherol deficiency were observed in pregnant mice after the administration of the tocopheryl quinone (death and resorption of the embryos during the latter part of the gestation period), these effects could not be reversed by tocopherol itself. It was found, however, that vitamin K in small amount prevented the appearance of the deficiency symptoms. It is to be noted that the animals did not show the hypoprothrombinemia characteristic of vitamin-K deficiency but did show hemorrhage in the reproductive system. Thus the biological relationship between vitamin K and α -tocophervl quinone is complicated and obscure, even though structural considerations indicate the possibility of metabolic antagonism. At the same time, such studies as these may ultimately lead to a more complete understanding of the mode of action of those vitamins whose function is as yet unknown.

Biotin and Analogs. A variety of structural analogs of biotin have been prepared, some of which appear to be antagonists of biotin action, i.e., antibiotins, under certain circumstances. Interest in the preparation and possible biological activity of biotin analogs is partly due to the hope that knowledge so gained may aid in an understanding of the mode of action in biological systems of biotin itself, which at the present time is quite obscure despite the known and extraordinary biological potency of this vitamin. The relation to biotin of some analogs of biotin which have been shown by Dittmer and du Vigneaud⁴¹ to have antibiotin activity is as follows:

²⁹ Overman, Field, Baumann, and Link: J. Nutr., 23, 589 (1942).

⁴⁰ Woolley: J. Biol. Chem., 159, 59 (1945).

⁴¹ Dittmer and du Vigneaud: Science, 100, 129 (1944).

Evidence for competition between biotin and its structural analogs has been obtained largely by the use of yeast and bacteria. Inhibition of growth of microörganisms by the three structural analogs whose formulas are given is overcome in each case by the presence of an excess of biotin, but the three differ among themselves in antibiotin potency and likewise show some differences with different microörganisms. Desthiobiotin for example inhibits the growth of L. casei but for yeast is a growth stimulant, i.e., it replaces biotin. It is probable that this is due to the ability of the yeast cell to convert desthiobiotin into biotin. Biotin sulfone is inhibitory to the growth of both yeast and L. casei, as is imidazolidone caproic acid, and this inhibition is reversed by biotin. It is interesting to note that all of the antibiotins mentioned combine with avidin (see p. 1117).

Another group of synthetic structural analogs of biotin has been described by English, *et al.*⁴³ The most potent in the group, in terms of the inhibition of growth of *L. casei*, has the following structure:

⁴² Dittmer, Melville, and du Vigneaud: Science, **99**, 203 (1944). See also Tatum: J. Biol. Chem., **160**, 455 (1945).

⁴³ English, Clapp, Cole, Halverstadt, Lampen, and Roblin: J. Am. Chem. Soc., 67, 295 (1945).

 γ -3,4-Ureylene-cyclohexyl-butyric acid

Other members of the series differ from the structure shown in the type of main ring system and the length of the side chain. Practically all of the compounds described act as antibiotins against either yeast or *L. casei*, but with varying effectiveness, and in every case the inhibition of growth is overcome by the presence of sufficient biotin.

ANALOGS OF HORMONES

Relatively little is known concerning the existence of structural antagonism among the various hormones of known structure. The various protein hormones are of course out of consideration in this connection because their structures are not known; the concept of an "antihormone" for a protein hormone has an immunological connotation rather than one of structural analogy. Among the hormones of known structure, it has been pointed out by Woolley that the naturally occurring estrogens and androgens are structural analogs of each other, and it is suggested that the known instances of biological antagonism between these two groups of compounds may be related to structural similarity and competitive properties. Woolley has also cited as an instance of structural antagonism the interesting findings of Kuhn⁴⁴ in connection with the sex hormones of algae. Kuhn showed that the two sex hormones were not different compounds but *cis* and *trans* modifications of the same compound. The factor determining sex was the ratio between these two forms.

Another probable example of structural analogy is found in the case of the synthetic compound diethylstilbestrol. If the structure of this compound is compared with those of the sex hormones (see p. 689), the possibility of an explanation of the hormonal activity of diethylstilbestrol in terms of structural analogy or competition becomes evident, although there is no experimental evidence as yet to support this view.

It appears likely, therefore, that as further knowledge is gained in the field of hormone chemistry and physiology, the existence of competitive inhibition and modification of biological action by structural differences may become as firmly established for some of the hormones as it now is for vitamins and specific amino acids.

ANALOGS OF OTHER METABOLITES

In addition to the specific examples which have been cited of metabolic antagonism between naturally occurring metabolites and synthetic struc-

44 Kuhn: Angew. Chem., 53, 1 (1940).

tural analogs, the concept is rapidly being applied to other classes of compounds of biological importance, such as purines, porphyrins, choline and related compounds, amines, etc. A detailed consideration of these appears unprofitable at this time; references to certain of them will be found in the reviews by Welch and by Woolley cited in the Bibliography. There is no doubt, however, but that the field of structural analogs and metabolic antagonism is becoming of fundamental importance not only in biochemistry but in related subjects such as pharmacology and medicine.

Appendix

I. REAGENTS AND SOLUTIONS

REAGENTS FOR PARTICULAR METHODS ARE DESCRIBED IN THE TEXT AND FOOTNOTES FOR THESE METHODS.

SEE INDEX

Acid Digestion Mixture. To 50 ml. of 5 per cent copper sulfate solution add 300 ml. of 85 per cent phosphoric acid and mix. Add 100 ml. of concentrated sulfuric acid (NH $_3$ -free) and mix. Keep in a glass-stoppered bottle, protected against the absorption of ammonia from laboratory atmosphere.

Alcohol-Ether Mixture. Mix three volumes of 95 per cent redistilled alcohol and 1 volume of redistilled ether.

Alizarin. A 1 per cent solution of alizarin mono-sodium sulfonate in water.

Alkaline Pyrogallate Reagent. Prepare a solution of potassium hydroxide by dissolving 160 g. in 130 ml. of water. In 200 ml. of this solution dissolve 10.0 g. of pyrogallic acid.

Almén's Reagent. Prepare by dissolving 5 g. of tannic acid in 240 ml. of 50 per cent alcohol and adding 10 ml. of 25 per cent acetic acid.

Aluminum Hydroxide Cream. To a 1 per cent solution of ammonium alum at room temperature add a slight excess of a 1 per cent solution of ammonium hydroxide. Wash by decantation until the wash water shows only the faintest trace of residue on evaporation. For the preparation of other forms of alumina see p. 286.

o-Aminobenzaldehyde Reagent. Mix 3 g. of crystalline o-nitrobenzaldehyde with 50 g. of crystalline ferrous sulfate. Add 75 ml. of concentrated ammonia. Heat on a steam bath for one hour. Distil off the o-aminobenzaldehyde with steam. The mixture before distillation will keep for two weeks.

Ammoniacal Silver Solution. Dissolve 26 g. cf silver nitrate in about 500 ml. of water, add enough ammonium hydroxide to redissolve the precipitate which forms upon the first addition of the ammonium hydroxide, and make the volume of the mixture up to 1 liter with water.

Ammonium Molybdate Solution. See Molybdate Solution, p. 1229. Ammonium Thiocyanate Solution. This solution is made of such a strength that 1 ml. of it is equal to 1 ml. of the standard silver nitrate solution mentioned below. To prepare the solution dissolve 12.9 g. of ammonium thiocyanate, NH₄SCN, in a little less than a liter of water. In a small flask place 20 ml. of the standard silver nitrate solution, 5 ml. of a cold saturated solution of ferric alum, and 4 ml. of nitric acid (sp. gr. 1.2), add water to make the total volume 100 ml., and thoroughly mix the contents of the flask. Now run in the ammonium thiocyanate solution from a buret until a permanent red-brown tinge is produced. This is the end-reaction and indicates that the last trace of silver nitrate

has been precipitated. Take the buret reading and calculate the amount of water necessary to use in diluting the ammonium thiocyanate in order that 10 ml. of this solution may be exactly equal to 10 ml. of the silver nitrate solution. Make the dilution and titrate again to be certain that the solution is of the proper strength.

Antifoaming Oil Mixture (Use like caprylic alcohol). To 1 volume of crude fuel oil add about 10 volumes of toluene.

Asbestos for Suction Filters. The asbestos is shredded, placed in a wide mouth flask, and covered with 10 per cent HCl. Heat on a water bath for five hours. Filter on a Buchner funnel, wash free from acid, return to the flask, cover with 5 per cent NaOH, and heat on a water bath for three hours. Filter, wash free from alkali, then with dilute acid and finally with water until free from acid. Suspend in a large volume of water, allowing it to settle for five minutes. Pour off the upper two-thirds and discard. Repeat the washing of the desired coarse portion several times until the supernatant liquid remains nearly clear.

Barfoed's Solution. Dissolve 13.3 g. of neutral, crystallized copper acetate in 200 ml. of water, filter if necessary, and add 1.8 ml. of glacial acetic acid.

Barfoed's Solution (Tauber-Kleiner Modification). Dissolve 24 g. of copper acetate (Merck, normal, c.p.) in 450 ml. of boiling water. If a precipitate forms, do not filter. Immediately add 25 ml. of 8.5 per cent lactic acid (Mallinckrodt, U.S.P., 85 per cent) to the hot solution. Shake; nearly all the precipitate will dissolve. Cool, dilute to 500 ml., and after sedimentation filter off the impurities.

Baryta Mixture. A mixture consisting of 1 volume of a saturated solution of barium nitrate and 2 volumes of a saturated solution of barium hydroxide.

Basic Lead Acetate Solution. This solution possesses the following formula:

Lead acetate	180 g.
	110 g.
Distilled water to make	1000 g.

Dissolve the lead acetate in about 700 ml. of distilled water, with boiling. Add this hot solution to the finely powdered lead oxide and boil for one-half hour with occasional stirring. Cool, filter, and add sufficient distilled water to the filtrate to make the weight 1 kg.

Benedict's Solution. Benedict's modification of the Fehling solution, which does not deteriorate upon long standing, has the following composition:

Copper sulfate	17.3 g.
Sodium citrate	173.0 g.
Sodium carbonate	100.0 g.
Distilled water to make	1 liter

With the aid of heat dissolve the sodium citrate and carbonate in about 800 ml. of water. Pour (through a folded filter paper if necessary) into a glass graduate and make up to 850 ml. Dissolve the copper sulfate in about 100 ml. of water. Pour the carbonate-citrate solution into a large

beaker or casserole, and add the copper sulfate solution slowly, with constant stirring, and make up to 1 liter. The mixed solution is ready for use and does not deteriorate upon long standing.

Benedict's Quantitative Sugar Reagent.

Copper sulfate (crystallized)	18.0 g.
Sodium carbonate (crystallized, one-half the weight of the	J
anhydrous salt may be used)	200.0 g.
Sodium or potassium citrate	200.0 g.
Potassium thiocyanate	125.0 g.
Potassium ferrocyanide (5 per cent solution)	
Distilled water to make a total volume of	1000.0 ml.

With the aid of heat dissolve the carbonate, citrate, and thiocyanate in enough water to make about 800 ml. of the mixture and filter if necessary.

Dissolve the copper sulfate separately in about 100 ml. of water and pour the solution slowly into the other liquid, with constant stirring. Add the ferrocyanide solution, cool, and dilute to exactly 1 liter. Of the various constituents, the copper salt only need be weighed with exactness. Twenty-five ml. of the reagent are reduced by 50 mg. of glucose.

Benedict's Sulfur Reagent.

Crystallized copper nitrate, sulfur-free or of known sulfur	
content	200 g.
Sodium or potassium chlorate	50 g.
Distilled water to	1000 ml.

Benzidine Solution. Place 4.33 ml. of glacial acetic acid in a small Erlenmeyer flask, warm to 50°, and add 0.5 g. of benzidine. Heat the flask for eight to ten minutes in water at 50°. To the resultant solution add 19 ml. of distilled water. This solution may be kept for several days without deterioration.

Bial's Reagent.

Orcinol	1.5 g.
Concentrated HCl	$500 \mathrm{\ ml}.$
Ferric chloride (10 per cent)	20-30 drops

 α , α' -Bipyridine Solution. Dissolve 0.2 g. of α , α' -bipyridine (Edwal Laboratories, 732 Federal St., Chicago) in 100 ml. of 10 per cent acetic acid.

Biuret Paper (Kantor and Gies). Immerse filter paper in Gies' Biuret Reagent (below), then dry and cut into strips.

Biuret Reagent (Gies). This reagent consists of 10 per cent KOH solution to which 25 ml. of 3 per cent CuSO₄ solution per liter have been added. This imparts a slight though distinct color to the clear liquid.

Biuret Reagent (Welker). Add 1 per cent copper sulfate solution, drop by drop, with constant stirring, to some 40 per cent sodium hydroxide solution until the mixture assumes a deep blue color.

Black's Reagent. Make by dissolving 5 g. of ferric chloride and 0.4 g. of ferrous chloride in 100 ml. of water.

Boneblack, Purification of. Treat 250 g. of commercial boneblack with 1500 ml. of 1:4 HCl solution. Boil for half an hour. Filter the bone-

black from the acid solution by means of a Buchner funnel and aspirating pump. Wash with hot water until the washings are neutral to litmus paper. Dry and powder.

Bromine Water. Add a few drops of liquid bromine (Caution! Very corrosive!) to about 100 ml. of H₂O, and shake. Prepare fresh when reagent becomes colorless.

Buffer Solutions, Standard. See pp. 23 to 26.

Carmine-fibrin. Run fibrin through a meat chopper, wash carefully, and place in a 0.5 per cent ammoniacal carmine solution (1 g. of carmine dissolved in 1 ml. of ammonia and diluted to 200 ml.) for 24 hours or until the maximum coloration of the fibrin (a dark red) is obtained. The fibrin is then washed in water and water acidified with acetic acid. It is preserved under glycerol.

Cleaning Solution. To a few grams of sodium bichromate crystals dissolved in a minimum quantity of water, add about 500 ml. of concentrated sulfuric acid (technical grade is satisfactory).

Cochineal Solution. A saturated solution of cochineal in 30 per cent alcohol.

Congo Red. Dissolve 0.5 g. of Congo red in 90 ml. of water and add 10 ml. of 95 per cent alcohol.

Congo Red-Fibrin. This may be prepared by placing fibrin in faintly alkaline Congo red solution and heating to 80° C. The fibrin is then washed and preserved under glycerol.

Copper Sulfate Solutions for Specific Gravity Determination.

A. Saturated Copper Sulfate Solution. Place 4 lb. of "fine crystals," or pulverized CuSO₄·5H₂O, in a 4 liter bottle, and add about 2.5 liters of distilled water. Stopper and shake vigorously for 5 minutes. Immediately at the close of the shaking period, insert a thermometer into the solution and record the temperature to the nearest half degree Centigrade. When this has been done, immediately decant the supernatant solution from the excess solid, then clarify by filtration through cotton or a dry filter paper into a clean dry bottle. This solution, which has been saturated with copper sulfate at a known temperature and is therefore of known composition, is used at once to make up a stock copper sulfate solution of sp. gr. 1.100.

B. STOCK COPPER SULFATE SOLUTION OF SP. GR. 1.100. From the table (p. 1225) determine the volume of saturated copper sulfate solution which is to be diluted to 1 liter to prepare a solution of sp. gr. 1.100. Measure out the indicated volume of saturated copper sulfate solution into a 500-ml. graduated cylinder. Pour the cylinder contents into a 1-liter volumetric flask, allowing the cylinder to drain for 30 seconds. Dilute the flask contents to the mark with distilled water, stopper, and mix well by inversion. Because of a contraction in volume, the meniscus of the solution will now be somewhat below the mark. Allow to stand for one minute for drainage, then add enough distilled water to bring the meniscus again to the mark, stopper, and again mix well by inversion. Pour into a clean dry 4-liter bottle. Rinse the flask with distilled water, discarding the rinsings, and repeat the above preparation three more

Volume of Saturated Copper Sulfate Solution to Dilute to 1 Liter to Prepare Stock Solution of D $\frac{25}{25}$ = 1,1000

times, thus preparing 4 liters of stock copper sulfate solution of sp. gr. 1.100.

This stock solution, used for the preparation of the standards described below, should be labeled with its temperature at the time of preparation, since it may be used indefinitely provided the temperature at the time of use is within 5° C. of the temperature at the time of preparation.

C. STANDARD COPPER SULFATE SOLUTIONS OF KNOWN SPECIFIC GRAVITY. A 100-ml. portion of copper sulfate solution of any desired sp. gr. between 1.008 and 1.075, accurate to ± 0.0003 , may be prepared from the stock solution of sp. gr. 1.100 as follows: measure from a buret into a 100-ml. volumetric flask a volume of stock solution less by 1 ml. than the value represented by the second and third decimal places of the desired sp. gr. (For instance, if the desired sp. gr. is 1.055, 54 ml. of stock solution are taken; for a sp. gr. of 1.017, 16 ml. are taken and so on.)

After measuring out the stock solution, dilute the contents of the 100-ml. flask to the mark with distilled water and mix well. This solution may be used at any temperature within 15° to 20° of the temperature at preparation. Smaller portions than 100 ml. may be prepared by using proportionately reduced volumes.

Cross and Bevan's Reagent. Prepare by combining two parts of concentrated hydrochloric acid and one part of zinc chloride, by weight.

Digitonin Solution. Dissolve 1 g. of digitonin (Hoffmann-La Roche, Inc., Nutley, N. J.) in 1 liter of distilled water and place in a refrigerator for 24 hours. Filter. Concentrate the entire filtrate and make up to exactly 500 ml. (To hasten evaporation draw a rapid stream of air, filtered through cotton, over the surface of the solution in a tared flask, which is immersed in a boiling water bath until the desired weight is reached.)

Ehrlich's Aldehyde Reagent. A solution of p-dimethylaminobenzaldehyde acidified with HCl.

Ehrlich's Diazo Reagent. Two separate solutions should be prepared and mixed in definite proportions when needed for use.

- a. 5 g. of sodium nitrite dissolved in 1 liter of distilled water.
- b. 5 g. of sulfanilic acid and 50 ml. of hydrochloric acid in 1 liter of distilled water.

Solutions (a) and (b) should be preserved in well-stoppered vessels and mixed in the proportion 1:50 when required. It is said that greater delicacy is secured by mixing the solutions in the proportion 1:100. The sodium nitrite deteriorates upon standing and becomes unfit for use in the course of a few weeks.

Esbach's Reagent. Dissolve 10 g. of pieric acid and 20 g. of citric acid in 1 liter of water.

Exton's Reagent. Dissolve 200 g. of Na₂SO₄·10H₂O in 800 ml. of water. Cool to 35° and add 50 g. of sulfosalicylic acid. Dissolve and dilute to 1 liter.

Fehling's Solution. Fehling's solution is a mixture of copper sulfate solution and alkaline tartrate solution, prepared as follows:

Copper sulfate solution = 34.65 g. of copper sulfate dissolved in water and made up to 500 ml. Alkaline tartrate solution = 125 g. of potassium hydroxide and 173 g. of Rochelle salt dissolved in water and made up to 500 ml.

These solutions should be preserved separately in rubber-stoppered bottles and mixed in equal volumes when needed for use. This is done to prevent deterioration.

Ferric Hydroxide (Oxide) Suspension. Dissolve 100 g. of ferric ammonium sulfate in 200 ml. of water. Pour all at once with vigorous stirring into 800 ml. of a mixture containing 10.8 g. of ammonia and 27.5 g. of ammonium sulfate. Stir vigorously for one-half hour. Make to 4 liters with water. Let settle and decant. Repeat washing about 12 times, adding a few ml. of concentrated ammonia to first two wash waters.

Folin-McEllroy Reagent. Dissolve 100 g. of sodium pyrophosphate, 30 g. of disodium phosphate and 50 g. of dry sodium carbonate in approximately 1 liter of water by the aid of a little heat. Dissolve separately

13 g. of copper sulfate in about 200 ml. of water. Pour the copper sulfate solution into the phosphate-carbonate solution and shake.

Furfural Solution. Add 1 ml. of furfural to 1000 ml. of distilled water.

Fusion Mixture. 20 g. of sodium carbonate plus 10 g. of potassium nitrate.

Guaiac Solution. Dissolve 0.5 g. of guaiac resin in 30 ml. of 95 per cent alcohol.

Gum Ghatti Solution. Fill a liter cylinder with cold water. Just below the surface suspend a wire screen on which are placed 20 g. of soluble gum ghatti. Let stand 18 to 24 hours. Remove the screen and filter, or strain through clean cloth.

Günzberg's Reagent. Dissolve 2 g. of phloroglucinol and 1 g. of vanillin in 100 ml. of 95 per cent alcohol.

Haines' Solution. This solution may be prepared by dissolving 8.314 g. of copper sulfate in 400 ml. of water, adding 40 ml. of glycerol and 500 ml. of 5 per cent potassium hydroxide solution.

Hopkins-Cole Reagent. To 1 liter of a saturated solution of oxalic acid add 60 g. of sodium amalgam and allow the mixture to stand until the evolution of gas ceases. Filter and dilute with 2 to 3 volumes of water.

Hopkins-Cole Reagent (Benedict's Modification). Ten g. of powdered magnesium are placed in a large Erlenmeyer flask and shaken up with enough distilled water to liberally cover the magnesium. 250 ml. of a cold, saturated solution of oxalic acid are now added slowly. The reaction proceeds very rapidly and with the liberation of much heat, so that the flask should be cooled under running water during the addition of the acid. The contents of the flask are shaken after the addition of the last portion of the acid and then poured upon a filter, to remove the insoluble magnesium oxalate. A little wash water is poured through the filter, the filtrate acidified with acetic acid to prevent the partial precipitation of the magnesium on long standing, and made up to a liter with distilled water. This solution contains only the magnesium salt of glyoxylic acid.

Hübl's Iodine Solution. A solution of iodine and mercuric chloride used to determine iodine numbers of unsaturated compounds. (See Iodine Solution, Wijs).

Hydrochloric Acid Standard (0.1 N) Solution. See p. 808.

Hypobromite Solution. The ingredients of this solution should be prepared in the form of *two* separate solutions which may be united as needed.

- a. Dissolve 125 g. of sodium bromide in water, add 125 g. of bromine, and make the total volume of the solution 1 liter.
- b. A solution of sodium hydroxide having a specific gravity of 1.25. This is approximately a 22.5 per cent solution.

Preserve both solutions in rubber-stoppered bottles and when needed for use mix 1 volume of solution (a), 1 volume of solution (b), and 3 volumes of water.

Iodine Solution. Prepare a 2 per cent solution of potassium iodide and add sufficient iodine to color it a deep yellow.

Iodine Solution (0.1 N). Weigh 12.685 g. of pure resublimed iodine into a small weighing bottle using a porcelain spatula. Dissolve 18 g. of pure KI in about 150 ml. of water. Transfer the iodine to a liter flask, washing out the last traces with some of the KI solution, which is then poured into the flask. Stopper and shake occasionally until dissolved. If necessary, a few more crystals of KI may be added to aid solution. Dilute to the mark and mix well. Keep in a glass-stoppered bottle in a cool dark place. Standardize at once against 0.1 N sodium thiosulfate solution. Measure out accurately 25 ml. of the iodine solution into an Erlenmeyer flask, run in sodium thiosulfate until the color is pale yellow, then add a few ml. of a 1 per cent solution of starch (preferably soluble starch) and titrate to disappearance of blue color. Care should be taken near the end-point.

Iodine Solution (Wijs). Weigh into a 300-ml. flask 9.4 g. of iodine trichloride. Add about 200 ml. of glacial acetic acid. Stopper with a cork carrying a CaCl₂ tube and heat on the water bath until solution is complete. Rub 7.2 g. of iodine to a fine powder in a mortar, wash with glacial acetic acid into a second flask, and heat this in the same way to dissolve the iodine. Pour the contents of both flasks into a liter volumetric flask. Add glacial acetic acid. Measure 10 ml. of the solution into a 500-ml. Erlenmeyer flask. Add 10 ml. of 10 per cent KI and about 200 ml. of water. Titrate with standard sodium thiosulfate solution and determine the iodine equivalent of 1 ml. of the solution.

Iodine-Zinc Chloride Reagent. Dissolve 20 g. of ZnCl₂ in 8.5 ml. of water and, when cool, introduce the iodine solution (3 g. of KI and 1.5 g. of I in 60 ml. of water) drop by drop until iodine begins to precipitate.

Kraut's Reagent. Dissolve 272 g. of KI in water and add 80 g. of bismuth subnitrate dissolved in 200 g. of HNO₃ (sp. gr. 1.18). Permit the KNO₃ to crystalize out, then filter it off and make the filtrate up to 1 liter with water.

Lead Acetate, Basic. (See Basic Lead Acetate.)

Lime Water. Shake up an excess of calcium oxide or hydroxide with distilled water and leave well-stoppered over night. Decant clear supernatant solution and keep free from CO₂ of air.

Litmus-Milk Powder. Add 1 part of powdered litmus to 50 parts of dried milk powder. To make a litmus milk solution, add 1 part of this powder to 9 parts of water.

Lohmann's Reagent. Add 25 ml, of concentrated nitric acid to 100 g. of mercuric nitrate octahydrate, followed by 25 ml. of water. Warm to dissolve.

Lugol's Solution. Dissolve 5 g. of iodine and 10 g. of potassium iodide in 100 ml. of distilled water.

Magnesia Mixture. Dissolve 175 g. of magnesium sulfate and 350 g. of ammonium chloride in 1400 ml. of distilled water. Add 700 g. of concentrated ammonium hydroxide, mix thoroughly, and preserve the mixture in a glass-stoppered bottle.

Magnesium Nitrate Solution for Ignition. Dissolve 320 g. of calcined magnesia in nitric acid, avoiding an excess of the latter; then add

a little calcined magnesia in excess, boil, filter from the excess of magnesia, ferric oxide, etc., and dilute with water to 2 liters.

Methyl Orange. Dissolve 0.1 g. of methyl orange in 100 ml. of distilled water.

Methyl Red. Saturated solution in 50 per cent alcohol.

Milk of Lime. A 1.5 per cent suspension of CaO in water. To be labeled: "Shake before using."

Millon's Reagent. Digest 1 part (by weight) of mercury with 2 parts (by weight) of nitric acid (sp. gr. 1.42) and dilute the resulting solution with 2 volumes of water.

Molisch's Reagent. A 5 per cent alcoholic solution of α -naphthol.

Molybdate Solution. Dissolve 100 g. of molybdic acid in 144 ml. of ammonium hydroxide (sp. gr. 0.90) and 271 ml. of water; slowly and with constant stirring pour the solution thus obtained into 489 ml. of nitric acid (sp. gr. 1.42) and 1148 ml. of water. Keep the mixture in a warm place for several days, or until a portion heated to 40° C. deposits no yellow precipitate of ammonium phosphomolybdate. Decant the solution from any sediment and preserve in glass-stoppered bottles.

Mörner's Reagent. Prepare by thoroughly mixing 1 volume of formalin, 45 volumes of distilled water, and 55 volumes of concentrated sulfuric acid.

 α -Naphthol Solution. Dissolve 1 g. of α -naphthol in 100 ml. of 95 per cent alcohol.

Nessler's Reagent: (A) FORMULA OF FOLIN AND WU. Nessler's solution is an alkaline solution of the double iodide of mercury and potassium (Hgl₂·2KI). Into a 500-ml. Florence flask introduce 150 g. of potassium iodide and 100 g. of iodine; add 100 ml. of water and an excess of metallic mercury, 140 to 150 g. Shake the flask continuously and vigorously for 7 to 15 minutes or until the dissolved iodine has nearly all disappeared. The solution becomes quite hot. When the red iodine solution begins to become visibly pale, though still red, cool in running water and continue the shaking until the reddish color of the iodine has been replaced by the greenish color of the double iodide. The whole operation does not usually take more than 15 minutes. Decant the solution, washing mercury and flask with liberal quantities of distilled water. Dilute the solution and washings to 2 liters. If the cooling was begun in time, the resulting reagent is clear enough for immediate dilution with 10 per cent alkali and water and the finished solution can be used at once for nesslerization.

From this stock solution of potassium mercuric iodide prepare final Nessler's solutions as follows: Into a flask of at least 5 liters capacity introduce 3500 ml. of 10 per cent sodium hydroxide solution, add 750 ml. of the double iodide solution and 750 ml. of distilled water, making 5 liters of solution. The 10 per cent NaOH should be made from a saturated solution (containing about 75 g. per 100 ml.) which has been allowed to stand until the carbonate has settled, the clear solution being decanted and used. This solution should have been standardized with an accuracy of at least 5 per cent. Nessler's reagent should be used in the ratio of

10 ml. per 100 ml. of solution to be nesslerized, except where excessive amounts of acids are present, as in direct nesslerization procedures.

The alkalinity of the Nessler's reagent is important and may be checked by titrating with it 20 ml. portions of N HCl. A good end-point with phenolphthalein should be obtained at 11 to 11.5 ml. If as low as 9.5 ml. are required, the solution is too alkaline. One ml. of the dilute (1:1) acid digestion mixture should also require 9 to 9.3 ml. of Nessler's solution to neutralize it.

- (B) FORMULA OF KOCH AND McMeekin. Dissolve 22.5 g. of iodine in 20 ml. of water containing 30 g. of potassium iodide. After the solution is complete, add 30 g. of pure metallic mercury, and shake the mixture well, keeping it from becoming hot by immersing it in tap water from time to time. Continue this until the supernatant liquid has lost all of the yellow color due to iodine. Decant the supernatant aqueous solution and test a portion by adding a few drops thereof to 1 ml. of a 1 per cent soluble starch solution. Unless the starch test for iodine is obtained, the solution may contain mercurous compounds. To the remaining solution add a few drops of an iodine solution of the same concentration as employed above, until a faint excess of free iodine can be detected by adding a few drops thereof to 1 ml. of the starch solution. Dilute to 200 ml. and mix well. To 975 ml. of an accurately prepared 10 per cent sodium hydroxide solution now add the entire solution of potassium mercuric iodide prepared above. Mix thoroughly and allow to clear by standing.
- (c) Formula of Bock and Benedict. Place 100 g. of mercuric iodide and 70 g. of potassium iodide in a liter volumetric flask and add about 400 ml. of water. Rotate until solution is complete. Now dissolve 100 g. of NaOH in about 500 ml. of water, cool thoroughly and add with constant shaking to the mixture in the flask, then make up with water to the liter mark. This usually becomes perfectly clear. When the small amount of brownish-red precipitate which forms settles out, the supernatant fluid is ready to be poured off and used.

Neutral Olive Oil. Shake ordinary olive oil with a 10 per cent solution of sodium carbonate, extract the mixture with ether, and remove the ether by evaporation. The residue is neutral olive oil.

Neutral Red. A 1 per cent solution in 50 per cent alcohol.

p-Nitrophenol. A 1 per cent solution in 50 per cent alcohol.

Nylander's Reagent. Digest 2 g. of bismuth subnitrate and 4 g. of Rochelle salt in 100 ml. of a 10 per cent solution of potassium hydroxide. The reagent should then be cooled and filtered.

Obermayer's Reagent. Add 2 to 4 g. of ferric chloride to a liter of hydrochloric acid (sp. gr. 1.19).

Oxalic Acid Standard (0.1 N) Solution. See p. 807.

Permutit. A synthetic aluminum silicate obtained from the Permutit Company, New York. Only such preparations as pass through a 60-mesh sieve but not through an 80-mesh sieve should be used. It should give off very little dust or turbid material to water and settle in a few seconds. It may be used more than once by washing first with water, then with 2 per cent acetic acid and finally with water again.

Phenol Reagent (Folin and Ciocalteu). See p. 879.

Phenolphthalein. Dissolve 1 g. of phenolphthalein in 100 ml. of 95 per cent alcohol.

Phenylhydrazine Acetate Solution. This solution is prepared by mixing 1 volume of glacial acetic acid, 1 volume of water, and 2 volumes of phenylhydrazine (the base).

Phenylhydrazine Mixture. This mixture is prepared by combining 2 parts of phenylhydrazine hydrochloride and 3 parts of sodium acetate by weight. These are thoroughly mixed in a mortar. A mixture of better keeping quality may be made by mixing equal weights of the hydrochloride and anhydrous sodium acetate.

Phosphomolybdic Acid. Saturate some sodium carbonate solution with pure molybdic acid. Add 1 part of crystalline disodium phosphate to 5 parts of the acid and evaporate to dryness. Fuse in a porcelain dish at a dull red heat. Dissolve the sodium phosphomolybdate in 10 parts of water and add nitric acid until the solution turns a golden yellow color.

Phosphotungstic Acid. Dissolve 100 g. of sodium tungstate and 60 to 80 g. disodium phosphate in 500 ml. of water. Add nitric acid to an acid reaction.

Picric Acid, Pure. Picric acid as purchased contains 10 per cent of added water. By exposure to the air between large filter papers (best in a warm place) the water disappears by evaporation. Dry picric acid may be prepared in this way. If the alkaline picrate formed from this acid gives too deep a color, it may be purified as follows:

- A. RECRYSTALLIZATION OF PICRIC ACID FROM ACETIC ACID. Dissolve 100 g. of picric acid (previously thoroughly dried at 80 to 90° C.) with the aid of heat in 150 ml. of glacial acetic acid in an Erlenmeyer flask and continue the heating on an electric plate until the mixture boils. Pour the hot solution upon a fluted filter contained in a dry funnel which has been previously heated, and collect the filtrate in a dry beaker. Cover with a watch glass and let stand over night at room temperature. If crystallization fails to occur, seed with a small crystal of pure picric acid. At the end of two hours, filter with suction on a hardened filter, and wash with about 35 ml. of cold glacial acetic acid. Suck as free from acetic acid as possible and dry at about 80° to 90°, with occasional stirring, until there is no odor of acetic acid. Conduct operations in a good current of air.
- B. SODIUM PICRATE METHOD OF FOLIN. Transfer 500 g. of moist picric acid to a Florence flask of 1500 ml. capacity. Add 500 ml. of acetone. Shake, with a little warming under hot tap water, until all the crystals have dissolved. Add 20 g. of active charcoal (Norit). Shake, and filter into another flask. During this filtration keep the funnel closed with a watch glass to prevent evaporation.

Dissolve 250 g. of anhydrous sodium carbonate and 100 g. of sodium chloride in 2500 ml. of warm water in a 4-liter beaker. While stirring with an agate-ware spoon, add the acetone solution gradually to the alkaline salt solution. When the reaction (CO₂ evolution) is finished, let stand, preferably in cold water, for about 30 minutes, and filter on a large

Buchner funnel (diam. 20 cm.). Wash with about 2 liters of sodium chloride solution (7 per cent) and suck as dry as possible.

If the original picric acid is of good quality, the sodium picrate on the Buchner funnel will be pure, but it is a little safer to recrystallize it once as follows:

Return the precipitate to the 4-liter beaker and add 2 liters of boiling water and 20 g. of sodium carbonate. To the resulting hot solution add gradually, with stirring, 150 g. of sodium chloride, cool, filter, and wash as before with 7 per cent sodium chloride solution. Then wash once or twice with a more dilute sodium chloride solution (2 per cent) and finally wash once with methyl alcohol to remove most of the remaining chloride and water. Dry, either at room temperatures or over a radiator.

TEST FOR THE PURITY OF SODIUM PICRATE. Make 100 ml. of a 3 per cent solution. Transfer 5 ml. and 10 ml. to test tubes graduated at 25 ml. Dilute each to about 22 ml., add 2 ml. of 5 per cent sodium hydroxide, dilute to volume, mix, and let stand for 10 minutes. Then add 4 g. of powdered potassium chloride, mix by inversion for about 1 minute, filter on a 9-cm. quantitative filter paper, and compare the two filtrates in the colorimeter. If the picrate is pure, the two filtrates will have the same color.

PICRIC ACID. The process for the preparation of pure picric acid is exactly the same as described above, up to the final washing with methyl alcohol, except that hardened filter paper should be used on the Buchner funnel.

One simply converts the purified sodium picrate in the Buchner funnel into picric acid by treating it with dilute hydrochloric acid.

Prepare at least 2 liters of such acid (1 vol. of conc. acid to 4 vols. of water). Disconnect the filtering flask from the suction pump. Pour the acid over the picrate. Stir up the precipitate with a porcelain or glass spoon, so as to make sure that the acid has acted on it all. Use plenty of the acid. Unchanged picrate can be distinguished by its darker color. When no more picrate is visible, connect again with the suction pump, and filter to dryness. Then wash five or six times with cold distilled water and suck as dry as possible. Temperatures up to 90° C. can safely be used for the drying of picric acid.

Picric Acid. Saturated Solution. This may be prepared either by allowing district water to stand in contact with an excess of picric acid with occasional shaking, or by making a 1.2 per cent solution.

Potassium Mercuric Iodide. Dissolve 6.775 g. of dry crystalline mercuric chloride and 5 g. of potassium iodide separately in water. Mix. Dilute to 1000 ml.

Potassium Permanganate Standard (0.1 N) Solution. Dissolve 3.162 g. of pure potassium permanganate in a liter of distilled water, allow to stand a few days, and filter through glass wool. Standardize against 0.1 N oxalic acid solution or against pure dry sodium or potassium oxalate. One ml. of 0.1 N permanganate is equivalent to 6.7 mg. of sodium oxalate. (See also footnote 224, p. 590.)

Potassium Persulfate Solution (Saturated). Add 100 ml. of distilled water to 7 g. of pure potassium persulfate in a glass-stoppered bottle. Undissolved excess settles and compensates for loss by decomposition.

Ringer's Solution. To 960 ml. of 0.154 M NaCl solution add 20 ml. of 0.154 M KCl solution and 20 ml. of 0.11 M CaCl₂ solution.

Roberts' Reagent. Mix 1 volume of concentrated nitric acid and 5 volumes of a saturated solution of magnesium sulfate.

Rosenheim's Iodo-potassium Iodide Solution. Dissolve 2 g. of iodine and 6 g. of potassium iodide in 100 ml. of water. This is different from Lugol's solution where the proportion of iodine to potassium iodide is one to two.

Sahli's Reagent. This reagent consists of a mixture of equal parts of 48 per cent solution of potassium iodide and 8 per cent solution of potassium iodate.

Schweitzer's Reagent. To ten parts of ammonium hydroxide (sp. gr. 0.90), add three parts distilled water. To this mixture, add a slight excess of copper carbonate, shake vigorously and allow to stand over night. Siphon off the clear, supernatant liquid.

Selivanoff's Reagent. Dissolve 0.05 g. of resorcinol in 100 ml. of dilute (1:2) hydrochloric acid.

Sodium Acetate Solution. Dissolve 100 g. of sodium acetate in 800 ml. of distilled water, add 100 ml. of 30 per cent acetic acid to the solution, and make the volume of the mixture up to 1 liter with distilled water.

Sodium Alcoholate (0.1 N) Solution. The sodium alcoholate is made by dissolving 2.3 g. of cleaned metallic sodium in 1 liter of absolute alcohol. It may be standardized against pure benzoic acid in washed chloroform, or against 0.1 N HCl provided the alcoholate solution contains not more than traces of carbonate.

Sodium Alizarin Sulfonate. Dissolve 1 g. of sodium alizarin sulfonate in 100 ml. of water.

Sodium Cobaltinitrite Solution. Prepare according to Kramer and Tisdall as follows:

SOLUTION A. 25 g. of cobalt nitrate crystals are dissolved in 50 ml. of water and to this solution are added 12.5 ml. of glacial acetic acid.

Solution B. 120 g. of sodium nitrite (potassium-free) (Merck) are dissolved in 180 ml. of water. This gives a total volume of about 220 ml. To all of Solution A are added 210 ml. of Solution B. An evolution of nitric oxide gas occurs at once. Air is drawn through the solution until the gas has passed off. The reagent is placed in the ice chest and filtered each time before using. It will keep at least 1 month.

To 20 ml. of this sodium cobaltinitrite solution add 2 ml. of 40 per cent silver nitrate solution. Shake vigorously and filter to remove trace of insoluble precipitate.

Sodium Hydroxide (Saturated Solution). Shake up about 110 g. of best quality NaOH with 100 ml. of distilled water in a 300 ml. Erlenmeyer flask (Pyrex). Stopper and allow to stand for a couple of days or

until the sodium carbonate settles to the bottom leaving a clear solution of NaOH practically free from carbonate, and containing about 75 g. of NaOH per 100 ml.

Sodium Hydroxide Standard (0.1 N) Solution. See pp. 807 and 808. Sodium Thiosulfate Standard (0.1 N) Solution. Weigh out 25 g. of ordinary c.p. sodium thiosulfate or 24.83 g. of the pure dry recrystallized salt. Dissolve in water and dilute to a liter. Boiled distilled water must be used. Keep in a bottle with a siphon arrangement and carrying a sodalime tube to exclude CO₂. It is best standardized against acid potassium iodate KH(IO₃)₂. Weigh out accurately 0.3249 g. of acid potassium iodate. Dissolve in 50 ml. of water, heating gently if necessary. Transfer the solution to a 100-ml. flask, rinsing the beaker carefully and make to mark with water. This solution is exactly decinormal. Pipet 25 ml. into an Erlenmeyer flask, add 1 g. of potassium iodide dissolved in a little water, and a few cubic centimeters of dilute hydrochloric acid. Titrate immediately with the thiosulfate solution. When the solution becomes pale yellow add a few ml. of 1 per cent solution of soluble starch and titrate to loss of blue color.

Sodium Tungstate Solution. A 10 per cent solution of sodium tungstate in water. The c.p. sodium tungstate made by the J. T. Baker Chemical Co., Phillipsburg, N. J., or by the Mallinckrodt Chemical Co., St. Louis, Mo., is satisfactory. (See also p. 512). If not easily soluble, prepare a hot 10 per cent solution, cool, and titrate 25 ml., with 10 per cent NaOH and phenolphthalein, to a pink color which lasts for three minutes. Add a proportional amount of NaOH to the main solution.

Soluble Starch. Suspend 3 g. of raw potato starch in 100 ml. of redistilled 95 per cent alcohol, add 0.75 ml. of concentrated HCl, and heat on a boiling water bath with a reflux condenser for exactly ten minutes. Add at once an amount of normal sodium bicarbonate solution just sufficient to neutralize 0.75 ml. of the acid, using methyl orange as indicator. Decant through a filter and wash with several portions of alcohol. Dry at room temperature, sieve and preserve.

Soluble Starch Solution. A solution of soluble starch suitable for most iodometric titrations and with good keeping qualities is made according to Pincussen by dissolving 1 g. of soluble starch in 10 ml. of boiling water and adding to 90 ml. of saturated NaCl solution.

Starch-Iodic Acid Test Paper. This test paper is prepared as follows: Saturate a good quality of filter paper with 0.5 per cent starch paste to which has been added sufficient iodic acid to make a 1 per cent solution of iodic acid and allow the paper to dry in the air. Cut it in strips of suitable size and preserve for use.

Starch Paste. Grind 2 g. of starch powder in a mortar with a small amount of water. Bring 200 ml. of water to the boiling point and add the starch mixture from the mortar with continuous stirring. Bring again to the boiling point and allow it to cool. This makes an approximate 1 per cent starch paste which is a very satisfactory strength for general use.

Stoke's Reagent. A solution containing 2 per cent ferrous sulfate and 3 per cent tartaric acid. When needed for use a small amount should be placed in a test tube and ammonium hydroxide added until the pre-

cipitate which forms on the first addition of the hydroxide has entirely dissolved. This produces ammonium ferrotartrate, which is a reducing agent.

Sulfuric Acid, N/12. Add 2.5 ml. of concentrated sulfuric acid to a liter of distilled water. Standardize against alkali of known strength. (See p. 494.)

Sulfuric Acid, Two-thirds Normal. Add 35 g. of concentrated c.p. sulfuric acid to a liter of distilled water. Standardize against alkali of known strength.

Takayama's Solution. A mixture of 3 ml. of 10 per cent NaOH, 3 ml. of pyridine, 3 ml. of saturated solution of glucose and 7 ml. of water. The solution works rapidly in the cold if at least 24 hours old. With a fresh solution warming or more time is necessary. It keeps for one to two months.

Tannic Acid. A freshly prepared 5 per cent aqueous solution.

Tanret's Reagent. Dissolve 1.35 g. of mercuric chloride in 25 ml. of water, add to this solution 3.32 g. of potassium iodide dissolved in 25 ml. of water, then make the total solution up to 60 ml. with distilled water and add 20 ml. of glacial acetic acid to the mixture.

Tincture of Iodine. Dissolve 70 g. of iodine and 50 g. of potassium iodide in 50 ml. of distilled water. Dilute to 1000 ml. with 95 per cent alcohol.

Töpfer's Reagent. Dissolve 0.5 g. of dimethylaminoazobenzene in 100 ml. of 95 per cent alcohol.

Tropeolin 00. Dissolve 0.05 g. of tropeolin 00 in 100 ml. of 50 per cent alcohol.

Tungstate-Molybdate Reagent. To 10 g. of pure, NH_3 -free, molybdic acid in a flask add 50 ml. of N sodium hydroxide and boil gently for three to five minutes. Add about 150 ml. of water. Filter the hot solution and add to the filtrate a solution of 80 g. of sodium tungstate dissolved in about 600 ml. of water. Dilute to 1000 ml.

Uffelmann's Reagent. Add a 5 per cent solution of ferric chloride to a 1 per cent solution of phenol until an amethyst-blue color is obtained.

Uranium Acetate Solution. Dissolve about 35.0 g. of uranium acetate in 1 liter of water with the aid of heat and 3 to 4 ml. of glacial acetic acid. Let stand a few days and filter. Standardize against a phosphate solution containing 0.005 g. of P_2O_5 per ml. For this purpose dissolve 14.721 g. of pure air-dry sodium ammonium phosphate (NaNH₄-HPO₄ + 4H₂O) in water to make a liter. To 20 ml. of this phosphate solution in a 200-ml. beaker add 30 ml. of water and 5 ml. of sodium acetate solution (see p. 1233) and titrate with the uranium solution to the correct end-reaction as indicated in the method proper, p. 891. If exactly 20 ml. of uranium solution are required 1 ml. of the solution is equivalent to 0.005 g. of P_2O_5 . If stronger than this dilute accordingly and check again by titration.

Wiis Iodine Solution. See under Iodine Solutions.

Winkler's Reagent. Cuprous chloride 40 g., ammonium chloride 50 g., distilled water to 150 ml. For use mix this solution with ammonium hydroxide (sp. gr. 0.9) in the proportion of 3:1.

II. USEFUL INFORMATION CONCERNING COMMON LABORATORY ACIDS AND ALKALIES

Substance	Specific Gravity (at Room Temperature)	Per Cent by Weight	A pproximate Normality

III. COMPOSITION OF FOODS

TABLE OF FOOD COMPOSITION*

EXPLANATION OF TABLE AND TERMS

This table was prepared on a 100-g. basis, since most original data are reported on this basis. For the sake of uniformity the mineral values and the values for all the vitamins except vitamin A are expressed in terms of milligrams. The word "trace" is used to represent small values that would have rounded to zero. It is recognized that in calculations these traces will be treated as zero, yet it seemed a little more realistic to recognize the presence of small amounts of substances where they exist.

Parentheses are used to denote values imputed usually from some other form of the same food or from similar foods. Parentheses also indicate values of nutrients covered by specifications for enrichment, such as vitamin A in margarine, and iron, thiamine, riboflavin, and niacin in enriched flour and bread. In each case the figure given is the minimum level specified in standards of identity promulgated under the Food, Drug and Cosmetic Act.

A space (a dash in the original publication) has been left in the few cases where no reliable data were available but where there was reason to suppose a measurable amount of a nutrient to be present. This seemed preferable to an imputed zero.

Army ration components are identified by an asterisk. Many of these foods were prepared or packed to meet Army specifications, and the nutritive values are for the most part averages obtained from special analyses of samples from Army purchases.

^{*}Quoted from Miscellaneous Publication No. 572, U.S. Department of Agriculture, 1945. The data were prepared by the Bureau of Human Nutrition and Home Economics in cooperation with the National Research Council.

Note: Asteriak indicates Army ration component; parentheses, imputed value.

19 Based on pink salmon. Canned red salmon may have a value several times

higher.

10 Nary bean meal, farinaceous flour up to 15 per cent.

11 Contributed by tornatoes.

12 Pea meal, farinaceous flour up to 15 per cent.

13 "Available" carbohydrate.

value is higher.

21 168 mg; may not be available because of presence of oxalic acid.

21 105 mg; may not be available because of presence of oxalic acid.

22 105 mg; may not be available because of presence of oxalic acid.

23 Based on yellow corn; white corn contains only a trace.

24 Based on pared eucumber; unpared contains about 260 L. U. vitamin A per 100 g.

25 Green bunching onions contain about 23 mg. of ascorbic acid per 100 g. 24 Based on peanuts without skins; when skins are included the thiamine

White flour		0.6		50		
Whole wheat flour	0.5	0.7-1.4	0.06	30		

^{*} To date (1946) many of the values found in the literature for the concentrations of these vitamins in foods are unreliable because of the methods employed for assay. The figures in this table have been selected as the best available data. Present literature values for the pteroylglutamic (folic) acid levels in foods are untrustworthy because of the presence of conjugated forms of the vitamin and of inhibitors which interfere with the enzymatic dissociation of the complexes. No quantitative systematic study of the biotin content of foods has as yet been reported.

V. ACCESSORY NUTRITIONAL DATA ON FOODS

The data presented here are reproduced by permission from the 1946 Nutritional Charts prepared by the H. J. Heinz Co., Pittsburgh, Pa. They have proved useful for many practical purposes. The alkaline or acid effect is given in terms of ml. of N alkali (+) or acid (-) corresponding to 100 g. or 100 ml. of food (see discussion on p. 1015). The measure of "average portion" as given is based upon the edible portion only and upon articles of average size. The food is calculated as in the raw state. These figures are not offered as exact data but merely as a guide in estimating average portions or servings; naturally there is considerable possible variation in this respect. For precise nutritional studies, all food consumed should be accurately measured. In these tables, T. = tablespoon, t. = teaspoon, c. = cup.

^{*} The infusion has little food value except for added sugar and cream. The analytical figures apply to dried coffee bean and dried tea leaves.

† These foods are alkaline, but because of substances in them which give rise to hippuric acid in the body, they increase the acidity of the urine (see p. 1015).

‡ Ripe olives are soaked in alkali during their manufacture, and the alkaline content is apt to be high

VIII. ANALYSIS OF VARIANCE

Table 1

Analysis of Variance (Assay No. 34005)

Sample: Vitamin A Concentrate
Number of groups: 4 (2 assay

Assay level: 217,200 U.S.P. u./g.
Number of rats per group (N): 9 males

and 2 reference)

	S_1	S_2	U ₁	U_2
Dose (mg.)		1 47 (0 5	0.00001 (1.5 (4.11)	0.01154 (0.5 (/ 1)
	0.88 (1.5 u.)	1.47 (2.5 u.)	0.00691 (1.5 "u.")	0.01154 (2.5 "u.")
	28 Y ₁	20	24	45
	31 Y ₂	49	32	68
	36	65	27	38
	35	37	31	27
	30	30	22	50
	10	37	34	45
	34	36	2 6	58
	30	35	29	32
	24	41	13	26 Y _n
Totals	258 (e)	350 (f)	238 (g)	389 (h)
Means	28.7	38.9	26.4	43.2

Calculation of sums of squares:

$$C = \frac{(e + f + g + \dots n)^2}{\text{Rows} \times \text{Columns}} = \frac{(258 + 350 + 238 + 389)^2}{9 \times 4} = \frac{(1235)^2}{36} = 42367.36$$

$$\text{Columns (between doses)} = \frac{e^2 + f^2 + g^2 + \dots n^2}{\text{Rows}} - C$$

$$= \frac{258^2 + 350^2 + 238^2 + 389^2}{9} - C$$

$$= \frac{397,029}{9} - 42,367.36 = 1746.97$$

$$\text{Total} = Y_1^2 + Y_2^2 + \dots Y_n^2 - C$$

$$= 28^2 + 31^2 + 36^2 + \dots + 26^2 - C$$

$$= 47,791 - 42,367.36$$

$$= 5423.64$$
Experimental error = total - columns = $5423.64 - 1746.97 = 3676.67$

Table 2 FACTORIAL ANALYSIS OF VARIANCE BETWEEN DOSES

Table 3 Analysis of Variance

Variations Due to	Degrees of Freedom (DF)	Sum of Squares (SS)	Mean Square SS ÷ DF = MS	Variance Ratio MS ÷ s² = F	Signifi- cant F*
Difference between samples Slope of dose-response curve Departure from parallelism Experimental error	1 1 32	10.03 1640.25 96.69 3676.67	10.03 1640.25 96.69 114.90 (s ²)	0.09 14.28 0.84	4.15 4.15 4.15
Total	35	5423.64			

$$s = \sqrt{114.90} = 10.72$$

^{*} From Snedecor: "Statistical Methods Applied to Experiments in Agriculture and Biology," 4th ed. Ames, Iowa, Collegiate Press, 1946, p. 224.

Table 4 CALCULATION OF ESTIMATE OF POTENCY

$$M = \log \frac{\text{potency of } U}{\text{potency of } S} = \frac{\text{KID}}{B}$$

K = 1 (for two-dose assays; for three dose assays K = 1.635)

$$I = log \frac{large \ dose}{small \ dose} = log \ 1.667 = 0.2219$$

D = 3.17B = 40.50from factorial analysis (Table 2, above)

$$M = \frac{1 \times 0.2219 \times 3.17}{40.50} = 0.0174$$

Log estimated potency of sample (EP) = log of assumed potency of sample (AP) + M

$$Log (AP) = log 217,200 = 5.3369$$

 $M = 0.0174$

 $\log (EP) = 5.3543$

antilog 5.3543 = 226,100 = Estimated Potency of Sample in Vitamin A units per gram

Table 5 CALCULATION OF ERROR OF ESTIMATE

$$S_{M} = log \ standard \ error = \frac{sKI \ \sqrt{B^{2} + D^{2}}}{B^{2}}$$

where

s = standard deviation of assay = 10.72

$$K = 1$$
$$I = 0.2219$$

$$B^2 = 1640.25$$

 $D^2 = 10.03$ from factorial analysis (Table 2, above)

$$S_{M} = \frac{10.72 \times 1 \times 0.2219 \times \sqrt{1650.28}}{1640.25} = 0.0589$$

 $log (EP) \pm S_M = log (limits of potency)$

$$5.3543 + 0.0589 = 5.4132$$

$$5.3543 - 0.0589 = 5.2954$$

antilog
$$5.4132 = 259,000$$

antilog
$$5.2954 = 197,400$$

Difference
$$= 61,600$$

$$\frac{1}{2}$$
 difference = 30,800

Estimated potency and standard error = 226,100 ± 30,800 units of Vitamin A per gram.

Standard error as per cent of estimate = 13.6 per cent

IX. MAINTENANCE OF ANIMALS FOR NUTRITION EXPERIMENTS

Introduction. Laboratory animals should be housed in well-ventilated rooms free from drafts in order to avoid colds or the blowing around of finely divided dietary dust. Rooms should be diffusely lighted during the day and darkened at night, the alternating periods of light and darkness being regular from day to day. Exposure of rats (or chicks) to direct sunlight, even though filtered through window glass, must be avoided in vitamin D assay work. Rats are nocturnal animals and excessive noise or activity during the day interferes with their normal habits.

Air-conditioning of rooms is desirable but not essential except where extreme temperatures would otherwise occur. The optimum environmental temperature for small animals is $24 \pm 2^{\circ}$ C. Provision should be made for screening windows and for frequent washing and flushing of walls and floors, which should be sealed against vermin and wild rodents.

Extermination of insects such as roaches, flies, or bedbugs should be commenced as soon as they are observed. The most effective methods for exterminating these insects are as follows:

ROACHES AND FLIES. Spraying rooms and equipment with a potent pyrethrum-lethane-DDT spray.¹

Bedbugs. Paint walls, crevices and equipment with a 5 per cent solution of DDT in kerosene. One application may suffice to eradicate a severe infestation; if not, repeat after 6 weeks.

Excreta should be removed at least every other day. Paper rolls under racks of raised-bottom cages facilitate this operation. Hot tin-dipped galvanized wire cages are preferred. These should be cleaned once every week or two depending upon the number of occupants per cage. Cages should be scraped, scrubbed in hot soap solution or soaked in hot trisodium phosphate solution and finally rinsed thoroughly in hot, then cold water.

Rats.² Selectively bred albino or piebald rats are the animals par excellence for nutrition experiments.³ Black rats are of course more suit-

¹ Many insecticidal sprays contain insufficient concentration of active pyrethrins. A very effective product is Fumol, made by The Fumol Corporation, Long Island City, N. Y. Hand spraying is not nearly so efficient as the use of an electric power spray.

² For handbooks on the care of laboratory animals and their use in experimental work, see Haberland: "Die operative Technik der Tierexperimentes," Berlin, Springer, 1926; Pittenger: "Biologic Assays," The Blakiston Company, 2d ed., Philadelphia, 1928; Munch: "Bioassays," Baltimore, Williams and Wilkins Co., 1931; "Manual of Biological Assaying," Philadelphia, Lippincott, 1937; Main: "The Care of a Small Rat Colony," St. Louis, C. V. Mosby Co., 1939; Griffith and Farris: "The Rat in Laboratory Investigation," Philadelphia, J. B. Lippincott Co., 1942.

See also Greenman and Duhring: "The Breeding and Care of the Albino Rat," Wistar Institute, Philadelphia, 1931. Extensive biometric data may be found in Donaldson: "The Rat," 2d ed., Philadelphia, Wistar Institute, 1924; Hunt: "A Laboratory Manual of the Anatomy of the Rat," New York, The Macmillan Co., 1925. See also Howell: "Anatomy of the Wood Rat," Baltimore, Williams and Wilkins Co., 1926, and especially Greene: "Anatomy of the Rat," Philadelphia, The American Philosophical Society, 1935.

³ Rats for vitamin assay work should be bred under the direct control of the assayer. Breeders and experimental rats may be obtained from: Wistar Institute of Anatomy, Philadelphia, Pa.; Rockland Farms, New City, N. Y.; Carworth Farms, New City, N. Y.; Sprague-Dawley, Madison, Wis.

able for study of achromotrichia although white rats develop a condition described as "rusting," comparable to graying of black fur. In their dietary habits rats are, like man, omnivorous. Their period of growth (see Fig. 315) extends over approximately 300 days and their life span is about three years. Thus they live through their cycle at about 30 times the rate of the human species. Rats multiply rapidly and the large litters which they produce permit of a high degree of experimental control. They require but little food and are hence economical to use. For studies of certain nutritional deficiencies to which the rat is immune, notably scurvy, other species of animals must be employed. Variation

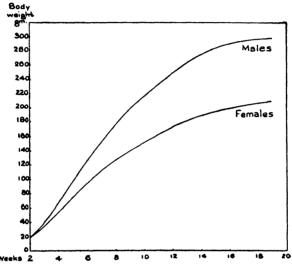

Fig. 315. Normal growth of male and female albino rats. (F.R.L. Colony, 1946.)

in species requirements (rat vs. chick) was partly responsible for the discovery of the multiple nature of vitamin D and of the vitamin B complex.

Rats attain sexual maturity at about 75 days, but should not be mated for breeding purposes until the one hundred tenth day. One male may be caged with as many as three females at one time. Pregnant females should be isolated before litters are cast, unless only one female occupies the cage with the male. The gestation period is about 22 days. The young are usually weaned when three to four weeks old. If the number of pups in a litter exceeds 8, it should be reduced to that number to protect the mother and at the same time produce sturdier rats. If litters are cast in wire-mesh cages, the mesh should be less than ½ inch and shredded paper or cellophane should be furnished for bedding or nesting.

Rats may be marked by staining the fur with dyes (e.g., methylene blue or picric acid), by means of an ear tattoo-punch, or by numbering

⁴ Keeler: Science, 92, 205 (1940).

permanently (from 0 to 99) by using combinations of nine types of cuts (slits, V-shaped notches, or holes) in both ears (see Fig. 316).

For breeding and stock purposes in small colonies the cage illustrated in Fig. 317 may be employed; for larger laboratories racks of suspended

Fig. 316. Scheme for numerical ear-marking of rats.

drawer-type cages are most suitable. These may be equipped to carry outside water bottles and to provide for paper rolls for the collection and removal of excreta. (See Fig. 318.) When they are ready for experiments the rats should be transferred to individual cages of the type illus-

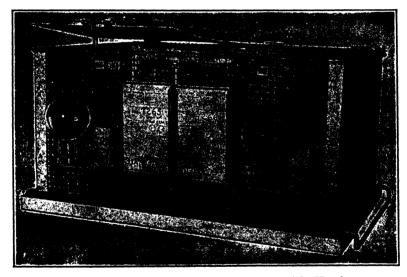

Fig. 317. Individual breeding cage for rats, with Hendryx water fountains, removable partition, double lid, positive action catch, and sliding tray. trated in Fig. 319. These cages are of all-wire construction and have false bottoms to minimize access to excreta.⁵ They are easily sterilized.

Specially prepared diets should be fed in a nonscatter type of food cup to permit the collection of more accurate data on food consumption. Suitable for this purpose is a 3 or 4 oz. screw-cap ointment jar with a

¹ Cages and accessories may be obtained from the Norwich Wire Works, Norwich, New York; the Geo. H. Wahmann Mfg. Co., Baltimore, Md.; or the A. B. Hendryx Co., New Haven, Connecticut.

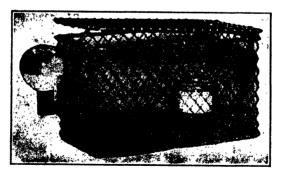

Fig. 319. Individual rat cage, of all wire construction, with Hendryx water fountain, positive action catch, and nonscatter feed cup made of screw top ointment jar stamped with 1½" hole. (Constructed to specifications of Food Research Laboratories, Inc., by Norwich Wire Works, Norwich, N. Y.)

hard plastic cap through which a 30-mm. hole is cut. (See food cup inside cage in Fig. 319.) Dietary supplements may be weighed or measured in small opal glass cups (rouge pots). Oils or liquid supplements are preferably fed directly into the mouth from a tuberculin syringe fitted with a needle (No. 16 or 18) ground to a smooth, blunt tip. For nutritional balance experiments, in which separation and collection of urine and feces are necessary, cages of the type shown in Figs. 320, 321, and 322 may be

Fig. 321. (Right.) Cross-section of metabolism cage for small animals.

used. The activity cages (Fig. 323) may be employed as illustrated for studies in voluntary activity, or may be driven by a pulley to produce enforced activity.

Rats may be weighed on a spring balance (Chatillon or Hanson), but for more exact work an Exact Weight or Toledo scale of 250 to 500 g. capacity, sensitive to 1 g. should be used. (See Figs. 324 and 325.) These balances are also suitable for weighing food cups. Records are kept of

These caps are obtainable from the Armstrong Cork Company, Lancaster, Pa.

BASAL DIET:

SUPPLEMENT: DOSAGE:

Fig. 328. Growth curve chart.

mented with milk or fresh vegetables such as carrots or lettuce, once or twice a week. Specially prepared rations for rats and other laboratory animals are available on the market and have proved quite satisfactory. Mixed poultry rations (growing mash) or calf meal may also be used. For careful nutritional research it is necessary to use a uniform stock diet

⁸ Raiston Purina Co., St. Louis, Mo., supplies such rations in the form of compressed "checkers" and meal (Purina Laboratory Chow for rats and mice, and special chows for guinea pigs, rabbits, dogs, etc.). Similar rations are available through Rockland Farms, New City, New York.

[•] A modification by Hawk and Oser (unpublished data) of the Sherman Diet B (J. Biol. Chem., 53, 49 (1922); 60, 5 (1924)). The latter consists of two-thirds whole wheat, one-third dried whole milk, and salt to the extent of 2 per cent of the wheat. The addition of yeast and pork liver produces better results in breeding, and the addition of CaCO₃ improved the Ca: P ratio (= 1.2:1).

11 Obtained from Valentine Meat Juice Co., Richmond, Va.

¹² In some laboratories a more highly restricted diet may be used with safety in vitamin A work. For this purpose skim milk powder may be substituted for whole milk.

whose efficiency has been established through several generations of rats. It is desirable that rats reared for investigations on the fat-soluble vitamins be fed diets which limit or control their reserves of the vitamins in question.

Typical diets which have proved successful are shown on p. 1272. These may be prepared by means of scales of the type illustrated in Fig. 329.

Salt Mixtures. Synthetic diet mixtures used in nutritional research on rats include special combinations of inorganic salts whose composition is based on the analysis of their milk¹³ or urine. The original Osborne-Mendel and McCollum-Davis salt mixtures, given below, have been modified by the U.S. Pharmacopoeia XII to include readily available commercial forms of the chemicals employed (see p. 1163). The modification of the Osborne-Mendel mixture by Hawk and Oser includes salts which yield a similar stoichiometric mixture, but by avoiding acids and carbonates eliminates the need for evaporation and dehydration.

OSBORNE-MENDEL SALT MIXTURE ¹⁴								
CaCO ₃	134.8	H_3PO_4	103.2	Fe citrate 112 H ₂ O	6.34			
K ₂ CO ₃	141.3	HCl	53.4	NaF	0.062			
$MgCO_3$	24.2	H_2SO_4	9.2	KAl(SO ₄) ₂	0.0245			
Na_2CO_3	34.2	Citric acid + H ₂ O	111.1	$MnSO_4$	0.079			
				KI				

All amounts are given in grams. The acids are added to the carbonates and ferric citrate, and stock solutions of the other salts are then added in proper amount. After effervescence is completed the mixture is dried at 90° to 100° C. and ground to a fine powder. These amounts of phosphoric, hydrochloric and sulfuric acids are equivalent to 71, 121, and 5.2 ml., respectively, of the concentrated acids. See also p. 1163.

Guinea Pigs (Cavies). The most suitable guinea pig for laboratory work is the English short smooth-haired variety, whose manifold coloring facilitates identification. Not all pure white guinea pigs are albinos since they may have dark-colored instead of pink eyes.

Guinea pigs must be housed away from drafts in dry cages, preferably with false bottoms although beds of sawdust or shavings are satisfactory. Dry hay should be provided at all times. They are herbivorous and may be fed clean hay and grain (oat meal, bran, wheat middlings, etc.) supplemented with fresh vegetables (carrots, beets, alfalfa, lettuce, celery, etc.). The moist vegetables must be sound and wholesome as guinea pigs will reject spoiled food. Similarly diets containing fats (e.g., codliver oil) must not be fed when rancid. The addition of dried yeast to the grain mixture is frequently desirable. Specially prepared diet mixtures for guinea pigs are available commercially. 19 Water should be fed sparingly when fresh vegetables are supplied.

Most investigators purchase guinea pigs on the market, since their nutritional history is seldom of importance. However, they should be purchased from a reputable breeder since they are prone to carry pulmonary and other infections when raised or shipped under adverse conditions.20 Guinea pigs breed about once every three or four months, the gestation period being from 65 to 70 days. Mating should commence not before the age of three months. The lactation period should last about two to three weeks.

White Mice. The white mouse has been employed with some success in studies in nutrition.21 Some of the advantages of the mouse include a smaller food requirement, more rapid growth, ease of handling, and rapid rate and regularity of reproduction. The dietary needs of the mouse are similar to those of the rat, although a somewhat higher protein content should be supplied.

Advantages of the rat over the mouse for nutritional work include the fact that the rat has been more extensively studied thus affording

McCollum and Davis: J. Biof. Chem., 33, 55 (1918).
 Steenbock and Nelson: J. Biol. Chem., 56, 355 (1923).

¹⁹ See footnote 8, p. 1271.

²⁰ Carworth Farms and Rockland Farms are recommended. See footnote 3, p. 1263. ²¹ Beard: Am. J. Physiol., 75, 645, 658, 668, 682 (1926). Bing and Mendel: J. Nutrition, 2, 49 (1929). For ophthalmia studies see Pomerene and Beard: Am. J. Physiol., 92, 282 (1930). Woolley: J. Biol. Chem. 129, 29 (1941) used the mouse for inositol studies and Nielsen and Black: J. Nutrition, 28, 203 (1944) for the study of biotin and pteroylglutamic seid deficiencies.

more norms for comparison; and the fact that it is hardier than the mouse, and thus not so prone to contract minor illnesses, or to be adversely influenced by changes in temperature, etc.

It has been claimed that mice require vitamin C for normal development.²²

Dogs.²³ The feeding of a purely "synthetic" food mixture for long periods, in metabolism tests using dogs as experimental animals, is a procedure for the successful accomplishment of which investigators in metabolism have long striven. It remained for Cowgill to solve this important problem in dietary technique. His work was an extension of that initiated by Karr.²⁴

The principles upon which the procedure is based are that the diet consist of a mixture of isolated food substances which supply the body with all factors necessary for proper nutrition, except a single dietary factor; and that the variable nutritive factor shall be administered apart from the diet mixture. In this discussion vitamin B (complex) is regarded as this variable nutrition factor.

In a test where vitamin B is the variable factor, the diet²⁵ should contain (1) protein, proper in kind and amount;²⁶ (2) carbohydrate,²⁷ and fat²⁸ to furnish satisfactory energy; (3) mineral salts,²⁹ proper in kind and

- ²² Kleiner and Tauber: Food Research, 1, 399 (1936).
- ²³ Cowgill: J. Biol. Chem., 56, 725 (1923). This procedure has been used at Yale University for periods of five months and over with excellent results.
 - ²⁴ Karr: J. Biol. Chem., 44, 255 (1920).
- ²⁵ Calculation of the Diet. Construct the diet on a kg. of body weight basis, or form what might be called a kilo unit of food. Dogs weighing 7 kg. and over require for the maintenance of body weight between 70 and 80 Calories per kg. per day. 80 Calories has been selected as the number to be desired in the kilo unit of food. This permits maintenance in adult animals and allows a slight increase of body weight in growing dogs. Dogs weighing considerably less than 7 kg. require slightly more energy intake in order to maintain their body weight; this fact, however, does not invalidate the choice of 80 Calories as a unit quantity. Any variation in energy intake from this figure due to the size of the animal will not seriously affect the intake of nitrogen and salt mixture if liberal quantities such as 0.8 g. of the former and at least 6.2 g. of the latter be furnished with every 80 Calories or kilo unit of food. For further discussion of the basis for this diet consult the original paper.
- ²⁶ This may be casein, extracted meat (from the Valentine Meat Juice Co., Richmond, Va.) or commercial coagulated egg albumin. Casein is to be preferred.
- ²⁷ Sucrose is a desirable source of carbohydrate; pure starch or dextrin make the diet too pasty when moistened by saliva. Whole cereals, however, are suitable
 - ²⁸ See footnote 30, p. 1276.
 - 29 Cowgill suggests the use of one of the following salt mixtures:

SALT MIXTURE (KARR, 1920)	SALT MIXTURE (COWGILL)							
	NaCl 38.0							
	Mg citrate							
	KH ₂ PO ₄ 12.2							
	CaHPO + 2H ₂ O 7.8							
	KCI 7.0							
Tourist III (Edgor B Bottleton) is 11 in the second	Fe citrate 1.8							
	KI 0.5							

Karr's salt mixture, when fed along with bone ash on the basis of 0.2 g. and 0.4 g., respectively, per kilo unit of food, the latter serving as a source of phosphate, has given successful results with the dog during periods lasting over five months.

Where 0.4 g. of agar-agar per kilo unit is used as a source of roughage, Cowgill's sait

amount; (4) sufficient vitamin A;³⁰ (5) roughage,³¹ and (6) water.³² The energy requirement as shown in the table of the "kilo unit" below is somewhat high for dogs whose activity is restricted, e.g. in metabolism cages. In such cases it is advisable to reduce the calories to 60–70 per kg. of body weight by substituting sucrose for lard. The vitamin B (the

Kuo	Untim	OB	CASEIN	Roon*

Totals	16.74	80.2	100.0

^{*} This kilo unit contains 80 calories, 45 per cent of which are furnished by fat, and 0.8 mg. of nitrogen. † See footnote 29, p. 1275.

variable factor) should be fed separately from the rest of the diet, in the form of dried yeast (about 0.4 g. per kilo unit of food) or preferably a synthetic vitamin mixture; or the various components of the vitamin B complex may be fed as separate supplements. Excessive amounts of sugar in the diet of dogs will cause diarrhea, hence cereals (but not pure starch) are better sources of carbohydrate. It has been claimed that meat is an indispensable article of diet in tests on dogs. As a matter of fact, meat in the feeding of dogs is not essential if the diet is adequate with respect to protein and other nutrients.

Cowgill's work shows that "monotony of diet is not per se the cause of failure of appetite: loss of the desire to eat is rather an expression either (1) of the failure of the food being fed to nourish the animal properly, or (2) of an adjustment of the dog to its energy requirement when offered more than is necessary of a food mixture that is adequate in all respects."

mixture may be used on the basis of 0.3 g. per kilo unit of food. It is supposed to furnish the dog the various essential inorganic substances equal to or slightly in excess of that eliminated through the kidney by a normal organism during 24 hours, these amounts being expressed in terms of g. eliminated per kilo of body weight per day. 0.3 g. of this mixture per kilo unit of food contains a liberal amount of the various inorganic substances desired in the synthetic diet. Karr's salt mixture is particularly satisfactory when bone ash is used as roughage. These salt mixtures may be replaced by one of those given on p. 1273.

Although codliver oil is the outstanding source of vitamin A, Cowgill prefers the use

³⁰ Although codliver oil is the outstanding source of vitamin A, Cowgill prefers the use of butterfat. If ordinary butter with its variable water and salt content is used, the diet may become rancid. Lard may be used as a source of the bulk of the calories.

³¹ Bone ash has proved very useful for this purpose.

³² Not mentioned by Cowgill in his procedure. However, a uniform water ingestion is very essential in certain types of metabolism work (see Hawk: Biochem Bull., 3, 420 (1914) and "Endocrinology and Metabolism," vol. 3, p. 275, Appleton, 1924). In certain types of nutrition experiment, the animal should be given a uniform volume of water daily.

X. STUDENT EXERCISES

1. Demonstrations of Vitamins A, B₁, D, and G: Divide at least six rats 21 to 28 days old into two groups so that there are twice as many rats in one as in the other. Keep the rats in individual cages and follow the instructions for their care outlined on p. 1263, et seq. Feed ad lib. one of the following diets to the larger group (experimental) and to the other group (preventive controls) feed the same diet plus one of the indicated supplements daily (except Sundays).

(a) Vitamin A Deficient Diet (see p. 1162): Supplements: One drop U.S.P. codliver oil daily; or one γ of β-carotene in 0.1 ml. of cottonseed oil; or

3 drops of butterfat.

Weigh rats semi-weekly and note changes in growth, vaginal smears (usually during the fourth week), condition of the eyes, and appearance of the fur. Compare the experimental group with the control group. Allow half of the experimental group to continue on the basal diet until they die, at which time perform autopsies, noting the presence of localized infections in the respiratory tract, tongue abscesses, renal calculi, etc. When growth has definitely ceased on the basal diet, begin to feed the remainder of the experimental group one drop of codliver oil (or other source of vitamin A). Record your observations.

(b) Thiamine Deficient Diet (see p. 1070): Supplements: 1.0 g. of compressed yeast; 3.0 g. of whole wheat flour; 5γ of crystalline thiamine diluted in 100 mg. of confectioners' sugar-cornstarch mixture (1:1).

Weigh rats semi-weekly. Beginning with the third week note signs of polyneuritis. Spin the rats by rolling the tail between the hands. Convulsive seizures following this treatment are evidence of polyneuritis. When this is observed for two or three consecutive days, begin to feed half of the experimental group a thiamine-containing supplement. Allow the remainder of the experimental group to continue on the basal diet until death. Plot growth curves and compare with curative and preventive control groups.

(c) Vitamin D Deficiency (see p. 1162): Supplements: One drop of U.S.P. codliver oil; or 0.1 g. of irradiated yeast, 33 or one hour's exposure to sunlight (if the weather is sufficiently warm); or 15 minutes' exposure at a distance of 30 inches from a source of ultraviolet light. Feed the experimental and preventive control groups either of the rachitogenic diets described on

p. 1162.

Record body weights at semi-weekly intervals, and after three weeks examine each rat for evidence of rickets. Note posture, gait, paralysis of hind legs, enlargement of knee joint, etc. Sacrifice one rat from each group, perform autopsy (note beading of rib cartilage) and line test of the tibia as described on p. 1166. If possible, take roentgenograms of at least one rat in each group (cf. Fig. 310). After definite, gross signs of rickets are observed in the experimental group (between three and four weeks), add a vitamin D supplement to the diet of half the group for a two-week curative period. Repeat above examinations for rickets. Compare all animals at autopsy. Dissect tibiae free from connective tissue, wrap in marked filter paper, extract for 24 hours with acetone in a Soxhlet extractor, dry in oven, and determine bone ash on "dry fat-free basis."

(d) Riboflavin Deficient Diet (see p. 1054): Supplements: 3 ml. whole milk; or, 0.2 g. of dried brewers' yeast; or, 10 γ of crystalline riboflavin.

Weigh rats semi-weekly. When growth ceases in the experimental group, continue half of the group on the basal diet and add to the diet of the other half the same supplement fed the preventive control group. Plot growth

²³ Irradiated yeast may be prepared by exposing a thin layer (½ inch) of dried brewers' yeast at a distance of 18 inches from a quartz mercury vapor or carbon are lamp for 20 minutes, raking over the surface every five minutes.

curves over a total period of six to eight weeks. Note any signs of alopecia or dermatitis.

2. Demonstration of Vitamin C (Scurvy): Divide six guinea pigs weighing about 280 to 300 g. into an experimental group of four, and a preventive control group of two. Feed both groups ad lib., one of the scorbutigenic diets described on p. 1141, supplementing the diet of the preventive controls daily with one of the following: 1.5 ml. of fresh orange juice; or, a fresh carrot or small potato; or, 0.5 ml. of freshly prepared 0.1 per cent ascorbic acid. Liquid supplements should be pipetted directly into the mouth; the ascorbic acid solution may be sweetened with cane sugar.

Weigh guinea pigs semi-weekly; beginning with the fourteenth day examine daily for signs of scurvy (see p. 1141) in the experimental group, particularly sensitive joints, hemorrhagic gums, loose teeth, and characteristic posture. These should become pronounced during the fourth or fifth weeks. However, when definite symptoms are noted and growth has stopped, begin to feed half the experimental group the same antiscorbutic supplement which the preventive controls receive. Terminate the experiment after a six weeks' curative period. Autopsy each guinea pig either at death or at termination, comparing the negative controls with the preventive and curative groups. Examine especially for enlarged joints in ribs (beading) and leg bones, subcutaneous and intramuscular hemorrhages, loose, fragile teeth and soft hemorrhagic gums.

- 3. Demonstration of Vitamin E: Place two male (A and B) and two female (C and D) rats at weaning, on the vitamin E deficient diet described on p. 1174 and two males (E and F) and one female (G) on the same diet supplemented with a daily allotment of 3 drops of non-rancid wheat germ oil. At the age of about three months, mate these rats in the following sequence (removing the supplement-fed rats from the cage for their daily dose of wheat germ oil):
 - I. Male E with females C and D.

Allow mating to continue until each female shows a typical resorption. (The first impregnation may result in the birth of a litter.) (See IV.)

II. Male F with female G.

Allow mating to continue until two live litters are born and carried through the lactation period.

III. Males A and B with female G.

After one month, during which no pregnancy should result, kill male A, weigh the testicles and examine histologically. Compare with normal male E, of the same age.

- IV. Begin feeding male B and female C, 3 drops of wheat germ oil daily at conclusion of previous matings. Mate F with C and D. Only C should produce a live litter while D should show resorption.
- V. Male B with female G.

No live litter should result in spite of the proved fertility of female G.

Record your observations and draw conclusions as to the effect of vita-

min E deficiency on male and female fertility.

4. Studies on the Planning of Experimental Diets: With the aid of the data given in the various tables on pp. 1237 to 1256, and of other available reference books from which the calorific value, nitrogen content, vitamin content, etc., may be obtained, plan experimental diets as described below, using the following dietary constituents: Casein, egg albumin, gelatin, gluten, whole wheat, lean beef heart, dried milk, dried liver, starch, sugar, agar, lard, hydrogenated vegetable oil, butter, butterfat, codliver oil, yeast (dried or compressed), orange juice, tomato juice, salt mixtures (see pp. 1163, 1273, and 1274) etc.

Plan diets which may be predicted to have the following effects, and hand in a report to your instructor explaining the reasons for your selections. Include in this report the calorific value, the protein content, and any other properties of the diet your instructors.

any other properties of the diet your instructor may suggest.

- 1. A diet that will produce ophthalmia.
- 2. A diet that will promote growth but cause rickets.
- 3. A diet that will cure or prevent rickets.
- 4. A diet that will prevent growth but not cause rickets.
- 5. A diet that will restore growth following Diet 4.
- 6. A diet that will prevent normal reproduction.
- 7. A diet that will cause scurvy.
- 8. A diet that will cure or prevent scurvy.
- 9. A diet that will cause ketonuria.
- 10. A diet that will correct this ketonuria.
- 11. A diet that will cause polyneuritis.
- 12. A diet that will cure polyneuritis.
- 13. A diet that will be conducive to longevity and the birth and rearing of sturdy offspring.
- 14. A diet that will produce a dermatitis in rats.
- 15. A diet that will cure this dermatitis.
- 16. A diet that will cause anemia in rats.
- 17. A diet that will correct this anemia.

origin, 429	Hoffmann reaction for tyrosine, 126
oxygen dissociation curve, 426	Höjer method for vitainin C, 1140 (fint. 274) Homocysteine, 130, 943-944
preparation, 441	Homogentisic acid, 741, 957
reduced, 444	Hopkins-Cole reaction, 155, 173
role in neutrality regulation, 609-620	reagent, Appendix I
spectroscopic examination, 444	Hordein, 177
Hemoglobinometers, 557-558	Horismascope, 762
Hemoglobinuria, 767	Hormones, 683-712
Hemolysis, 421, 436	adrenotropic, 685, 708
Hemophilia, coagulation defect, 432	analogs, 1218
Hemp-seed calculus, 803	anterior-pituitary-like (see Prolan)
Henderson-Hasselbalch equation, 22, 160, 614	anti-, 709
Henriques-Sørensen method for amino acid nitro-	carbohydrate metabolism, control of by, 918
gen, 837	chart, 684
Heparin, 432	chemistry, 685
clinical use, 432	corticotropic, 684, 708
Hepatoflavin, 1025, 1051, 1073	definition and discussion, 683-712
Herter-Foster method for indole, 409 (fint, 6)	diabetogenic, 708
naphthaquinone reaction for indole, 397	female sex, 684, 690
Hertzian waves, 1149	International Standard Unit, 692
Hesperidin, 1026, 1143-1144	follicle-stimulating, 684
Hesperitin, 1026 Hexahydrohexahydroxybenzene (see Inositol)	glycostatic, 708, 919
Hexahydro-2-oxo-1-thieno (3,4) imidazole-4-va-	glycotropic, 708, 919
leric acid (see Biotin)	gonadotropic, 684, 708
Hexanoic acid, 923	growth, 684, 708 interstitial-cell-stimulating, 708
Hexokinase, 246, 267, 273, 703, 910, 919	ketogenic, 708
Hexone bases (see Amino acids, basic)	lactogenic (see Prolactin)
Hexopentosans, 48	luteinizing, 684
Hexosans, 48	male sex, 684, 690
Hexones, 51	International Standard Unit, 690
Hexuronic acid, 1128	nitrogenous, 701
Hickman molecular distillation, 1039	of adrenal gland, 685
"High energy phosphate bond," 234, 239, 241, 244	preparation, 695-701
Hildebrand method for hydrogen-ion concentra-	of duodenum, 354, 711
tion, 35	of gastric secretion (see Enterogastrone)
Hiller and Van Slyke method for precipitation of	of islets of Langerhans (see Insulin)
blood proteins, 494 (fint. 15)	of ovary, 684
McIntosh, and Van Slyke colorimetric method	preparation, 690
for proteins in urine, 867	of pituitary gland, 707-709
Hippuric acid, 393, 737, 854, 967, 1015	preparation, 710
conjugation, 393, 737, 1015	of testis, 684
experiments, 738, 967	of thyroid gland (see Thyroxine)
formation in human body, 967	ovarian, 684, 690
Griffith's method, 854	steroid, 685, 690
in urinary sediments, 792	testicular, 684, 690
in urine, 737, 854	thyrotropic, 684–708
clinical interpretation, 856	units (International Standard), 690, 691, 703,
Lücke's reaction, 738	706

Horn, composition, 217	Hydroxyproline, 131, 947
Horowitz-Beadle method for choline, 1124	metabolism, 947
Hubbell, Mendel, and Wakeman salt mixture,	Hydroxystearic acid, 256
Appendix IX Hübl iodine solution, 96	Hyodesoxycholic acid, 371
Hulett-Bonner method for standard HCl, 808	Hyperglycemia, 522, 917, 928, 980
Human milk, 201–206	produced by carbohydrate ingestion, 980 Hyperinsulinism, 523
composition, 202–204	Hypersecretion acidity curve, 344
curds, 201–202	Hypertensin, 711
differences between cow and, 202, 205-206	Hyperthyroidism, 451, 704
fatty acids, 206	Hypertonic solutions, 421
Hunter and Givens modification of Krüger and	Hypobromite solution, preparation, Appendix I
Schmidt method, 852	Hypophysis (see Pituitary)
Huppert test for bile pigments, 376, 770	Hypoproteinemia, 418
Hürthle's experiment, 251	Hypothyroidism, 706
Hyaline casts in urinary sediments, 796	Hypotonic solutions, 421
Hydnocarpic acid, 89	Hypoxanthine, 191, 195, 239, 251-252, 745
Hydrases, 267	chloride, crystalline form, 252
Hydrobilirubin (see Urobilin)	formula, 191
Hydrochloric acid, free, test, 337	oxidase, 191
of gastric juice, 317-319, 326	silver nitrate, crystalline form, 252
origin, theories, 318–319	tests, 195
seat of formation, 318-319	
solution, constant boiling, 808	I
standard (0.1 N), 808	
Hydrogen acceptor, 278	ICSH (see Interstitial-cell-stimulating hormone)
electrode, 34	Icteric index, 542
electrometric titration of acids and bases	clinical interpretation, 543
using, 39	determination, 542
-ion concentration, 17, 346, 811-813 chart, 24	Idose, 51
colorimetric determination, 29-32, 346, 635,	Imidazolacetic acid, 390
811	Imidazole acids, tests, 397 Imidazolformic acid, 390
determination by Hildebrand's method, 35	Imidazolidone caproic acid, 1217
with glass electrode, 38	Imidazolpropionic acid, 390
with quinhydrone electrode, 37	Immune serums, 439
electrometric determination, 32-38	Immunological determination of blood species,
indicators, 24-32, 334-338	439
influence on enzyme action, 270	reactions of proteins, 165
of blood plasma (see Blood plasma)	Indican, 390, 735-736, 878
of gastric contents, 317, 346	in blood, determination, 608
of urine, 811	in urine, determination, 878
as influenced by alkali, 1018	Parker's method for, in urine, 878
as influenced by diet, 1017	tests for, 736
clinical interpretation, 813	Indicator solutions, preparation, 31, 334-338;
determination, 811	(see also Appendix I)
titritable acidity and, 28, 32, 813	Indicators (see Hydrogen-ion concentration)
peroxide in milk, detection, 211	chart, 24, 336

stimulation of gastric secretion, 316, 324

relation of, to volume and specific gravity of

relationship, of nutrition, 316, 324, 969, 997

Vitamin-(Continued) Water-(Continued) P-(Continued) test meal, 342 formula, 1148 Watson method for urobilingen, 883 (fint. occurrence, 1143 173) Vitamins, 1022-1192 Waxes, 86, 93; (see also Lipids) analogs, 1212 Waxy casts in urinary sediments, 797-798 clinical aspects, 1186 Webster, Hill, and Eidinow method for ultracontent vs. potency, 1024 violet intensity, 1150 (fint. 296) deficiencies, 1186 Weidel reaction, 195 definition, 1022 Weinbach method for sodium in blood, 595 dietary allowances recommended by National Weiss test for urochromogen, 786 Welker and Tracy method for deproteinizing Research Council, 1027 distribution, 1022, Appendixes III and IV urine, 815 evaluation of sources (A.M.A.), 1031 biuret reagent. Appendix I human requirements, 1030 Hektoen, Kretschmer protein, 765 "major" and "minor," 1030 method for purine bases, 852 microbiological determination, 1052-1053 Werner hypothesis, 723-724 physiological availability, 1181 Westphal balance, 718 relation of, to enzymes, 1023 Weyl test for creatinine, 734 student exercises, Appendix X Wharton's jelly glycoprotein, 169 synonyms, 1025 Whev. 201 table of recognized, 1025 White blood cells (see Leukocytes) vitamers, 1025 fibrous connective tissue, 217 Vitreous humor mucin, 169 Meiklejohn, Deutsch, Kark critique of uro-Voisenet-Rhode reaction, 131 bilinogen methods, 883 (ftnt. 174) Volhard and Löhlein method for peptic activity. Whitehorn method for chlorides in blood, 57; 348 Wijs iodine solution, 97 Wilbur and Addis method for urobilinogen, 882 -Arnold method for chlorides, 893 Volhard-Harvey method for chlorides, 894 (fint. (fint. 172) Wilkinson and Peters benziding peroxidas re Voltera method for phenols in urine, 878 action, 208 Vulpian reaction for adrenaline, 702 Willstätter and collaborators' method for anylolytic activity, 361 for lipase, 288 Winkler reagent, 641 W factor (see Biotin) Wohlgemuth's method for amylolytic activity. Wallace and Diamond method for urobilinogen, Hawk modification, 409 (fint. 3) Wolff technic for protein concentration in gartric Walpole acetale buffers, 811 contents, 353 Warburg tissue slice procedure, 290-294, 300 Wong method for iron and hemoglobin in blood, calibration of vessel and manometer, 297 564 measurement of, anaerobic glycolysis, 304 Wool, amino acid content, 109 of oxygen consumption, 300 vellow enzyme, 267, 278 x Water at meals, influence, 316, 324, 999 balance, 998 Xanthine, 190-192, 195, 239, 253, 745 deficiency, influence, 970 distribution of in body fluids, 999 bases (see Purine bases) equilibrium, 998 crystalline form, 253 hormonal control of water-electrolyte balance.

Xanthine, 190-192, 195, 239, 253, 745
bases (see Purine bases)
crystalline form, 253
formula, 191
in urinary sediments, 793
isolation of, from meat extract, 253
oxidase, 191, 267
silver nitrate, 253
tests, 195
Weidel reaction, 195
Xanthophylls, 206
Xanthoproteic reaction, 155
Xanthydrol, use of, in urea determination, 828
Xerosis in avitaminosis A, 1032
Xerophthalmia, 1031
X-rays, 1149, 1159

Xyloketose, 67 Xylose, 47, 50, 54, 66 relative sweetness, 54

Y

Y factor (see Pyridoxine) Yeast, adenylic acid, 189 autoclaved, 1070 enzymes, 266-267 fermentation, 60 influence on growth (see Thiamine; Riboflavin) irradiated preparation, Appendix X niacin, 1090 porit factor (see Folic acid) hucleic acid preparation, 194 tests, 194 nuclcoprotein preparation, 193 tests, 193 ribose nucleic acid from, 194 sucrase preparation, 288 vitamins (see Thiamine; Riboflavin) Yellow elastic connective tissue, 220

Yellow elastic connective tissue—(Continued) enzyme, 267, 278, 290, 300 Youngburg and Folin modification of Van Slyke and Cullen method for urea in urine, 825 method for lipid phosphorus, 541

Z

Zein, 168, 177, 972
decomposition products, 108
Zeller test for melanin, 784
Zeolite column, use as adsorbent, 1063-1067
Zinc, 608, 901, 987, 1014
determination, 608, 901
in carbonic anhydrase, 267, 1014
in enzymes, 1014
in nutrition, 1014
-insulin, 702
Zwischenferment, 277
Zwitterion, 115
Zymase, 265, 271
Zymogen, 271, 320
Zymohexase, 267
